CONTENTS IN BRIEF

PART 1 MATERNITY NURSING

UNIT 1 INTRODUCTION TO MATERNITY NURSING

1 21st Century Maternity Nursing, 1
2 Community Care: The Family and Culture, 17

UNIT 2 REPRODUCTIVE YEARS

3 Assessment and Health Promotion, 39
4 Reproductive System Concerns, 74
5 Infertility, Contraception, and Abortion, 109

UNIT 3 PREGNANCY

6 Genetics, Conception, and Fetal Development, 140
7 Anatomy and Physiology of Pregnancy, 168
8 Nursing Care of the Family During Pregnancy, 186
9 Maternal and Fetal Nutrition, 227
10 Assessment of High Risk Pregnancy, 249
11 High Risk Perinatal Care: Preexisting Conditions, 267
12 High Risk Perinatal Care: Gestational Conditions, 302

UNIT 4 CHILDBIRTH

13 Labor and Birth Processes, 342
14 Pain Management, 356
15 Fetal Assessment During Labor, 382
16 Nursing Care of the Family During Labor and Birth, 401
17 Labor and Birth Complications, 441

UNIT 5 POSTPARTUM PERIOD

18 Maternal Physiologic Changes, 483
19 Nursing Care of the Family During the Postpartum Period, 490
20 Transition to Parenthood, 510
21 Postpartum Complications, 530

UNIT 6 NEWBORN

22 Physiologic and Behavioral Adaptations of the Newborn, 556
23 Nursing Care of the Newborn and Family, 582
24 Newborn Nutrition and Feeding, 633
25 The High Risk Newborn, 663

PART 2 PEDIATRIC NURSING

UNIT 7 CHILDREN, THEIR FAMILIES, AND THE NURSE

26 21st Century Pediatric Nursing, 718
27 Family, Social, Cultural, and Religious Influences on Child Health Promotion, 732
28 Developmental and Genetic Influences on Child Health Promotion, 750

UNIT 8 ASSESSMENT OF THE CHILD AND FAMILY

29 Communication, History, and Physical Assessment, 771
30 Pain Assessment and Management in Children, 828

UNIT 9 HEALTH PROMOTION AND SPECIAL HEALTH PROBLEMS

31 The Infant and Family, 864
32 The Toddler and Family, 922
33 The Preschooler and Family, 952
34 The School-Age Child and Family, 985
35 The Adolescent and Family, 1010

UNIT 10 SPECIAL NEEDS, ILLNESS, AND HOSPITALIZATION

36 Chronic Illness, Disability, and End-of-Life Care, 1051
37 Impact of Cognitive or Sensory Impairment on the Child and Family, 1084
38 Family-Centered Care of the Child During Illness and Hospitalization, 1109
39 Pediatric Variations of Nursing Interventions, 1130

UNIT 11 HEALTH PROBLEMS OF CHILDREN

40 Respiratory Dysfunction, 1195
41 Gastrointestinal Dysfunction, 1246
42 Cardiovascular Dysfunction, 1318
43 Hematologic and Immunologic Dysfunction, 1362
44 Genitourinary Dysfunction, 1393
45 Cerebral Dysfunction, 1417
46 Endocrine Dysfunction, 1461
47 Integumentary Dysfunction, 1493
48 Musculoskeletal or Articular Dysfunction, 1531
49 Neuromuscular or Muscular Dysfunction, 1571

APPENDIXES

A Growth Measurements, 1601
B Common Laboratory Tests and Test Results, 1603
C Pediatric Vital Signs and Parameters, 1613

Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ABOUT THE AUTHORS

Shannon E. Perry is Professor Emerita, School of Nursing, San Francisco State University. She received her diploma in nursing from St. Joseph Hospital School of Nursing, Bloomington, Illinois; a Baccalaureate in Nursing from Marquette University; an MSN from the University of Colorado Medical Center; and a PhD in Educational Psychology with a specialty in Child Development from Arizona State University. She completed a 2-year postdoctoral fellowship in perinatal nursing at the University of California, San Francisco, as a Robert Wood Johnson Clinical Nurse Scholar.

Dr. Perry has had clinical experience as a staff nurse, head nurse, and supervisor in surgical nursing, obstetrics, pediatrics, gynecology, and neonatal nursing. She has served as an expert witness and a legal consultant. She has taught in schools of nursing in several states and was Interim Director and Director of the School of Nursing and Director of the Child and Adolescent Development Baccalaureate Program at San Francisco State University. She was Marquette University College of Nursing Alumna of the Year in 1999 and the University of Colorado School of Nursing Distinguished Alumna of the Year in 2000. She received the San Francisco State University Alumni Association Emeritus Faculty Award in 2005 and the Excellence in Education Award from the Beta Upsilon chapter of Sigma Theta Tau International in 2012.

She is co-author of *Maternity Nursing* (8th edition), *Maternity & Women's Health Care* (10th edition), and *Clinical Companion for Maternity & Newborn Nursing* (2nd edition) and has authored numerous articles on maternal-newborn topics and the legal aspects of nursing. She is a Fellow in the American Academy of Nursing and a member of the STTI Foundation Fellows Committee and the STTI International Services Task Force. Dr. Perry's experience in international nursing includes teaching international nursing courses in the United Kingdom, Ireland, Italy, Thailand, Ghana, and China and participating in health missions in Ghana, Kenya, and Honduras. For her "exemplary contributions to nursing, public service, and selfless commitment and passion in shaping the future of international health," she received the President's Award from the Global Caring Nurses Foundation, Inc, in 2008. In January 2012, she and 47 other women climbed Mt. Kilimanjaro, the highest mountain in Africa, to raise awareness of human trafficking and to raise funds to support projects to combat human trafficking.

Marilyn J. Hockenberry is the Bessie Baker Distinguished Professor of Nursing and Professor of Pediatrics at Duke University. She serves as a Chair for the Duke Institutional Review Board and is Co-Chair of the Oncology Nursing Center of Excellence within the Duke Translational Nursing Institute. For over 18 years she served as the Director of the Pediatric Nurse Practitioner Program in the Texas Children's Cancer Center. Her research focuses on symptom management and treatment-related side effects experienced by children who have cancer. Dr. Hockenberry's current NIH-funded research studies are evaluating the treatment-related symptoms and neurocognitive deficits of leukemia treatment. She has authored over 80 articles and has served as the senior editor on the Wong nursing textbooks for many years.

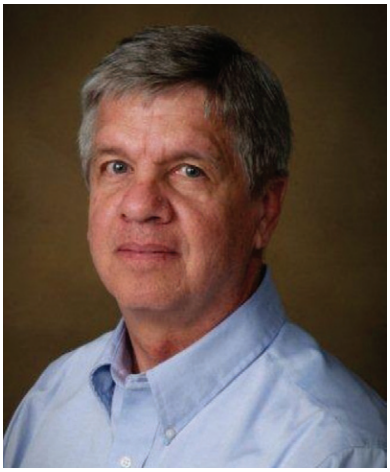
Dr. Hockenberry completed her prenursing education at Mt. Vernon Nazarene College and received her Bachelors of Science from Capital University. She received her Masters of Science from Texas Woman's University and her PhD with distinction from the Medical College of Georgia. She is a Fellow of the American Academy of Nursing.

Deitra Leonard Lowdermilk is Clinical Professor Emerita, School of Nursing, University of North Carolina at Chapel Hill. She received her BSN from East Carolina University and her MEd and PhD in Education from the University of North Carolina at Chapel Hill. She is certified in In-Patient Obstetrics by the National Certification Corporation, and she is a Fellow in the American Academy of Nursing. In addition to being a nurse educator for over 34 years, Dr. Lowdermilk has clinical experience as a public health nurse and as a staff nurse in labor and delivery, postpartum, and newborn units, and she has worked in gynecologic surgery and cancer care units.

Dr. Lowdermilk has been recognized for her expertise in nursing education. She has repeatedly been selected as Classroom and Clinical Teacher of the Year by graduating seniors. She was a recipient of the Educator of the Year Award from both the District IV Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) and the North Carolina Nurses Association. She also received the 2005 AWHONN Excellence in Education Award.

She is active in AWHONN and has served as Chair of the North Carolina Section of AWHONN and as chair and member of various committees in AWHONN at the national, district, state, and local levels. She has served as guest editor for the *Journal of Obstetric, Gynecologic, and Neonatal Nursing* and served on editorial boards for other publications.

Dr. Lowdermilk's most significant contribution to nursing has been to promote excellence in nursing practice and education in women's health through integration of knowledge into practice. In 2005 she received the first Distinguished Alumni Award from East Carolina University School of Nursing for her exemplary contributions to the nursing profession in the area of maternal child care and the community. In 2011 she was inducted into the Hall of Fame for the College of Nursing at East Carolina University.



David Wilson received his BSN from Dallas Baptist College (now University) and his MSN from Texas Woman's University. He has more than 20 years of neonatal intensive care experience in Texas and Oklahoma. During his nursing career, David has worked in a number of positions, including staff nurse, neonatal educator, outreach educator, nutrition support coordinator, and BLS and Neonatal Resuscitation Program instructor. David was involved in medical missions in Costa Rica and Colombia for 2 years. David has also been nursing faculty at several universities either on a full-time or adjunct basis for 15 years. Writing for nursing publications is an endeavor he has enjoyed for many years. He has authored several articles pertaining to neonatal and pediatric nursing, has served as a reviewer for two nursing journals, and has been an author and contributor with Mosby/Elsevier since 1993. David is currently a staff nurse and PALS coordinator in the Children's Hospital at Saint Francis in Tulsa, Oklahoma.

Kitty Cashion is a Clinical Nurse Specialist in the Maternal-Fetal Medicine Division at the University of Tennessee Health Science Center, Memphis, College of Medicine, Department of Obstetrics and Gynecology. She received her BSN from the University of Tennessee College of Nursing in Memphis and her MSN in Parent-Child Nursing from Vanderbilt University School of Nursing in Nashville, Tennessee. Ms. Cashion is certified as a High Risk Perinatal Nurse through the American Nurses Credentialing Center (ANCC).

Ms. Cashion's job responsibilities at the University of Tennessee include providing education regarding low and high risk obstetrics to staff nurses in West Tennessee community hospitals. In addition, she works part-time as an OB case manager at Alpha Maxx Healthcare in Memphis, Tennessee, and teaches OB clinical for nursing students at Northwest Mississippi Community College in Senatobia, Mississippi, and at Union University in Germantown, Tennessee.

Ms. Cashion has been an active AWHONN member, holding office at both the local and state levels. She is currently the Legislative Chair for the AWHONN Tennessee Section. Ms. Cashion has also served as an officer and board member of the Tennessee Perinatal Association and is an active volunteer for the Tennessee chapter of the March of Dimes Birth Defects Foundation.

Ms. Cashion has contributed to several obstetric nursing textbooks in the past and co-authored a series of Virtual Clinical Excursions workbooks to accompany four obstetric nursing textbooks published by Elsevier. More recently, she is one of the authors of *Maternity Nursing* (8th edition), *Maternity & Women's Health Care* (10th edition), and *Clinical Companion for Maternity & Newborn Nursing* (2nd edition).

Kathryn R. Alden is Clinical Associate Professor in the School of Nursing at the University of North Carolina at Chapel Hill. She earned a bachelor's degree in nursing from UNC Charlotte, a master's degree from UNC Chapel Hill, and a doctorate in education from North Carolina State University. Dr. Alden has extensive experience as a nursing educator for baccalaureate students. At UNC Chapel Hill, she serves as course coordinator for maternal/newborn nursing and as lead academic counselor for the undergraduate nursing program. She has been recognized for her clinical teaching expertise and for her work in student counseling. Dr. Alden is an international board-certified lactation consultant who teaches prenatal breastfeeding classes for expectant parents as well as continuing education programs on breastfeeding for health care professionals.

Dr. Alden was an early adopter of human patient simulation and has been instrumental in the use of this teaching strategy with undergraduate nursing students. She has created numerous simulation scenarios, including two cases for Elsevier's *Simulation Learning System*. She has co-authored chapters on simulation for the Agency for Healthcare Research and Quality (AHRQ), the National League for Nursing, and other nursing texts. As an author, associate editor, and co-editor for Elsevier, Dr. Alden has contributed to numerous maternity textbooks.

PREFACE

This fifth edition of *Maternal Child Nursing Care* combines essential maternity and pediatric nursing information into one text. The text focuses on the care of women during their reproductive years and the care of children from birth through adolescence. The issues and concerns of childbearing women and the health care of children are the primary concentrations. The promotion of wellness and the management of common women's health problems and child development in the context of the family are also addressed. As we move further into the twenty-first century, this fifth edition of *Maternal Child Nursing Care* is designed to address the changing needs of women during their childbearing years and children during their developing years.

Maternal Child Nursing Care was developed to provide students with the knowledge and skills they need to become competent critical thinkers and to attain the sensitivity needed to become caring nurses. This fifth edition has been revised and refined in response to comments and suggestions from educators, clinicians, and students. It includes the most accurate, current, and clinically relevant information available.

APPROACH

Professional nursing practice continues to evolve and adapt to society's changing health priorities. The rapidly changing health care delivery system offers new opportunities for nurses to alter the practice of maternity and pediatric nursing and to improve the way care is given. Increasingly, nursing practice must be evidence based. It is incumbent on nurses to use the most up-to-date and scientifically supported information on which to base their care. To assist nurses in providing this type of care, **Evidence-Based Practice** boxes with implications for practice are included throughout the text.

Consumers of maternity and pediatric care vary in age, ethnicity, culture, language, social status, marital status, and sexual orientation. They seek care from a variety of health care providers in numerous health care settings, including the home. To meet the needs of these consumers, clinical education must offer students a variety of health care experiences in settings that include hospitals and birth centers, homes, clinics, private physicians' offices, shelters for the homeless or for women and children in need of protection, and other community-based settings.

Care Management has been used as an organizing framework for discussion in the nursing care chapters. This approach demonstrates how nursing must collaborate with other health care disciplines to provide the most comprehensive care possible to women and children. **Nursing Care Plans** reinforce the problem-solving approach to patient care. In chapters that focus on complications of childbearing, reproductive conditions, and childhood illnesses, medical interventions are included along with nursing care management. Throughout the discussion of assessment and care, we alert the nurse to signs of potential problems and provide informational boxes that highlight warning signs and emergency situations.

Patient education is an essential component of the nursing care of women and children. The chapter on women's health promotion and screening emphasizes teaching for self-care to promote wellness and to encourage preventive care. The chapter on transition to parenthood focuses on teaching for new parents and infants at home. Special boxes highlight community care throughout the text. **Family-Centered Care** boxes incorporate family considerations important to the care of women and children. Issues concerning grandparents, siblings, and different family constellations are addressed. In the pediatric chapters, these boxes focus on the special learning needs of families. **Legal Tips** are integrated into the maternity section to emphasize issues related to the care of women and infants. **Alerts** are located throughout the text to draw attention to important information on medications, nursing care, and safety.

This fifth edition features a contemporary design with logical, easy-to-follow headings and an attractive four-color design that highlights important content and increases visual appeal. Hundreds of color photographs and drawings throughout the text, many of them new, illustrate important concepts and techniques to further enhance comprehension. To help students learn essential information quickly and efficiently, we have included numerous features that prioritize, condense, simplify, and emphasize important aspects of nursing care. In addition, the text encourages students to think critically.

SPECIAL FEATURES

- **Atraumatic Care** boxes emphasize the importance of providing competent care without creating undue physical and psychologic distress. Although many of the boxes provide suggestions for managing pain, atraumatic care also considers approaches to promoting self-esteem and preventing embarrassment.
- **Community Focus** boxes emphasize community issues, provide resources and guidance, and illustrate nursing care in a variety of settings.
- **Critical Thinking Case Studies** present students with real-life situations and encourage them to make appropriate clinical judgments. Answer guidelines are provided in *TEACH for Nurses*.
- **Cultural Competence** boxes describe beliefs and practices about pregnancy, childbirth, parenting, and women's health concerns.
- **Emergency** boxes alert students to the signs and symptoms of various emergency situations and provide interventions for immediate implementation.
- **Evidence-Based Practice** boxes are incorporated throughout the book. Findings that confirm effective practices or that identify practices with unknown, ineffective, or harmful effects are located within the narrative.
- **Family-Centered Care** boxes highlight the needs or concerns of families that should be addressed when family-centered care is provided.
- **Guidelines** boxes provide students with examples of various approaches to implementing care.

- **Home Care** boxes emphasize patient and family self-care and provide information to help students transfer learning from the hospital to the home setting.
- **Key Points** at the end of each chapter help the reader summarize major points, make connections, and synthesize information. The Key Points are expanded online and can be found on this book's Evolve site.
- **Learning Objectives** focus students' attention on the important content to be mastered.
- **Legal Tips** are integrated throughout Part 1 to provide students with relevant information to deal with important legal matters in the context of maternity nursing.
- **Medication Guide** boxes and **Medication Alerts** include key information about medications used in maternity and newborn care, including their indications, adverse effects, and nursing considerations.
- **Nursing Alerts** call the reader's attention to critical information that could lead to deteriorating or emergency situations.
- **Nursing Care Plans** are provided for many commonly encountered situations and disorders. Rationales are included for nursing interventions that might not be immediately evident to students.
- **Patient Teaching** boxes assist students to help patients and families become involved in their own care with optimal outcomes.
- **Resources,** including websites and contact information for organizations and educational resources available for the topics discussed, are listed throughout.
- **Safety Alerts** call the reader's attention to potentially dangerous situations that should be addressed by the nurse.
- During assessment, the nurse must be alert for **Signs of Potential Complications;** these are included in chapters that cover uncomplicated pregnancy and childbirth.
- A highly detailed, cross-referenced **index** allows readers to quickly access needed information.

TEACHING AND LEARNING PACKAGE

Several ancillaries for this text have been developed for instructors and students to use in classroom and clinical settings.

For Students

Evolve: Evolve is an innovative website that provides a wealth of content, resources, and state-of-the-art information on maternity and pediatric nursing. Learning resources for students include Animations, Case Studies, Content Updates, Glossary, Printable Key Points, Nursing Skills, and NCLEX-Style Review Questions.

Simulation Learning System (SLS): The Simulation Learning System (SLS) is an online toolkit that helps instructors and facilitators effectively incorporate medium- to high-fidelity simulation into their nursing curriculum. Detailed patient scenarios promote and enhance the clinical decision-making skills of students at all levels. The SLS provides detailed instructions for preparation and implementation of the simulation experience, debriefing questions that encourage critical thinking, and learning resources to reinforce student comprehension. Each scenario in the SLS complements the textbook content and helps bridge the gap between lectures and clinical practice. The SLS provides the perfect environment for students to practice what they are learning in the text for a true-to-life, hands-on learning experience.

Study Guide: This comprehensive and challenging study aid presents a variety of questions to enhance learning of key concepts and content from the text. Multiple-choice and matching questions and Critical Thinking Case Studies are included. Answers for all questions are included at the back of the study guide.

Virtual Clinical Excursions: Virtual Hospital and Workbook Companion: A Virtual Hospital and workbook package has been developed as a virtual clinical experience to expand student opportunities for critical thinking. This package guides the student through a virtual clinical environment and helps the user apply textbook content to virtual patients in that environment. Case studies are presented that allow students to use this textbook as a reference to assess, diagnose, plan, implement, and evaluate "real" patients using clinical scenarios. The state-of-the-art technologies reflected in this virtual hospital demonstrate cutting-edge learning opportunities for students and facilitate knowledge retention of the information found in the textbook. The clinical simulations and workbook represent the next generation of research-based learning tools that promote critical thinking and meaningful learning.

For Instructors

Evolve includes these teaching resources for instructors:

Electronic Test Bank in ExamView format contains more than 1850 NCLEX-style test items, including alternate-format questions. An answer key with page references to the text, rationales, and NCLEX-style coding is included.

TEACH for Nurses includes teaching strategies; in-class case studies; and links to animations, nursing skills, and nursing curriculum standards such as QSEN, concepts, and BSN Essentials.

Electronic Image Collection, containing more than 700 full-color illustrations and photographs from the text, helps instructors develop presentations and explain key concepts.

PowerPoint Slides, with lecture notes for each chapter of the text, assist in presenting materials in the classroom. ***Case Studies*** and ***Audience Response Questions*** for i-clicker are included.

A ***Curriculum Guide*** that includes a proposed class schedule and reading assignments for courses of varying lengths is provided. This gives educators suggestions for using the text in the most essential manner or in a more comprehensive way.

ACKNOWLEDGMENTS

Thanks to Pat Gingrich for preparing the Evidence-Based Practice boxes in Part 1; to Julie Perry Nelson, Loveland, CO, and Cheryl Briggs, RN, Annapolis, MD, for many new photographs; and to those parents who permitted us to use photos of their infants and families. Very special thanks to Heather Bays, Jodi Willard, and Laurie Gower, whose support was crucial for the completion of this project. Thanks also to those faculty and students who provided reports and offered suggestions to ensure accuracy.

Shannon E. Perry
Deitra Leonard Lowdermilk

Special thanks to Patrick Barrera for his continued support of the Wong legacy textbooks. We are so thankful for the supportive staff at Elsevier for their continued devotion to excellence in pediatric nursing education.

Marilyn J. Hockenberry
David Wilson

CHAPTER

1

21st Century Maternity Nursing

Shannon E. Perry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe the scope of maternity nursing.
- Evaluate contemporary issues and trends in maternity nursing.
- Examine social concerns in maternity nursing.
- Explain risk management and standards of practice in the delivery of nursing care.
- Discuss legal and ethical issues in perinatal nursing.
- Examine *Healthy People 2020* goals related to maternal and infant care.

Maternity nursing encompasses care of childbearing women and their families through all stages of pregnancy and childbirth and the first 4 weeks after birth. Throughout the prenatal period nurses, nurse practitioners, and nurse-midwives provide care for women in clinics and physicians' offices and teach classes to help families prepare for childbirth. Nurses care for childbearing families during labor and birth in hospitals, in birthing centers (e.g., www.birthcenters.org), and in the home. Nurses with special training may provide intensive care for high risk neonates in special care units and high risk mothers in antepartum units, in critical care obstetric units, or in the home. Maternity nurses teach about pregnancy; the process of labor, birth, and recovery; and parenting skills. They provide continuity of care throughout the childbearing cycle.

Nurses caring for women have helped make the health care system more responsive to women's needs. They have been critically important in developing strategies to improve the well-being of women and their infants and have led the efforts to implement clinical practice guidelines and practice using an evidence-based approach. Through professional associations nurses can have a voice in setting standards and influencing health policy by actively participating in the education of the public and state and federal legislators (e.g., www.nursingworld.org; www.can-nurses.ca; www.awhonn.org; www.capwhn.ca). Some nurses hold elective office and influence policy directly. For example, Mary Wakefield, a nurse, is the administrator of the Health Resources and Services Administration, the agency that oversees approximately 7000 community clinics that serve low-income and uninsured people.

ADVANCES IN THE CARE OF MOTHERS AND INFANTS

Although tremendous advances have taken place in the care of mothers and their infants during the past 150 years (Box 1-1), serious problems exist in the United States related to the health and health care of mothers and infants. Lack of access to prepregnancy and pregnancy-related care for all women and the lack of reproductive health services for adolescents are major concerns. Sexually transmitted infections, including acquired immunodeficiency syndrome (AIDS), continue to affect reproduction adversely.

EFFORTS TO REDUCE HEALTH DISPARITIES

Racial and ethnic diversity is increasing within North America. It is estimated that by the year 2050, 54% of the population will be minority, with 46% of the population European-American, 15% African-American, 30% Hispanic, 9.2% Asian-American, 2% American Indians and Alaska Natives, and 0.6% Native Hawaiian and Other Pacific Islanders (U.S. Census Bureau, 2008).

Significant disparities in **morbidity** and mortality rates are experienced by African-Americans, Native Americans, Hispanics, Alaska Natives, and Asian/Pacific Islanders compared to Caucasians. Shorter life expectancy, higher infant and maternal mortality rates, more **birth defects,** and more sexually transmitted infections are found among these ethnic and racial minority groups. The disparities are thought to result from a complex interaction among biologic factors,

environment, and health behaviors. Disparities in education and income are associated with differences in morbidity and mortality.

The Health Resources and Services Administration (HRSA) Health Disparities Collaboratives are part of a national effort to eliminate disparities and improve delivery systems of health care for all people in the United States who are cared for in HRSA-supported health centers. Over 900 community health centers have implemented the collaboratives and are successful in improving quality of care (Chin, 2011). The National Institutes of Health has a commitment to improve the health of minorities and provides funding for research and training of minority researchers (www.nih.gov). The National Institute of Nursing Research includes in its strategic plan support of research that promotes health equity and eliminates health disparities.

BOX 1-1 HISTORIC OVERVIEW OF MILESTONES IN THE CARE OF MOTHERS AND INFANTS

1847—James Young Simpson in Edinburgh, Scotland used ether for an internal podalic version and birth; the first reported use of obstetric anesthesia
1861—Ignaz Semmelweis wrote *The Cause, Concept and Prophylaxis of Childbed Fever*
1906—First U.S. program for prenatal nursing care established
1908—Childbirth classes started by the American Red Cross
1909—First White House Conference on Children convened
1911—First milk bank in the United States established in Boston
1912—U.S. Children's Bureau established
1915—Radical mastectomy determined to be effective treatment for breast cancer
1916—Margaret Sanger established first American birth control clinic in Brooklyn, New York
1918—Condoms became legal in the United States
1923—First U.S. hospital center for premature infant care established at Sarah Morris Hospital in Chicago, Illinois
1929—The modern tampon (with an applicator) invented and patented
1933—Sodium pentothal used as anesthesia for childbirth; *Natural Childbirth* published by Grantly Dick-Read
1934—Dionne quintuplets born in Ontario, Canada, and survive partly due to donated breast milk
1935—Sulfonamides introduced as cure for puerperal fever
1941—Penicillin used as a treatment for infection
1941—Papanicolaou (Pap) tests introduced
1942—Premarin approved by the Food and Drug Administration (FDA) as treatment for menopausal symptoms
1953—Virginia Apgar, an anesthesiologist, published Apgar scoring system of neonatal assessment
1956—Oxygen determined to cause retrolental fibroplasia (now known as retinopathy of prematurity)
1958—Edward Hon reported on the recording of the fetal electrocardiogram (ECG) from the maternal abdomen (first commercial electronic fetal monitor produced in the late 1960s)
1958—Ian Donald, a Glasgow physician, was first to report clinical use of ultrasound to examine the fetus
1959—*Thank You, Dr. Lamaze* published by Marjorie Karmel
1959—Cytologic studies demonstrated that Down syndrome is associated with a particular form of nondisjunction now known as trisomy 21
1960—American Society for Psychoprophylaxis in Obstetrics (ASPO/Lamaze) formed
1960—International Childbirth Education Association founded
1960—Birth control pill introduced in the United States
1962—Thalidomide found to cause birth defects
1963—Title V of the Social Security Act amended to include comprehensive maternity and infant care for women who were low income and high risk
1963—Testing for PKU begun
1965—Supreme Court ruled that married people have the right to use birth control
1967—Rh_0(D) immune globulin produced for treatment of Rh incompatibility
1967—Reva Rubin published article on Maternal Role Attainment
1968—Rubella vaccine became available
1969—Nurses Association of the American College of Obstetricians and Gynecologists (NAACOG) founded; renamed Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) and incorporated as a 501(c)3 organization in 1993
1969—Mammogram became available
1972—Special Supplemental Food Program for Women, Infants, and Children (WIC) started
1973—Abortion legalized in United States
1974—First standards for obstetric, gynecologic, and neonatal nursing published by NAACOG
1975—The Pregnant Patient's Bill of Rights published by the International Childbirth Education Association
1976—First home pregnancy kits approved by FDA
1978—Louise Brown, first test-tube baby, born
1987—Safe Motherhood initiative launched by World Health Organization and other international agencies
1991—Society for Advancement of Women's Health Research founded
1992—Office of Research on Women's Health authorized by U.S. Congress
1993—Female condom approved by FDA
1993—Human embryos cloned at George Washington University
1993—Family and Medical Leave Act enacted
1994—DNA sequences of BRCA1 and BRCA2 identified
1994—Zidovudine guidelines to reduce mother-to-fetus transmission of HIV published
1996—FDA mandated folic acid fortification in all breads and grains sold in United States
1998—Newborns' and Mothers' Health Act went into effect
1998—COGNN becomes AWHONN Canada
1999—First emergency contraceptive pill for pregnancy prevention (Plan B) in women who had unprotected sex approved by FDA
2000—Working draft of sequence and analysis of human genome completed
2006—HPV vaccine available
2010—Centenary of the death of Florence Nightingale
2010—Patient Protection and Affordable Care Act signed into law by President Obama
2011—AWHONN Canada becomes the Canadian Association of Perinatal and Women's Health Nurses (CAPWHN)
2012—U.S. Supreme Court upheld individual mandate but not the Medicaid expansion provisions of the Patient Protection and Affordable Care Act
2012—Scientists reported findings of the ENCODE (**Enc**yclopedia **o**f **D**NA **E**lements) project showing that 80% of the human genome is active

HIV, Human immunodeficiency virus; *HPV,* human papilloma virus.

The Centers for Disease Control and Prevention (CDC) released the First Periodic Health Disparities and Inequalities Report—United States, 2011 (CDC, 2011). The report includes recent trends and variation in health disparities and inequalities in some social and health indicators and provides data against which to measure progress in eliminating disparities. Topics specific to perinatal nursing that are addressed are infant deaths, preterm births, and adolescent pregnancy and childbirth. Also in 2011 the U.S. Department of Health and Human Services (USDHHS) released an HHS Disparities Action Plan that provides a vision of "a nation free of disparities in health and health care" (USDHHS, 2011). Through this plan HHS will promote evidence-based programs, integrated approaches, and best practices to reduce disparities. The Action Plan complements the 2011 National Stakeholder Strategy for Achieving Health Equity prepared by the National Partnership for Action. This strategy proposes a comprehensive, community-driven approach to achieve health equity through collaboration and synergy (National Partnership for Action, 2011). Through these initiatives the United States is making a concerted effort to eliminate health disparities.

This chapter presents a general overview of issues and trends related to the health and health care of women and infants.

CONTEMPORARY ISSUES AND TRENDS

Healthy People 2020 Goals

Healthy People provides science-based 10-year national objectives for improving the health of all Americans. It has four overarching goals: (1) attaining high-quality, longer lives free of preventable disease, disability, injury, and premature death; (2) achieving health equity, eliminating disparities, and improving the health of all groups; (3) creating social and physical environments that promote good health for all; and (4) promoting quality of life, healthy development, and healthy behaviors across all life stages (www.healthypeople.gov/2020/about/default.aspx). The goals of ***Healthy People 2020*** are based on assessments of major risks to health and wellness, changes in public health priorities, and issues related to the health preparedness and prevention of our nation. Of the objectives of *Healthy People 2020*, 33 are related to maternal, infant, and child health (Box 1-2).

Millennium Development Goals

The United Nations **Millennium Development Goals (MDGs)** are eight goals to be achieved by 2015 that respond to the main

BOX 1-2 *HEALTHY PEOPLE 2020* MATERNAL, INFANT, AND CHILD HEALTH OBJECTIVES

- Reduce the rate of fetal and infant deaths.
- Reduce the 1-year mortality rate for infants with Down syndrome.
- Reduce the rate of child deaths.
- Reduce the rate of adolescent and young adult deaths.
- Reduce the rate of maternal mortality.
- Reduce maternal illness and complications caused by pregnancy (complications during hospitalized labor and delivery).
- Reduce cesarean births among low-risk (full-term, singleton, vertex presentation) women.
- Reduce low birth weight (LBW) and very low birth weight (VLBW).
- Reduce preterm births.
- Increase the proportion of pregnant women who receive early and adequate prenatal care.
- Increase abstinence from alcohol, cigarettes, and illicit drugs in pregnant women.
- Increase the proportion of pregnant women who attend a series of prepared childbirth classes.
- Increase the proportion of mothers who achieve a recommended weight gain during their pregnancies.
- Increase the proportion of women of childbearing potential with intake of at least 400 mcg of folic acid from fortified foods or dietary supplements.
- Reduce the proportion of women of childbearing potential who have low red blood cell folate concentrations.
- Increase the proportion of women delivering a live birth; increase those who receive preconception care services and practice key recommended preconception health behaviors.
- Reduce the proportion of people ages 18 to 44 years who have impaired fecundity (i.e., a physical barrier preventing pregnancy or carrying a pregnancy to term).
- Decrease postpartum relapse of smoking in women who quit smoking during pregnancy.
- Increase the proportion of women giving birth who attend a postpartum care visit with a health worker.
- Increase the proportion of infants who are put to sleep on their backs.
- Increase the proportion of infants who are breastfed.
- Increase the proportion of employers who have worksite lactation programs.
- Reduce the proportion of breastfed newborns who receive formula supplementation within the first 2 days of life.
- Increase the proportion of live births that occur in facilities that provide recommended care for lactating mothers and their babies.
- Reduce the occurrence of fetal alcohol syndrome (FAS).
- Reduce the proportion of children diagnosed with a disorder through newborn blood spot screening who experience developmental delay requiring special education services.
- Reduce the proportion of children with cerebral palsy born as LBW infants (less than 2500 g).
- Reduce occurrence of neural tube defects.
- Increase the proportion of young children with an autism spectrum disorder (ASD) and other developmental delays who are screened, evaluated, and enrolled in early intervention services in a timely manner.
- Increase the proportion of children, including those with special health care needs, who have access to a medical home.
- Increase the proportion of children with special health care needs who receive their care in family-centered, comprehensive, coordinated systems.
- Increase appropriate newborn blood-spot screening and follow-up testing.
- Increase the number of states, including the District of Columbia, that verify through linkage with vital records that all newborns are screened shortly after birth for conditions mandated by their state-sponsored screening program.
- Increase the proportion of screen-positive children who receive follow-up testing within the recommended time period.
- Increase the proportion of children with a diagnosed condition identified through newborn screening who have an annual assessment of services needed and received.
- Increase the proportion of VLBW infants born at level III hospitals or subspecialty perinatal centers.

Adapted from HealthyPeople.gov: *Maternal, infant, and child health,* 2012, www.healthypeople.gov/2020/topicsobjectives2020/objectiveslist.aspx?topicId=26.

BOX 1-3 UNITED NATIONS MILLENNIUM DEVELOPMENT GOALS

1. Eradicate extreme poverty and hunger.
2. Achieve universal primary education.
3. Promote gender equality and empower women.
4. Reduce child mortality.
5. Improve maternal health.
6. Combat HIV/AIDS, malaria, and other diseases.
7. Ensure environmental sustainability.
8. Develop a global partnership for development.

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus.

BOX 1-4 NATIONAL QUALITY FORUM SERIOUS REPORTABLE EVENTS PERTAINING TO MATERNAL AND CHILD HEALTH

- Maternal death or serious injury associated with labor or birth in a low-risk pregnancy while being cared for in a health care facility
- Death or serious injury of a neonate associated with labor or delivery in a low-risk pregnancy
- Artificial insemination with the wrong donor sperm or wrong egg

From National Quality Forum (NQF): *Serious reportable events in healthcare—2011 update: a consensus report,* Washington, DC, 2011, NQF.

development challenges in the world. They are drawn from the actions and targets contained in the Millennium Declaration that was adopted by 189 nations and signed by 147 heads of state and governments during the United Nations Millennium Summit in September 2000 (www.un.org/millenniumgoals/goals.html). Goals three through five of the MDGs relate specifically to women and children (Box 1-3).

Integrative Health Care

Integrative health care encompasses complementary and alternative therapies in combination with conventional Western modalities of treatment. Many popular alternative healing modalities offer human-centered care based on philosophies that recognize the value of the patient's input and honor the individual's beliefs, values, and desires. The focus of these modalities is on the whole person, not just on a disease complex. Patients often find that alternative modalities are more consistent with their own belief systems and also allow for more patient **autonomy** in health care decisions (Fig. 1-1). Examples of alternative modalities include acupuncture, macrobiotics, herbal medicines, massage therapy, biofeedback, meditation, yoga, and **chelation** therapy.

The National Center for Complementary and Alternative Medicine (NCCAM) (http://nccam.nih.gov/) is a United States government agency that supports research and evaluation of various alternative and complementary modalities and provides information to health care consumers about such modalities. It is one of the 27 institutes and centers included in the National Institutes of Health.

Problems with the U.S. Health Care System

Structure of the Health Care Delivery System

The U.S. health care delivery system is often fragmented and expensive and is inaccessible to many. Opportunities exist for nurses to alter nursing practice and improve the way care is delivered through managed care, integrated delivery systems, and redefined roles. Consumer participation in health care is increasing, and health care providers include them in decision-making; information is available on the Internet; and care is provided in a technology-intensive environment (Tiedje, Price, and You, 2008).

Reducing Medical Errors

Medical errors are a leading cause of death in the United States and result in as many as 98,000 deaths per year (Pham, Aswani, Rosen, et al., 2012). In Canada adverse events are implicated in up to 23,750 deaths per year (French, 2006). Since the Institute of Medicine

FIG 1-1 Nurse and patient during guided imagery session. (Courtesy Nurses Certificate Program in Interactive Imagery, Foster City, CA.)

(IOM) released its 1999 report, *To Err Is Human: Building a Safer Health System,* a concerted effort has been under way to analyze causes of errors and develop strategies to prevent them. Recognizing the multifaceted causes of medical errors, the Agency for Healthcare Research and Quality (AHRQ) (2000) prepared a fact sheet, *20 Tips to Help Prevent Medical Errors,* for patients and the public. Patients are encouraged to be knowledgeable consumers of health care and ask questions of providers, including physicians, midwives, nurses, and pharmacists.

In 2002 the National Quality Forum published a list of Serious Reportable Events in Healthcare. The list was updated in 2006 and again in 2011, resulting in a total of 29 events. Of these 29 events three pertain directly to maternity and newborn care (Box 1-4). The National Quality Forum published *Safe Practices for Better Healthcare* in 2003 and updated it most recently in 2010 (www.qualityforum.org). The 34 safe practices included should be used in all applicable health care settings to reduce the risk of harm that results from processes, systems, and environments of care. Table 1-1 contains a selection of practices from that document.

In August 2007 the Centers for Medicare & Medicaid Services (CMS) issued a rule that became effective October 2008 that denies payment for eight hospital-acquired conditions (O'Reilly, 2008). Five of the conditions are also on the National Quality Forum list. Conditions that might pertain to maternity nursing include a foreign object retained after surgery, air embolism, blood incompatibility, falls and trauma, and catheter-associated urinary tract infections. Almost 1300 U.S. hospitals waive (do not bill for) costs associated with serious reportable events (O'Reilly, 2008).

TABLE 1-1 SELECTED SAFE PRACTICES FOR BETTER HEALTH CARE

SAFE PRACTICE	PRACTICE STATEMENT
Safe Practice 2: Culture Measurement, Feedback, and Intervention	Health care organizations must measure their culture, provide feedback to leadership and staff, and undertake interventions that reduce patient safety risk.
Safe Practice 5: Informed Consent	Ask each patient or legal surrogate to "teach back" in his or her own words key information about the proposed treatments or procedures for which he or she is being asked to provide informed consent.
Safe Practice 11: Intensive Care Unit Care	All patients in general intensive care units (both adult and pediatric) should be managed by physicians who have specific training and certification in critical care medicine ("critical care certified").
Safe Practice 12: Patient Care Information	Ensure that care information is transmitted and appropriately documented in a timely manner and a clearly understandable form to patients and all of the patients' health care providers/professionals, within and between care settings, who need that information to provide continued care.
Safe Practice 19: Hand Hygiene	Comply with current Centers for Disease Control and Prevention (CDC) hand hygiene guidelines.
Safe Practice 34: Pediatric Imaging	When CT imaging studies are undertaken on children, "child-size" techniques should be used to reduce unnecessary exposure to ionizing radiation.

From National Quality Forum (NQF): *Safe practices for better healthcare—2010 update: a consensus report,* Washington, DC, 2010, NQF.
CT, Computed tomography.

High Cost of Health Care

Health care is one of the fastest-growing sectors of the U.S. economy. Currently 17.4% of the gross domestic product is spent on health care (Squires, 2012). Higher spending in the United States compared to 12 other industrialized countries is related to higher prices, readily accessible technology, and greater obesity (Squires, 2012). Most researchers agree that caring for the increased number of low-birth-weight (LBW) infants in neonatal intensive care units contributes significantly to overall health care costs.

Midwifery care has helped contain some health care costs. However, not all insurance carriers reimburse nurse practitioners and clinical nurse specialists as direct care providers. Nor do they reimburse for all services provided by nurse-midwives, a situation that continues to be a problem. Nurses must become involved in the politics of cost containment because they, as knowledgeable experts, can provide solutions to many health care problems at a relatively low cost.

Limited Access to Care

Barriers to access must be removed so pregnancy outcomes and care of children can be improved. The most significant barrier to access is the inability to pay. The number of uninsured people in the United States in 2010 was 49.9 million or 16.3% of the population (DeNavas-Walt, Proctor, and Smith, 2011). Lack of transportation and dependent child care are other barriers. In addition to a lack of insurance and high costs, a lack of providers for low-income women exists because many physicians either refuse to take Medicaid patients or take only a few such patients. This presents a serious problem because a significant proportion of births are to mothers who receive Medicaid.

Health Care Reform

In early 2010 President Obama signed into law the Patient Protection and Affordable Care Act. The Act aims to make insurance affordable, contain costs, strengthen and improve Medicare and Medicaid, and reform the insurance market. There are provisions to promote prevention and improve public health; improve the quality of care for all Americans; reduce waste, fraud, and abuse; and reform the health delivery system. There are some immediate benefits, but implementation of the act will occur over the next several years.

In 2012 26 states, several individuals, and the National Federation of Independent Business brought suit challenging the constitutionality of the individual mandate (requirement for most Americans to have minimum essential health insurance) and the Medicaid expansion (expand the scope of coverage and increase the number of individuals the states must cover). The Supreme Court upheld the individual mandate but not the Medicaid expansion (Sacks, 2012). The debate continues on how the plan will be implemented.

Health Literacy

Health literacy involves a spectrum of abilities, ranging from reading an appointment slip to interpreting medication instructions. These skills must be assessed routinely to recognize a problem and accommodate patients with limited literacy skills. Most patient education materials are written at too high a level for the average adult (Wilson, 2009). According to the National Assessment of Adult Literacy, only 12% of English-speaking adults in the United States have health literacy skills that are proficient (Kutner, Greenberg, Jin, et al., 2006). The CDC has a health literacy website (www.cdc.gov/healthliteracy) that highlights implementation of goals and strategies of the National Action Plan to Improve Health Literacy (USDHHS, Office of Disease Prevention and Health Promotion, 2010). Health literacy is part of the Patient Protection and Affordable Care Act.

As a result of the increasingly multicultural U.S. population, there is a more urgent need to address health literacy as a component of culturally and linguistically competent care. Health care providers contribute to health literacy by using simple, common words; avoiding jargon; and assessing whether the patient understands the discussion. Speaking slowly and clearly and focusing on what is important increase understanding.

Trends in Fertility and Birth Rate

Fertility trends and birth rates reflect women's needs for health care. Box 1-5 defines biostatistical terminology useful in analyzing

BOX 1-5 MATERNAL-INFANT BIOSTATISTICAL TERMINOLOGY

Abortus: An embryo or fetus that is removed or expelled from the uterus at 20 weeks of gestation or less, weighs 500 g or less, or measures 25 cm or less

Birth rate: Number of live births in 1 year per 1000 population

Fertility rate: Number of births per 1000 women between the ages of 15 and 44 years (inclusive), calculated on an annual basis

Infant mortality rate: Number of deaths of infants younger than 1 year of age per 1000 live births

Maternal mortality rate: Number of maternal deaths from births and complications of pregnancy, childbirth, and puerperium (the first 42 days after termination of the pregnancy) per 100,000 live births

Pregnancy-associated deaths: All deaths during pregnancy and within the 1 year following the end of pregnancy

Pregnancy-related deaths (subset of pregnancy-associated): Deaths that are a complication of pregnancy, an aggravation of an unrelated condition by the physiology of pregnancy, or a chain of events initiated by the pregnancy

Neonatal mortality rate: Number of deaths of infants younger than 28 days of age per 1000 live births

Perinatal mortality rate: Number of stillbirths and number of neonatal deaths per 1000 live births

Stillbirth: An infant who at birth demonstrates no signs of life such as breathing, heartbeat, or voluntary muscle movements

maternity health care. In 2009 the fertility rate (i.e., births per 1000 women from 15 to 44 years of age) was 66.7 (Kochanek, Kirmeyer, Martin, et al., 2012). The highest birth rates occurred among women between 25 and 29 years of age (110.5). The birth rate (i.e., number of live births in 1 year per 1000 population), was 13.5 in 2009; the teen birth rate was 39.1. In 2009 the proportion of births by unmarried women varied widely among racial groups in the United States: non-Hispanic black, 72.8%; Hispanic, 53.2%; and non-Hispanic white, 29% (Kochanek, Kirmeyer, Martin, et al., 2012).

Maternal Mortality

Worldwide approximately 800 women die each day of problems related to pregnancy or childbirth. In the United States in 2009, the annual **maternal mortality rate** (number of maternal deaths per 100,000 live births) was 17.8 (CDC, 2013). Although the overall number of maternal deaths is small, maternal mortality remains a significant problem because a high proportion of deaths are preventable, primarily through improving the access to and use of prenatal care services. In the United States there is significant racial disparity in the rates of maternal death: non-Hispanic black women (35.6), non-Hispanic white women (11.7), and women of other races (17.6) (CDC, 2013).

The leading causes of maternal death attributable to pregnancy differ over the world. In general three major causes have persisted for the last 50 years: hypertensive disorders, infection, and hemorrhage. Unsafe abortion is an additional factor. The three leading causes of maternal mortality in the United States today are gestational hypertension, pulmonary embolism, and hemorrhage. Factors that are strongly related to maternal death include age (younger than 20 years and 35 years or older), lack of prenatal care, low educational attainment, unmarried status, and non-Caucasian race. Worldwide strategies to reduce maternal mortality rates include improving access to skilled attendants at birth, providing postabortion care, improving family planning services, and providing adolescents with better reproductive health services (MDGs, 2008).

Maternal Morbidity

Although mortality is the traditional measure of maternal health and maternal health is often measured by neonatal outcomes, pregnancy complications are important. Currently no surveillance method is available to measure the incidence of maternal morbidity. It includes such conditions as acute renal failure, amniotic fluid embolism, cerebrovascular accident, eclampsia, pulmonary embolism, liver failure, obstetric shock, respiratory failure, septicemia, and complications of anesthesia (pulmonary, cardiac, central nervous system) (Berg, Mackay, Qin, et al., 2009). Maternal morbidity results in a high risk pregnancy. The diagnosis of high risk imposes a **situational crisis** on the family. The combined efforts of medical and nursing personnel are required to care for these patients, who often need the expertise of physicians and nurses trained in both critical care obstetrics and intensive care medicine or nursing.

Obesity

More than one third (36.2%) of women in the United States are obese (body mass index of 30 or greater); in Canada less than one fourth (23.9%) of women are obese. Obesity in women demonstrates significant racial disparities: in the United States 49.6% of non-Hispanic black women, 45.1% of Hispanic women, and 33.0% of non-Hispanic white women ages 20 years and older are obese (Flegal, Carroll, Ogden, et al., 2010; Shields, Carroll, and Ogden, 2011). Approximately 20% of women who give birth in the United States are obese. The two most frequently reported maternal medical risk factors are hypertension associated with pregnancy and diabetes, both of which are associated with obesity. Decreased fertility, congenital anomalies, miscarriage, and fetal death are associated with obesity. Obesity in pregnancy is associated with the use of increased health care services and longer hospital stays (Chu, Bachman, Callaghan, et al., 2008).

Regionalization of Perinatal Health Care Services

Not all facilities develop and maintain the full spectrum of services required for high risk perinatal patients. As a consequence, regionalization of hospital-based perinatal health care services occurred, and facilities within a geographic region were organized to provide different levels of care. This system of coordinated care was also applied to preconception and ambulatory prenatal care services.

Guidelines have been established regarding the level of care that can be expected at any given facility. In ambulatory settings providers must distinguish themselves by the level of care they provide. Basic care is provided by obstetricians, family practice physicians, certified nurse-midwives, and other advanced practice clinicians approved by local governance. Routine risk-oriented prenatal care, education, and support are provided. Providers offering specialty care are obstetricians who must provide fetal diagnostic testing and management of obstetric and medical complications in addition to basic care. Subspecialty care is provided by maternal-fetal medicine specialists and includes the aforementioned specialty care in addition to genetic testing, advanced fetal therapies, and management of severe maternal and fetal complications (AAP and ACOG, 2012). Collaboration among providers to meet the woman's needs is the key to reducing perinatal morbidity and mortality (AAP and ACOG, 2012).

High-Technology Care

Advances in scientific knowledge and the large number of high risk pregnancies have contributed to a health care system that emphasizes high-technology care. Maternity care has extended to preconception counseling, more and better scientific techniques to monitor the mother and fetus, more definitive tests for hypoxia and acidosis, and neonatal intensive care units. The labors of virtually all women who give birth in hospitals are monitored electronically despite the lack of evidence of efficacy of such monitoring. The numbers of assisted labors and births are increasing. Internet-based information is available to the public that enhances interactions among health care providers, families, and community providers. Point-of-care testing is available. Personal data assistants are used to enhance comprehensive care; the medical record is increasingly in electronic form.

Telehealth is an umbrella term for the use of communication technologies and electronic information to provide or support health care when the participants are separated by distance. It permits specialists, including nurses, to provide health care and consultation when distance separates them from those needing care. This technology has the potential to save billions of dollars annually for health care, but these technologic advances have also contributed to higher health care costs. In general high-technology care has flourished, whereas "health" care has become relatively neglected.

Social Media

Social media uses Internet-based technologies to allow users to create their own content and participate in dialog. The most common social media platforms are Facebook, Twitter, and LinkedIn (Duffy, 2011). Through use of these technologies, nurses can link with nurses with similar interests, share insights about patient care, and advocate for patients (Saver, 2010). However, there are pitfalls for nurses using this technology. Patient privacy and confidentiality can be violated, and institutions and colleagues can be cast in unfavorable lights with negative consequences for those posting the information. Nursing students have been expelled from school, and nurses have been fired or reprimanded by a Board of Nursing for injudicious posts. To help make nurses aware of their responsibilities when using social media, the American Nurses Association (ANA) published six principles for social networking and the nurse (Box 1-6). In addition, the National Council of State Boards of Nursing (NCSBN) issued a *White Paper: a Nurse's Guide to the Use of Social Media* (NCSBN, 2011). The paper details issues of confidentiality and privacy, possible consequences of inappropriate use of social media, common myths and misunderstandings of social media, and tips on how to avoid problems.

Community-Based Care

A shift in settings from acute care institutions to ambulatory settings, including the home, has occurred (see Chapter 2). Even childbearing women at high risk are cared for on an outpatient basis or in the home. Technology previously available only in the hospital is now found in the home. This has affected the organizational structure of care, the skills required in providing such care, and the costs to consumers.

Home health care also has a community focus. Nurses are involved in providing care for women and infants in homeless shelters and adolescents in school-based clinics and in promoting health at community sites, churches, and shopping malls. Nursing education curricula are increasingly community based.

BOX 1-6 ANA'S PRINCIPLES FOR SOCIAL NETWORKING AND THE NURSE

- Nurses must not transmit or place online individually identifiable patient information.
- Nurses must observe ethically prescribed professional patient-nurse boundaries.
- Nurses should understand that patients, colleagues, institutions, and employers may view postings.
- Nurses should take advantage of privacy settings and seek to separate personal and professional information online.
- Nurses should bring content that could harm a patient's privacy, rights, or welfare to the attention of appropriate authorities.
- Nurses should participate in developing institutional policies governing online contact.

From American Nurses Association: *Fact sheet: Navigating the world of social media,* Washington, DC, 2011, Author.

Childbirth Practices

Prenatal care can promote better pregnancy outcomes by providing early risk assessment and promoting healthy behaviors such as improved nutrition and smoking cessation. Prenatal care ideally begins before pregnancy because early decisions lay the foundation for the entire perinatal year. If at all possible, education continues in each trimester of pregnancy and extends through the early postpartum weeks. Some health care providers today promote preconception care as an important component of perinatal services. Preconception or early-pregnancy classes also emphasize health-promoting behavior and choices of care.

In 2006 69% of all women received care in the first trimester. Disparity in receiving prenatal care by race and **ethnicity** exists: 12.2% of Hispanic women, 11.8% of non-Hispanic blacks, and 5.2% of non-Hispanic whites received late or no prenatal care (Heron, Sutton, Xu, et al., 2010). In spite of these statistics, substantial gains have been made in the use of prenatal care since the early 1990s, which is attributed to the expansion in the 1980s of Medicaid coverage for pregnant women.

Women can choose physicians or nurse-midwives as primary care providers. In 2009 physicians (medical doctors [MDs] and doctors of osteopathy [DOs]) attended 92.1%, and certified nurse-midwives attended 7.4% of all hospital births (Martin, Hamilton, Ventura, et al., 2011) (see Critical Thinking Case Study). Home births accounted for 0.7% of U.S. births. The rate of vaginal births after cesarean **(VBACs)** declined, whereas **cesarean births** increased to 32.9% of live births in the United States in 2009 (Martin, Hamilton, Ventura, et al., 2011).

Women who choose nurse-midwives as their primary providers participate more actively in childbirth decisions and receive fewer interventions during labor. Certified nurse-midwives (CNMs) are registered nurses with education in the two disciplines of nursing and midwifery. Certified midwives (direct-entry midwives) are educated only in the discipline of midwifery. In the United States certification of midwives is through the American College of Nurse-Midwives (ACNM), the professional association for midwives. The Royal College of Midwives is the professional association for midwives in the United Kingdom. In Canada the Association of Ontario Midwives is the professional association, and the College of Midwives of Ontario is the regulatory body for midwives in Ontario;

CRITICAL THINKING CASE STUDY

Safety and Efficacy of Midwifery Care

A group of nurse-midwives is setting up practice in your hometown. They are to collaborate with one of the groups of obstetricians in the same city. A letter to the editor appeared in the local newspaper stating that the presence of midwives will jeopardize care of pregnant women in the community because midwives usually care for the poor and indigent, deliver babies at home, and therefore do not have the skills to work in hospitals and care for middle-class women who have insurance. The letter-writer urged the community to boycott the midwives to ensure safe childbirth for women in the community.

1. Evidence—Is there sufficient evidence to document the qualifications of nurse-midwives and their safety record to write a response to this letter?
2. Assumptions—Describe some assumptions about midwifery care:
   a. Education of midwives
   b. Practice sites of midwifery care
   c. Statistics about safety of midwifery care
3. What implications and priorities for education about midwifery care can be made at this time?
4. Does the evidence objectively support your conclusion?

FIG 1-2 Father "catching" newborn daughter who cried before her lower body had emerged. (Courtesy Darren and Julie Nelson, Loveland, CO.)

the other provinces of Canada have similar regulatory bodies (e.g., College of Midwives of British Columbia). Many national associations belong to the International Confederation of Midwives, which comprises 97 member associations from 86 countries in the Americas and Europe, Africa, and the Asia-Pacific region.

With family-centered care, fathers, partners, grandparents, siblings, and friends may be present for labor and birth. Fathers or partners may be present for cesarean births. Fathers or partners may participate in vaginal births by "catching the baby" or cutting the umbilical cord or both (Fig. 1-2). **Doulas** (i.e., trained and experienced female labor attendants) may be present to provide a continuous, one-on-one caring presence throughout the labor and birth. Ideally newborns are placed skin-to-skin with the mother immediately after birth and encouraged to breastfeed as soon as possible. Nonseparation is common; neonates often remain in the room with their parents and may never transfer to a newborn nursery. Parents actively participate in newborn care on mother/baby units, in nurseries, and in neonatal intensive care units.

Discharge of a mother and baby within 24 hours of birth has created a growing need for follow-up or home care. In some settings discharge may occur as early as 6 hours after birth. Legislation has been enacted to ensure that mothers and babies are permitted to stay in the hospital for at least 48 hours after vaginal birth and 96 hours after cesarean birth, although they may choose to leave earlier. Focused and efficient teaching is necessary to enable the parents and infant to make the transition safely from the hospital to the home.

Involving Consumers and Promoting Self-Management

Self-management is appealing to both patients and the health care system because of its potential to reduce health care costs. Maternity care is especially suited to self-management because childbearing is primarily health focused, women are usually well when they enter the system, and visits to health care providers can present the opportunity for health and illness interventions. Measures to improve health and reduce risks associated with poor pregnancy outcomes and illness can be addressed. Topics such as nutrition education, stress management, smoking cessation, alcohol and drug treatment, prevention of violence, improvement of social supports, and parenting education are appropriate for such encounters.

International Concerns

Female genital mutilation, infibulation (surgical closure of the labia majora), genital cutting, and *circumcision* are terms used to describe procedures in which part or all of the female external genitalia is removed for cultural or nontherapeutic reasons (WHO, 2006). Worldwide many women undergo such procedures. With the growing number of immigrants from Africa and other countries where female genital mutilation is practiced, nurses in the United States and Canada will increasingly encounter women who have undergone the procedure. These women are significantly more likely to have adverse obstetric outcomes resulting in one or two additional perinatal deaths per 100 births (WHO, 2006). Ethical dilemmas arise when the woman requests that after birth the perineum be repaired as it was after infibulation and the health care provider believes that such repair is unethical. The International Council of Nurses and other health professionals have spoken out against procedures that result in mutilation as harmful to women's health. In the United States performing female genital mutilation on a person younger than 18 years is a crime (Sandy, 2011).

Human trafficking is a $32 billion business that exists in the United States and internationally (Dovydaitis, 2010). Health care professionals may interact with victims who are in captivity. This provides an opportunity to identify victims, intervene to help them obtain necessary health services, and provide information about ways to escape from their situation (see Chapter 6).

THE FUTURE OF NURSING

In 2008 the Robert Wood Johnson Foundation and the IOM initiated a 2-year process to meet the need to assess and transform the

nursing profession. The IOM appointed the committee, which developed four key messages: (1) nurses should practice to the full extent of their education and training; (2) nurses should achieve higher levels of education and training through an improved education system that promotes seamless academic progression; (3) nurses should be full partners with physicians and other health care professionals in redesigning health care in the United States; and (4) effective workforce planning and policy making require better data collection and an improved information infrastructure (IOM, 2010). Throughout the United States individual states and nursing organizations are making concerted efforts to implement the recommendations of the report.

Trends in Nursing Practice

The increasing complexity of care for maternity and women's health patients has contributed to specialization of nurses working with these patients. This specialized knowledge is gained through experience, advanced degrees, and certification programs. Nurses in advanced practice (e.g., nurse practitioners and nurse-midwives) may provide primary care throughout a woman's life, including during the pregnancy cycle. In some settings the clinical nurse specialist and nurse practitioner roles are blended; and nurses deliver high-quality, comprehensive, and cost-effective care in a variety of settings. In other settings nurses educated in both critical care and high risk obstetrics are providing care in obstetric critical care units. Lactation consultants provide services in the hospital setting, in clinics and physician offices, and during home visits.

Nursing Interventions Classification

When the National IOM proposed that all patient records be computerized by the year 2000, a need for a common language to describe the contributions of nurses to patient care became evident. Nurses from the University of Iowa developed a comprehensive standardized language that describes interventions that are performed by generalist or specialist nurses. This language is included in the Nursing Interventions Classification (NIC) (Bulechek, Butcher, Dochterman, et al., 2013). Interventions commonly used by maternal-child nurses include those in Box 1-7.

Evidence-Based Practice

Evidence-based practice (i.e., providing care based on evidence gained through research and clinical trials) is emphasized increasingly. Although not all practice can be evidence based, practitioners must use the best available information on which to base their interventions. The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) *Standards and Guidelines for Professional Nursing Practice in the Care of Women and Newborns* (AWHONN, 2009) and the *Standards for Professional Perinatal Nursing Practice and Certification in Canada* (AWHONN, 2002) include an evidence-based approach to practice. Discussion of nursing care and evidence-based practice boxes throughout this text provide examples of evidence-based practice in perinatal and women's health nursing (see Evidence-Based Practice box).

Cochrane Pregnancy and Childbirth Database

The Cochrane Pregnancy and Childbirth Database was first planned in 1976 with a small grant from the World Health Organization to Dr. Iain Chalmers and colleagues at Oxford. In 1993 the Cochrane Collaboration was formed, and the Oxford Database of Perinatal Trials became known as the Cochrane Pregnancy and Childbirth Database. The Cochrane Collaboration oversees up-to-date, systematic reviews of randomized controlled trials of health care and disseminates these reviews. The premise of the project is that these types of studies provide the most reliable evidence about the effects of care.

The evidence from these studies should encourage practitioners to implement useful measures and abandon those that are useless or harmless. Studies are ranked in six categories:

BOX 1-7 CHILDBEARING CARE INTERVENTIONS

Level 1 Domain: Family

- Care that supports the family

Level 2 Class: Childbearing Care

- Interventions to assist in the preparation for childbirth and management of the psychologic and physiologic changes before, during, and immediately after childbirth

Level 3: Interventions

- Amnioinfusion
- Birthing
- Bleeding reduction: antepartum uterus
- Bleeding reduction: postpartum uterus
- Cesarean birth care
- Childbirth preparation
- Circumcision care
- Electronic fetal monitoring: antepartum
- Electronic fetal monitoring: intrapartum
- Environmental management: attachment process
- Family integrity promotion: childbearing family
- Family planning: contraception
- Family planning: infertility
- Family planning: unplanned pregnancy
- Fertility preservation
- Genetic counseling
- Grief work facilitation: perinatal death
- High risk pregnancy care
- Infant care: newborn
- Infant care: preterm
- Intrapartal care
- Intrapartal care: high risk delivery
- Kangaroo care
- Labor induction
- Labor suppression
- Lactation suppression
- Newborn care
- Nonnutritive sucking
- Phototherapy: neonate
- Postpartal care
- Preconception counseling
- Pregnancy termination care
- Prenatal care
- Reproductive technology management
- Resuscitation: fetus
- Resuscitation: neonate
- Risk identification: childbearing family
- Surveillance: late pregnancy
- Tube care: umbilical line
- Ultrasonography: limited obstetric

EVIDENCE-BASED PRACTICE

Seeking and Evaluating Evidence: A Necessary Competency for Quality and Safety

Throughout this text you will see Evidence-Based Practice boxes. These boxes provide examples of how a nurse might conduct an inquiry into an identified practice question. Curiosity and access to a virtual or real library are all the nurse needs to be confident that his or her practice has a sound foundation of evidence.

A literature search may reveal up to three levels of evidence. The first layer consists of primary studies. The strongest of these are randomized controlled trials. Well-designed studies, even small ones, add another piece to the puzzle.

These primary studies may be combined into the second level of evidence. In systematic analyses such as those in the Cochrane Database, the researcher uses a methodology to identify all studies relevant to a particular question. If the data are similar enough, they can be pooled into a meta-analysis. If the evidence is strong, some analyses will form the basis for recommendations for practice and to guide further inquiry.

At the tertiary level professional organizations such as the Agency for Healthcare Research and Quality (AHRQ) (www.ahrq.gov), or the National Guidelines Clearinghouse (NGC) (guideline.gov) may decide to address a broad practice question by sorting through all the available primary and secondary evidence and consulting experienced clinicians. After thoughtful review the committee of experts in the organization crafts its consensus statement. These recommendations for best practice stand on the shoulders of the systematic analysts, who stand on the many shoulders of the primary researchers.

Provided that the professional organization is well-respected and the process is rigorous, these guidelines in the consensus statement carry enormous authority. Individuals and institutions may choose to adopt them with confidence. An example of this is the Association of Women's Health, Obstetric and Neonatal Nurses(AWHONN) (www.awhonn.org) Late Preterm Infant Initiative. This initiative began in 2005 in response to the confusion that surrounded the care of infants who do not qualify for NICU admission yet require extra vigilance. Nurseries can adapt these recommendations to their specific institutions, enabling nurses to become more effective at caring for the unique problems of this population of neonates. Like AWHONN, most of the professional organizations make their guidelines available free of charge on their websites.

To develop common language and goals for nursing education, the Quality and Safety Education for Nurses (QSEN) (www.qsen.org) Project expert panel identified six competencies necessary to enable the new nurse to continuously improve the health care system: patient-centered care, teamwork and collaboration, evidence-based practice, quality improvement, safety, and informatics. Most nursing challenges require a combination of these competencies. Each competency is further defined as having targets for knowledge, skills, and attitude. The Evidence-Based Practice boxes in this textbook include examples that illustrate each of these targets specific to that competency. A mastery of QSEN competencies greatly enriches the nurse's ability to identify and improve patient and health care–system problems and communicate within the interdisciplinary team.

Pat Mahaffee Gingrich

NICU, Neonatal Intensive Care Unit.

1. Beneficial forms of care
2. Forms of care that are likely to be beneficial
3. Forms of care with a trade-off between beneficial and adverse effects
4. Forms of care with unknown effectiveness
5. Forms of care that are unlikely to be beneficial
6. Forms of care that are likely to be ineffective or harmful

Joanna Briggs Institute

Established in 1996 as an initiative of the Royal Adelaide Hospital and the University of Adelaide in Australia, the Joanna Briggs Institute (JBI) uses a collaborative approach for evaluating evidence from a range of sources (www.joannabriggs.edu.au). The JBI has formed collaborations with a variety of universities and hospitals around the world, including in the United States and Canada. In 2007 the JBI adopted the following grades of recommendation for evidence of feasibility, appropriateness, meaningfulness, and effectiveness: *A,* strong support that merits application; *B,* moderate support that warrants consideration of application; and *C,* not supported (The Joanna Briggs Institute, 2008). The JBI provides another source for perinatal nurses to access information to support evidence-based practice.

Outcomes-Oriented Practice

Outcomes of care (i.e., the effectiveness of interventions and quality of care) are receiving increased emphasis. Outcomes-oriented care measures effectiveness of care against benchmarks or standards. It is a measure of the value of nursing using quality indicators and answers the question, "Did the patient benefit or not from the care provided?" (Moorhead, Johnson, Maas, et al., 2012). The Outcome and Assessment Information Set (OASIS) is an example of an outcome system important for nursing. Its use is required by the CMS in all home health organizations that are Medicare accredited. The Nursing Outcomes Classification (NOC) is an effort to identify outcomes and related measures that can be used for evaluation of care of individuals, families, and communities across the care continuum (Moorhead, Johnson, Maas, et al., 2012). An example of outcomes classification is provided in Table 1-2.

A Global Perspective

Advances in medicine and nursing have resulted in increased knowledge and understanding in the care of mothers and infants and reduced perinatal morbidity and mortality rates. However, these advances have affected predominantly the industrialized nations. For example, approximately 3.2 million children have human immunodeficiency virus (HIV) or AIDS acquired through perinatal transmission; the majority of these children live in sub-Saharan Africa.

As the world becomes smaller because of travel and communication technologies, nurses and other health care providers are gaining a global perspective and participating in activities to improve the health and health care of people worldwide. Nurses participate in medical outreach, providing obstetric, surgical, ophthalmologic, orthopedic, or other services (Fig. 1-3); attend international meetings; conduct research; and provide international consultation. International student and faculty exchanges occur. More articles about health and health care in various countries are appearing in nursing journals. Several schools of nursing in the United States are World Health Organization Collaborating Centers.

STANDARDS OF PRACTICE AND LEGAL ISSUES IN DELIVERY OF CARE

Nursing standards of practice in perinatal and women's health nursing have been described by several organizations, including the ANA, which publishes standards for maternal-child health nursing; AWHONN, which publishes standards of practice and education for

TABLE 1-2 NURSING OUTCOMES CLASSIFICATION

Breastfeeding Establishment: Infant (1000)

Domain—Physiologic health (II)

Class—Nutrition (K)

Scale—Not adequate to totally adequate (f)

Definition: Infant attachment to and sucking from the mother's breast for nourishment during the first 3 weeks of breastfeeding

BREASTFEEDING ESTABLISHMENT: INFANT	NOT ADEQUATE 1	SLIGHTLY ADEQUATE 2	MODERATELY ADEQUATE 3	SUBSTANTIALLY ADEQUATE 4	TOTALLY ADEQUATE 5
Indicators					
100001. Proper alignment and latch-on	1	2	3	4	5
100002. Proper areolar grasp	1	2	3	4	5
100003. Proper areolar compression	1	2	3	4	5
100004. Correct suck and tongue placement	1	2	3	4	5
100005. Audible swallow	1	2	3	4	5
100006. Swallowing a minimum of 5 to 10 minutes per breast	1	2	3	4	5
100007. Minimum 8 feedings per day	1	2	3	4	5
100008. Urinations per day appropriate for age	1	2	3	4	5
100009. Loose, yellow, seedy stools per day appropriate for age	1	2	3	4	5
100010. Appropriate weight gain for age	1	2	3	4	5

perinatal nurses (Box 1-8); American College of Nurse-Midwives (ACNM), which publishes standards of practice for midwives; and the National Association of Neonatal Nurses (NANN), which publishes standards of practice for neonatal nurses. These standards reflect current knowledge, represent levels of practice agreed on by leaders in the specialty, and can be used for clinical benchmarking.

In addition to these more formalized standards, agencies have their own policy and procedure books that outline standards to be followed in that setting. In legal terms the **standard of care** is that level of practice that a reasonably prudent nurse would provide in the same or similar circumstances. In determining legal **negligence,** the care given is compared with the standard of care. If the standard was not met and harm resulted, negligence occurred. The number of legal suits in the perinatal area typically has been high. As a consequence, **malpractice** insurance costs are high for physicians, nurse-midwives, and nurses who work in labor and birth settings.

LEGAL TIP: Standard of Care
When you are uncertain about how to perform a procedure, consult the agency procedure book and follow the guidelines printed therein. These guidelines are the standard of care for that agency.

Risk Management

Risk management is an evolving process that identifies risks, establishes preventive practices, develops reporting mechanisms, and

FIG 1-3 Nurse interviewing a young girl accompanied by her mother in a clinic in rural Kenya. (Courtesy Shannon Perry, Phoenix, AZ.)

delineates procedures for managing lawsuits. Nurses should be familiar with concepts of risk management and their implications for nursing practice. These concepts can be viewed as systems of checks and balances that ensure high-quality patient care from preconception until after birth. Effective risk management minimizes the risk of injury to patients and the number of lawsuits against nurses, doctors, and hospitals. Each facility or site develops site-specific risk management procedures based on accepted standards and guidelines. The procedures and guidelines must be reviewed periodically.

To decrease risk of errors in the administration of medications, The Joint Commission (TJC) (2009) developed a list of abbreviations, acronyms, and symbols *not* to use (Table 1-3). In addition, each agency must develop its own list.

Sentinel Events

TJC describes a **sentinel event** as "an unexpected occurrence involving death or serious physical or psychological injury, or the risk thereof. Serious injury specifically includes loss of limb or function." These events are called *sentinel* because they signal a need for an immediate investigation and response (TJC, 2010). Reportable sentinel events in perinatal nursing include any maternal death related to the process of birth, any perinatal death unrelated to a congenital condition in an infant having a birth weight greater than 2500 g, severe neonatal hyperbilirubinemia (bilirubin greater than 30 mg/dL), and infant discharge to the wrong family (TJC, 2010). Other sentinel events that may occur in perinatal nursing include hemolytic transfusion reaction involving major blood group incompatibilities, leaving a foreign body (e.g., sponge or forceps) in a patient after surgery, and falls that result in death or major permanent loss of function that is a direct result of the injuries caused by the fall. When a sentinel event occurs, there must be a root cause analysis and an action plan formulated that identifies strategies to reduce the risk of future similar events.

Failure to Rescue

Failure to rescue, that is, the failure to recognize or act on early signs of distress, was introduced in the 1990s in relation to the care of adult postsurgical patients (Beaulieu, 2009; Simpson, 2005). Mothers and babies are generally healthy, and complications leading to death in obstetrics are comparatively rare. When applying the concept of failure to rescue to the perinatal setting,

BOX 1-8 STANDARDS OF CARE FOR WOMEN AND NEWBORNS

Standards That Define the Nurse's Responsibility to the Patient

Assessment
- Collection of health data of the woman or newborn

Diagnosis
- Analysis of data to determine nursing diagnosis

Outcome Identification
- Identification of expected outcomes that are individualized

Planning
- Development of a plan of care

Implementation
- Performance of interventions for the plan of care

Evaluation
- Evaluation of the effectiveness of interventions in relation to expected outcomes

Standards of Professional Performance That Delineate Roles and Behaviors for Which the Professional Nurse is Accountable

Quality of Care
- Systemic evaluation of nursing practice

Performance Appraisal
- Self-evaluation in relation to professional practice standards and other regulations

Education
- Participation in ongoing educational activities to maintain knowledge for practice

Collegiality
- Contribution to the development of peers, students, and others

Ethics
- Use of American Nurses Association (ANA) Code of Ethics for Nurses with Interpretive Statements (ANA, 2001) to guide practice

Collaboration
- Involvement of patient, significant others, and other health care providers in the provision of patient care

Research
- Use of research findings in practice

Resource Utilization
- Consideration of factors related to safety, effectiveness, and costs in planning and delivering patient care

Practice Environment
- Contribution to the environment of care delivery

Accountability
- Legal and professional responsibility for practice

From Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN), *Standards and guidelines for professional practice in the care of women and newborns,* ed 7, Washington, DC, 2009, Author.

TABLE 1-3 THE JOINT COMMISSION "DO NOT USE" LIST

DO NOT USE	POTENTIAL PROBLEM	USE INSTEAD
U, u (unit)	Mistaken for "0" (zero), the number "4" (four), or "cc"	Write "unit"
IU (International Unit)	Mistaken for IV (intravenous) or the number 10 (ten)	Write "International Unit"
Q.D., QD, q.d., qd (daily)	Mistaken for one another	Write "daily"
Q.O.D., QOD, q.o.d., qod (every other day)	Period after the Q mistaken for an "I" and the "O" for "I"	Write "every other day"
Trailing zero (X.0 mg)	Decimal point is missed	Write X mg
Lack of leading zero (.X mg)	Decimal point is missed	Write 0.X mg
MS	Can mean morphine sulfate or magnesium sulfate	Write "morphine sulfate"
MSO_4 and $MgSO_4$	Confused for one another	Write "magnesium sulfate"
Additional Abbreviations, Acronyms, and Symbols*		
> (greater than) < (less than)	Misinterpreted as the number "7" (seven) or the letter "L"; confused for one another	Write "greater than" Write "less than"
Abbreviations for drug names	Misinterpreted because of similar abbreviations for multiple drugs	Write drug names in full
Apothecary units	Unfamiliar to many practitioners Confused with metric units	Use metric units
@	Mistaken for the number "2" (two)	Write "at"
cc	Mistaken for U (units) when poorly written	Write "mL" or "ml" or "milliliters" ("mL" is preferred)
µg	Mistaken for mg (milligrams) resulting in one thousandfold overdose	Write "mcg" or "micrograms"

*For possible future inclusion in the Official "Do Not Use" List.

BOX 1-9 INSTITUTE OF MEDICINE COMPETENCIES FOR NURSING

- Patient-centered care
- Teamwork
- Collaboration
- Evidence-based practice
- Quality improvement
- Safety
- Informatics

From Institute of Medicine: *Health professions education: a bridge to quality,* Washington, DC, 2003, National Academies Press.

Simpson proposed evaluating the ability of the perinatal team to decrease the risk of adverse outcomes by measuring processes involved in common complications and emergencies in obstetrics (Simpson, 2005; 2006). Key components of failure to rescue are (1) careful surveillance and identification of complications, and (2) quick action to initiate appropriate interventions and activate a team response. For the perinatal nurse this involves careful surveillance, timely identification of complications, appropriate interventions, and activation of a team response to minimize patient harm (Beaulieu, 2009). Maternal complications that are appropriate for process measurement are placental abruption, postpartum hemorrhage, uterine rupture, eclampsia, and amniotic fluid embolism (Simpson, 2005; Simpson, 2006; Simpson, Knox, Martin, George, and Watson, 2011). Fetal complications include nonreassuring fetal heart rate and pattern, prolapsed umbilical cord, shoulder dystocia, and uterine hyperstimulation (Simpson, 2005; Simpson, 2006; Simpson, Knox, Martin, et al., 2011). Perinatal nurses can use these complications to develop a list of expectations for monitoring, timely identification, interventions, and roles of team members. The list can be used to evaluate the perinatal team's response. Promoting a culture of safety, effective communication, and team building are important in providing safe care during labor and birth (Simpson, Knox, Martin, et al., 2011).

Quality and Safety Education for Nurses

Quality and Safety Education for Nurses (QSEN) is an effort to provide nurses with the competencies to improve the quality and safety of the systems of health care in which they practice (Cronenwett, Sherwood, Barnsteiner, et al., 2007). The competencies for nursing delineated by the IOM (2003) (Box 1-9) were adapted by QSEN faculty members and defined by describing essential features of a competent and respected nurse. They then developed knowledge, skills, and attitudes (KSAs) for each competency. Incorporation of these KSAs into prelicensure education for nurses helps faculty plan learning experiences to prepare respected and qualified nurses. In this text QSEN competencies are incorporated into the evidence-based practice boxes.

Teamwork and Communication

Situation-Background-Assessment-Recommendation

The **situation-background-assessment-recommendation (SBAR)** technique gives a specific framework for communication among health care providers. SBAR is an easy-to-remember, useful, concrete mechanism for communicating important information that requires a clinician's immediate attention (Kaiser Permanente of Colorado, 2011) (Table 1-4). Failure to communicate is one of the major

TABLE 1-4 SAMPLE SBAR REPORT TO PHYSICIAN OR MIDWIFE ABOUT A CRITICAL SITUATION*

S	**Situation** I am calling about Mary Smith. I have just assessed her and she saturated a peripad in the last hour. Her blood pressure is 112/62, pulse 86, and respirations 18. I think she is bleeding excessively.
B	**Background** Mrs. Smith is 12 hours' postpartum after giving birth vaginally to a 9-lb, 12-oz term infant after an uncomplicated pregnancy. She had a rapid labor, just over 4 hours, and had no analgesia. She plans to bottle-feed this baby. She had an IV with 10 units of oxytocin (Pitocin), but it was completed and discontinued about 2 hours ago. This is her sixth birth. All were uncomplicated, and she had an uneventful recovery from them.
A	**Assessment** Her fundus becomes firm after massage but relaxes again. She has voided, and her bladder feels empty. I think she might have retained placenta and she needs to be examined.
R	**Recommendation** I would like you to come and examine her immediately. Do you want her IV restarted? Do you want her to have an Hb and HCT?

Hb, Hemoglobin; *HCT,* hematocrit; *IV,* intravenous infusion; SBAR, Situation-Background-Assessment-Recommendation.
*The SBAR tool was developed by Kaiser Permanente. This example was prepared by Shannon Perry.

reasons for errors in health care. The SBAR technique has the potential to serve as a means to reduce errors.

TeamSTEPPS

TeamSTEPPS was developed by the Department of Defense Patient Safety Program in collaboration with the AHRQ as a teamwork system for health professionals to provide higher-quality, safer patient care (www.teamstepps.ahrq.gov/about-2cl_3.htm). It provides an evidence base to improve communication and teamwork skills. Through this system medical teams use information, people, and resources to achieve the best possible clinical outcomes, increase team awareness and clarify roles and responsibilities of team members, resolve conflicts and improve sharing of information, and eliminate barriers to quality and safety.

ETHICAL ISSUES IN PERINATAL NURSING AND WOMEN'S HEALTH CARE

Ethical concerns and debates have multiplied with the increased use of technology and scientific advances. For example, with reproductive technology pregnancy is now possible in women who thought they would never bear children, including some who are menopausal or postmenopausal. Should scarce resources be devoted to achieving pregnancies in older women? Is giving birth to a child at an older age worth the risks involved? Should older parents be encouraged to conceive a baby when they may not live to see the child reach adulthood? Should a woman who is HIV positive have access to assisted reproduction services? Should third-party payers assume the costs of reproductive technology such as the use of induced ovulation and in vitro fertilizations? With induced ovulation and in vitro fertilization, multiple pregnancies occur, and multifetal pregnancy reduction (selectively terminating one or more fetuses) may be considered. Questions about **informed consent** and allocation of resources must be addressed with innovations such as intrauterine fetal surgery, fetoscopy, therapeutic insemination, genetic engineering, stem cell research, surrogate childbearing, surgery for infertility, "test tube" babies, fetal research, and treatment of very LBW (VLBW) babies. The introduction of long-acting contraceptives has created moral choices and policy dilemmas for health care providers and legislators (i.e., should some women [substance abusers, women with low incomes, or women who are HIV positive] be required to take the contraceptives?). With the potential for great good that can come from fetal tissue transplantation, what research is ethical? What are the rights of the embryo? Should cloning of humans be permitted? Discussion and debate about these issues will continue for many years. Nurses and patients, together with scientists, physicians, attorneys, lawmakers, ethicists, and clergy, must be involved in the discussions.

RESEARCH IN PERINATAL NURSING

Research plays a vital role in establishing maternity and women's health science. It can validate that nursing care makes a difference. For example, although prenatal care is clearly associated with healthier infants, no one knows exactly which nursing interventions produce this outcome. In the past medical researchers rarely included women in their studies; thus more research in this area is crucial. Many possible areas of research exist in maternity and women's health care. The clinician can identify problems in the health and health care of women and infants. Through research nurses can make a difference for these patients. Nurses should promote research funding and conduct research on maternity and women's health, especially concerning the effectiveness of nursing strategies for these patients.

Ethical Guidelines for Nursing Research

Research with perinatal patients may create **ethical dilemmas** for the nurse. For example, participating in research may cause additional stress to a woman concerned about outcomes of genetic testing or one who is waiting for an invasive procedure. Obtaining amniotic fluid samples or performing cordocentesis poses risks to the fetus. Nurses must protect the rights of human subjects (i.e., patients) in all of their research. For example, nurses can collect data on or care for patients who are participating in clinical trials. The nurse ensures that the participants are fully informed and aware of their rights as subjects. She or he may be involved in determining whether the benefits of research outweigh the risks to the mother and the fetus. Following the ANA ethical guidelines in the conduct, dissemination, and implementation of nursing research helps nurses ensure that research is conducted ethically.

KEY POINTS

- Maternity nursing focuses on women and their infants and families during the childbearing cycle.
- Nurses caring for women can play an active role in shaping health care systems to be responsive to the needs of contemporary women.
- Childbirth practices have changed to become more family focused and allow alternatives in care.
- Integrative medicine combines modern technology with ancient healing practices and encompasses the whole body, mind, and spirit.
- Evidence-based practice and outcomes orientation are emphasized in current practice.
- Risk management and learning from sentinel events can improve quality of care.
- *Healthy People 2020* provides an update on goals for maternal and infant health.
- Ethical concerns have multiplied with increasing use of technology and scientific advances.

CHAPTER

2

Community Care: The Family and Culture

Shannon E. Perry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe the main characteristics of contemporary family forms.
- Identify key factors influencing family health.
- Compare theoretic approaches for working with childbearing families.
- Relate the impact of culture on childbearing families.
- Discuss cultural competence in relation to one's own nursing practice.
- Identify key components of the community assessment process.
- List indicators of community health status and their relevance to perinatal health.
- Describe data sources and methods for obtaining information about community health status.
- Identify predisposing factors and characteristics of vulnerable populations.
- List the potential advantages and disadvantages of home visits.
- Explore telephonic nursing care options in perinatal nursing.
- Describe how home fits into the maternity continuum of care.
- Discuss safety and infection control principles as they apply to the care of patients in their homes.
- Describe the nurse's role in perinatal home care.

THE FAMILY IN CULTURAL AND COMMUNITY CONTEXT

The family and its cultural context play an important role in defining the work of maternity nurses. Despite modern stresses and strains, the family forms a social network that acts as a potent support system for its members. Family care-seeking behavior and relationships with providers are all influenced by culturally related health beliefs and values. Ultimately, all of these factors have the power to affect maternal and child health outcomes. The current emphasis in working with families is on wellness and **empowerment** for families to achieve control over their lives. It is essential that nurses become culturally competent in order to provide the most appropriate care possible.

Defining Family

The **family** has traditionally been viewed as the primary unit of socialization—the basic structural unit within a community. The family plays a pivotal role in health care, representing the primary target of health care delivery for maternal and newborn nurses. As one of society's most important institutions, the family represents a primary social group that influences and is influenced by other people and institutions. A variety of family configurations exist.

Family Organization and Structure

The *nuclear family* has long represented the traditional American family in which male and female partners and their children live as an independent unit, sharing roles, responsibilities, and economic resources (Fig. 2-1). In contemporary society, this idealized family structure actually represents only a relatively small number of families, and that number is steadily decreasing.

Many nuclear families have other relatives living in the same household. These extended family members include grandparents, aunts, uncles, or other people related by blood (Fig. 2-2). For some groups, such as African-American and Latin-American, extended family is an important resource in terms of preventive health behavior. The extended family is becoming more common as American society ages.

Multigenerational families, consisting of grandparents, children, and grandchildren, are becoming increasingly common. In 2010 they made up 4.4% of all households (Lofquist, Lugaila, O'Connell, et al., 2012). This may create stress as children must care for their

FIG 2-1 Nuclear family. (Courtesy Makeba Felton, Wake Forest, NC.)

FIG 2-2 Extended family. (Courtesy Makeba Felton, Wake Forest, NC.)

parents as well as their own children. In other instances, the grandparents are supporting the children and grandchildren or are sole caregivers for the grandchildren.

No-parent families are those in which children live independently in foster or kinship care such as living with a grandparent. An estimated 5.4 million children in the United States live with grandparents (U.S. Census Bureau, 2010).

Married-parent families (biologic or adoptive parents) make up 48.4% of American families. By race and Hispanic origin, this family structure is represented as follows (Lofquist, Lugaila, O'Connell, et al., 2012):

- Caucasian: 51.1%
- Hispanic: 50.1%
- African-American: 28.5%
- Asian: 59.7%
- American Indian and Alaska Native: 40.1%
- Native Hawaiian and Pacific Islander: 51.3%

Married-blended families, those formed as a result of divorce and remarriage, consist of unrelated family members (stepparents, stepchildren, and stepsiblings) who join to create a new household. These family groups frequently involve a biologic or adoptive parent whose spouse may or may not have adopted the child.

Cohabiting-parent families are those in which children live with two unmarried biologic parents or two adoptive parents. Hispanic children are almost twice as likely as African-American children to live in cohabiting-parent families and about four times as likely as Caucasian children to live in this kind of family arrangement (Lofquist, Lugaila, O'Connell, et al., 2012).

Single-parent families comprise an unmarried biologic or adoptive parent who may or may not be living with other adults. The single-parent family may result from the loss of a spouse by death, divorce, separation, or desertion; from either an unplanned or planned pregnancy; or from the adoption of a child by an unmarried woman or man.

The single-parent family tends to be vulnerable economically and socially, creating an unstable and deprived environment for the growth of children. This in turn affects health status, school achievement, and high risk behaviors for these children.

Homosexual families (lesbian and gay) may live together with or without children. Children in lesbian and gay families may be the offspring of previous heterosexual unions, conceived by one member of a lesbian couple through therapeutic insemination, or adopted.

The Family in Society

The social context for the family can be viewed in relation to social and demographic trends that define the population as a whole. Racial and ethnic diversity of the population has grown dramatically in the past three decades, necessitating consideration of such diversity in provision of health care.

THEORETIC APPROACHES TO UNDERSTANDING FAMILIES

Family Nursing

Family plays a pivotal role in health care, representing the primary target of health care delivery for maternal and newborn nurses. It is crucial that nurses assist families as they incorporate new additions into their family (see Nursing Care Plan). When treating the woman and family with respect and dignity, health care providers listen to and honor perspectives and choices of the woman and family. They share information with families in ways that are positive, useful, timely, complete, and accurate. The family is supported in participating in the care and decision making at the level of their choice.

Because so many variables affect ways of relating, the nurse must be aware that family members may interact and communicate with each other in ways that are distinct from those of the nurse's own family of origin. Most families will hold some beliefs about health that are different from those of the nurse. Their beliefs can conflict with principles of health care management predominant in the Western health care system.

Family Theories

A **family theory** can be used to describe families and how the family unit responds to events both within and outside the family. Each family theory makes certain assumptions about the family and has inherent strengths and limitations. Most nurses use a combination of theories in their work with families. A brief synopsis of several theories useful in working with families is included in Table 2-1. Application of these concepts can guide assessment and interventions for the family.

NURSING CARE PLAN

Incorporating the Infant into the Family

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
Readiness for Enhanced Family Coping related to adaptation of family to new infant	Family members will verbalize that individual and family goals are met during a smooth transition of new family member into the home.	Assess type and amount of support available to family on daily basis during postpartum period	To facilitate adaptation of family to situation of a new member
		Encourage family to use past successful coping mechanisms.	To enhance ability to cope with new situation and promote self-esteem
		Encourage mother to use family and other support or services	To carry out daily household tasks to permit her to focus on herself and infant
		Suggest that woman take time to rest when infant sleeps	To conserve energy for healing and limit responsibility to herself and infant
		Assess family structure and relationships, including culture	To evaluate if longer period of adjustment may be expected
		Teach family about sensory needs and capabilities of infant	To motivate family to meet infant's needs and set realistic expectations for infant's capabilities
		Refer to parent support group or community agencies, as needed	To facilitate and validate ongoing positive adjustment of family to new family member
Ineffective Role Performance related to developmental challenge of addition of new family member	Each family member will verbalize realistic expectations regarding his or her role in the family and formulate a plan to incorporate the role into overall family goals.	Assess family structure, roles, and each member's perception of his or her role in family	To evaluate impact of new member on structure and roles of family as perceived by members
		Evaluate individual's perception of goals and new roles during this transition	To promote early intervention and correct any misinterpretation
		Encourage discussion of family members' thoughts and feelings regarding this transition	To promote open communication and trust
		Provide positive reinforcement for family members' actions that promote positive environment for infant	To increase self-esteem and provide encouragement
		Refer to community support groups	To provide group reinforcement and further assistance
		Give information about sibling and grandparent classes and support groups as available	To promote empowerment and self-esteem for significant others in family

Family Assessment

When selecting a **family assessment** framework, an appropriate model for a perinatal nurse is one that is a health-promoting rather than an illness-care model. The low risk family can be assisted in promoting a healthy pregnancy, childbirth, and integration of the newborn into the family. The high risk perinatal family has illness-care needs, and the nurse can help meet those needs while also promoting the health of the childbearing family.

A family assessment tool such as the Calgary Family Assessment Model (CFAM) (Box 2-1) can be used as a guide for assessing aspects of the family. Such an assessment is based on "the nurse's personal and professional life experiences, beliefs, and relationships with those being interviewed" (Wright and Leahy, 2009) and is not "the truth" about the family but, rather, one perspective at one point in time.

The CFAM comprises three major categories: structural, developmental, and functional. Several subcategories are within each category. The three assessment categories and the many subcategories can be conceptualized as a branching diagram (Fig. 2-3). These categories and subcategories can be used to guide the assessment that will provide data to help the nurse better understand the family and formulate a plan of care. The nurse asks questions of family members about themselves to gain understanding of the structure, development, and function of the family at this point in time. Not all questions within the subcategories should be asked at the first interview, and some questions may not be appropriate for all families. Although individuals are the ones interviewed, the focus of the assessment is on interaction of individuals within the family.

Graphic Representations of Families

A family **genogram** (family tree format depicting relationships of family members over at least three generations) (Fig. 2-4) provides valuable information about a family and can be placed in the nursing care plan for easy access by care providers. An **ecomap,** a graphic portrayal of social relationships of the woman and family, may also help the nurse understand the social environment of the family and identify support systems available to them (Fig. 2-5). Software is available to generate genograms and ecomaps (www.interpersonaluniverse.net).

TABLE 2-1 THEORIES AND MODELS RELEVANT TO FAMILY NURSING PRACTICE

THEORY	SYNOPSIS OF THEORY
Family Systems Theory (Wright and Leahy, 2009)	The family is viewed as a unit, and interactions among family members are studied rather than studying individuals. A family system is part of a larger suprasystem and is composed of many subsystems. The family as a whole is greater than the sum of its individual members. A change in one family member affects all family members. The family is able to create a balance between change and stability. Family members' behaviors are best understood from a view of circular rather than linear causality.
Family Life Cycle (Developmental) Theory (Carter and McGoldrick, 1999)	Families move through stages. The family life cycle is the context in which to examine the identity and development of the individual. Relationships among family members go through transitions. Although families have roles and functions, a family's main value is in relationships that are irreplaceable. The family involves different structures and cultures organized in various ways. Developmental stresses may disrupt the life-cycle process.
Family Stress Theory (Boss, 1996)	How families react to stressful events is the focus. Family stress can be studied within the internal and external contexts in which the family is living. The internal context involves elements that a family can change or control, such as family structure, psychologic defenses, and philosophic values and beliefs. The external context consists of the time and place in which a particular family finds itself and over which the family has no control, such as the culture of the larger society, the time in history, the economic state of society, maturity of the individuals involved, success of the family in coping with stressors, and genetic inheritance.
McGill Model of Nursing (Allen, 1997)	Strength-based approach in clinical practice with families, as opposed to a deficit approach, is the focus. Identification of family strengths and resources; provision of feedback about strengths; assistance given to family to develop and elicit strengths and use resources are key interventions.
Health Belief Model (Becker, 1974; Janz and Becker, 1984)	The goal of the model is to reduce cultural and environmental barriers that interfere with access to health care. Key elements of the Health Belief Model include the following: perceived susceptibility, perceived severity, perceived benefits, perceived barriers, cues to action, and confidence.
Human Developmental Ecology (Bronfenbrenner, 1979; 1989)	Behavior is a function of interaction of traits and abilities with the environment. Major concepts include ecosystem, niches (social roles), adaptive range, and ontogenetic development. Individuals are "embedded in a microsystem [role and relations], a mesosystem [interrelations between two or more settings], an exosystem [external settings that do not include the person], and a macrosystem [culture]" (Klein and White, 1996). Change over time is incorporated in the chronosystem.

BOX 2-1 CALGARY FAMILY ASSESSMENT MODEL

There are three major categories of the Calgary Family Assessment Model (CFAM)—structural, developmental, and functional. Each category has several subcategories. In this box, only the major categories are included. A few sample questions are included.

Structural Assessment

Determine the members of the family, relationship among family members, and context of family.

Genograms and ecomaps (see Figs. 2-4; 2-5) are useful in outlining the internal and external structures of a family.

Sample questions

- Who are the members of your family?
- Has anyone moved in or out lately?
- Are there any family members who don't live with you?

Developmental Assessment

Describe the life cycle—that is, the typical trajectory most families experience.

Sample questions

- When you think back, what do you most enjoy about your life?
- What do you regret about your life?
- Have you made plans for your care as your health declines?

Functional Assessment

Evaluate the way in which individuals behave in relation to each other in instrumental and expressive aspects. (Instrumental aspects are activities of daily living; expressive aspects include communication, problem solving, roles, etc.)

Sample questions

- Which one of the family is responsible for making sure Grandma takes her medicine?
- Whose turn is it to fix dinner for Grandma?
- How can we get Martin to help with Grandma's care?

Data from Wright LM, Leahy M: *Nurses and families: a guide to family assessment and intervention*, ed 5, Philadelphia, 2009, FA Davis.

THE FAMILY IN A CULTURAL CONTEXT

Cultural Factors Related to Family Health

Culture of an individual is influenced by religion, environment, and historic events and plays a powerful role in the individual's behavior and patterns of human interaction. Culture is not static; it is an ongoing process that influences a woman throughout her entire life, from birth to death.

Cultural knowledge includes beliefs and values about each facet of life and is passed from one generation to the next. Cultural beliefs and traditions relate to food, language, religion, art, health and healing practices, kinship relationships, and all other aspects of

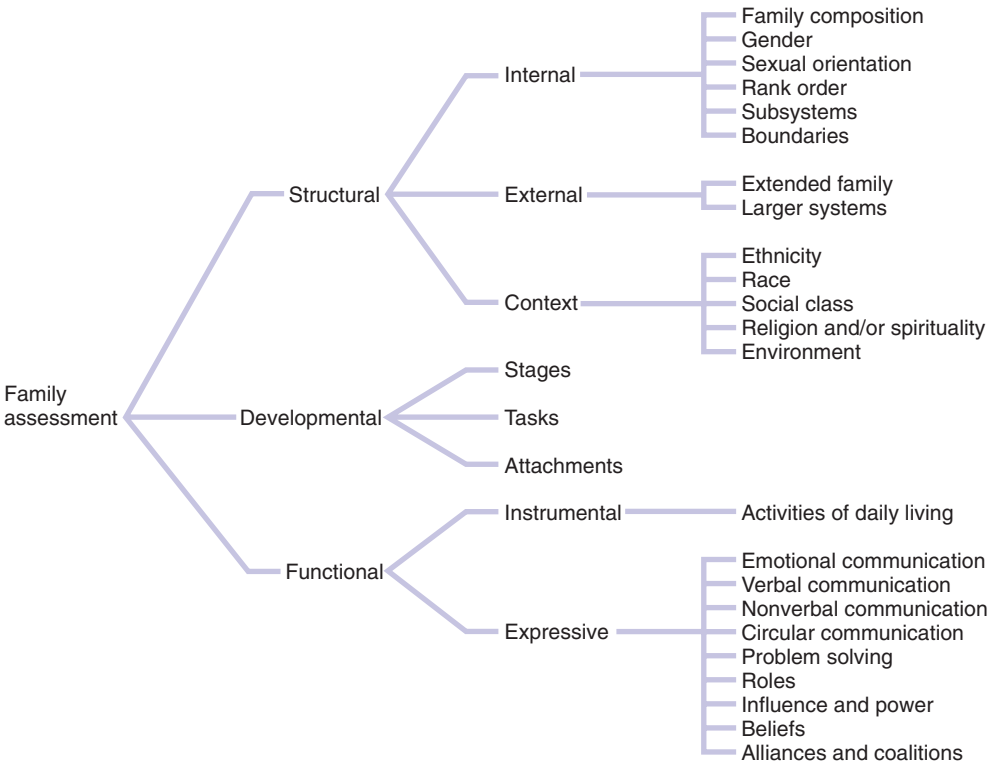

FIG 2-3 Branching diagram of Calgary Family Assessment Model (CFAM). (From Wright LM, Leahy M: *Nurses and families: a guide to family assessment and intervention,* ed 5, Philadelphia, 2009, FA Davis.)

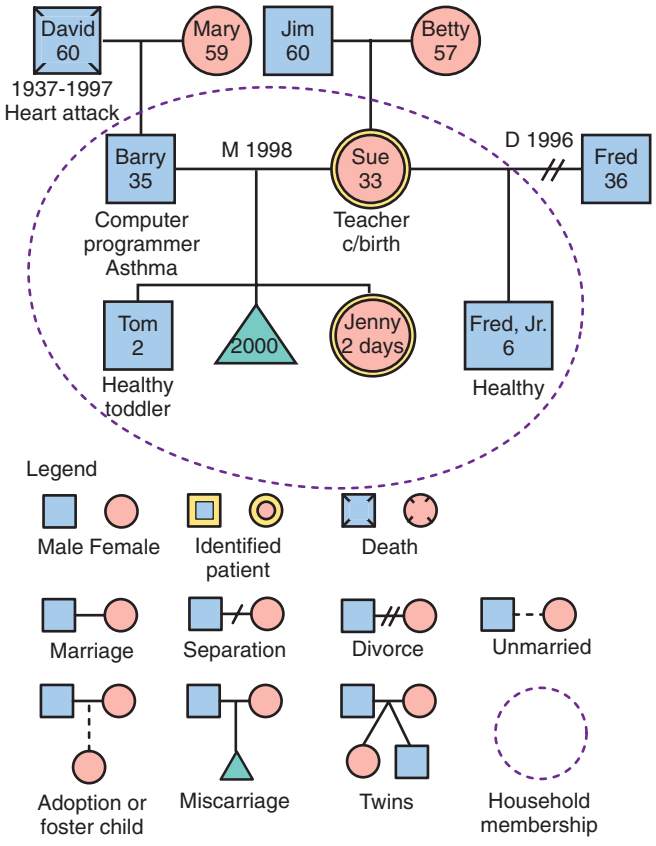

FIG 2-4 Example of a family genogram.

community, family, and individual life. Culture has also been shown to have a direct effect on health behaviors. Values, attitudes, and beliefs that are culturally acquired may influence perceptions of illness, as well as health care–seeking behavior and response to treatment. The political, social, and economic context of people's lives is also part of the cultural experience.

Culture, shared beliefs, and values of a group play a powerful role in an individual's behavior, particularly when the individual is sick. Understanding a culture can provide insight into how a person reacts to illness, pain, and invasive medical procedures, as well as patterns of human interaction and expressions of emotion. The effect of these influences must be assessed by health care professionals in providing health care and developing effective intervention strategies.

Many subcultures may be found within each culture. **Subculture** refers to a group existing within a larger cultural system that retains its own characteristics. A subculture may be an ethnic group or a group organized in other ways. For example, in the United States and Canada, many ethnic subcultures such as African-Americans, Asian-Americans, Hispanic-Americans, and Native Americans exist. It is important to note that subcultures also exist within these groups. In addition, the Caucasian population in America has multiple subcultures of its own. Because every identified cultural group has subcultures and because it is impossible to study every subculture in depth, greater differences may exist among and between groups than is generally acknowledged. It is important to be familiar with common cultural practices within these subgroups. However, it is also important to avoid the generalization that every person practices every cultural belief within a group.

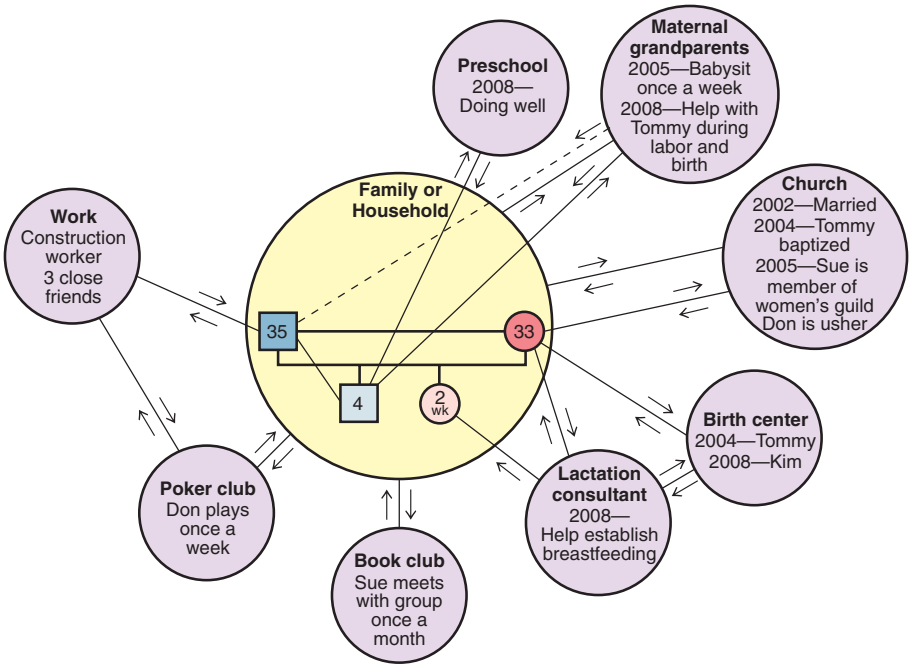

FIG 2-5 Example of an ecomap. An ecomap describes social relationships and depicts available supports.

In a multicultural society, many groups can influence traditions and practices. As cultural groups come into contact with each other, acculturation and assimilation may occur.

Acculturation refers to the changes that occur within one group or among several groups when people from different cultures come into contact with one another. People may retain some of their own culture while adopting some cultural practices of the dominant society. This familiarization among cultural groups results in overt behavioral similarity, especially in mannerisms, styles, and practices. Dress, language patterns, food choices, and health practices are often much slower to adapt to the influence of acculturation. In the United States, acculturation generally is thought to take three generations. An adult grandchild of an immigrant is usually fully Americanized.

During times of family transitions such as childbearing or during crisis or illness, a woman may rely on old cultural patterns even after she has become acculturated in many ways. This is consistent with the family developmental theory that states that during times of stress, people revert to practices and behaviors that are most comfortable and familiar.

Assimilation occurs when a cultural group loses its cultural identity and becomes part of the dominant culture. Assimilation is the process by which groups "melt" into the mainstream, thus accounting for the notion of a "melting pot," a phenomenon that has been said to occur in the United States. This is illustrated by individuals who identify themselves as being of Irish or German descent without having any remaining cultural practices or values linked specifically to that culture such as food preparation techniques, style of dress, or proficiency in the language associated with their reported cultural heritage. Spector (2013) asserts that in the United States, the melting pot, with its dream of a common culture, is a myth. Instead, a mosaic phenomenon exists in which we must accept and appreciate the differences among people.

Implications for Nursing

As our society becomes more culturally diverse, it is essential that nurses become culturally competent. Nurses must examine their own beliefs so that they have a better appreciation and understanding of the beliefs of their patients. Understanding the concepts of ethnocentrism and cultural relativism may help nurses care for families in a multicultural society.

Ethnocentrism is the view that one's own way of doing things is best (Giger, 2013). Although the United States is a culturally diverse nation, the prevailing practice of health care is based on the beliefs and practices held by members of the dominant culture, primarily Caucasians of European descent. This practice is based on the biomedical model that focuses on curing disease states.

Pregnancy and childbirth in this biomedical perspective are viewed as processes with inherent risks that are most appropriately managed by using scientific knowledge and advanced technology. The medical perspective stands in direct contrast to the belief systems of many cultures. Among many women, birth is viewed as a completely normal process that can be managed with a minimum of involvement from health care practitioners. When encountering behavior in women unfamiliar with the biomedical model or those who reject it, the nurse may become frustrated and impatient and may label the women's behavior as inappropriate and believe that it conflicts with "good" health practices. If the Western health care system provides the nurse's only standard for judgment, the behavior of the nurse is ethnocentric.

Cultural relativism is the opposite of ethnocentrism. It refers to learning about and applying the standards of another's culture to activities within that culture. The nurse recognizes that people from different cultural backgrounds comprehend the same objects and situations differently. In other words, culture determines viewpoint.

Cultural relativism does not require nurses to accept the beliefs and values of another culture. Instead, nurses recognize that the

CRITICAL THINKING CASE STUDY

Providing Culturally Appropriate Care

Elisabeth, a 22-year-old first-generation Mexican-American, comes into your office for her initial prenatal visit. You are concerned because Elisabeth's fundal height is consistent with 32 weeks of gestation and this is her first prenatal visit. Elisabeth, who lives with her husband, four children (ages 6, 4, and 3 years and 15 months), her mother, her aunt, and her uncle, states that she has been doing well this pregnancy and did not start prenatal care in her previous pregnancies until she was almost ready to give birth. She also comments that all the babies were full term with uneventful labors and births. In obtaining the history you note the presence of a safety pin in Elisabeth's shirt and wonder what this is for. You want to provide culturally competent care to this woman and her family.

1. Evidence—Is there sufficient evidence to support the components of culturally competent care for Elisabeth?
2. Assumptions—Describe an underlying assumption about culturally competent care for Elisabeth in relation to these topics:
   a. The view of pregnancy in Elisabeth's culture
   b. The role of family in Elisabeth's culture
   c. The acceptability for women of Elisabeth's age to begin having children at such young ages
   d. The religious beliefs that Elisabeth may have that affect contraception
3. What implications and priorities for nursing care can be made at this time?
4. Does the evidence objectively support your conclusion?

behavior of others may be based on a system of logic different from their own. Cultural relativism affirms the uniqueness and value of every culture.

Childbearing Beliefs and Practices

Nurses working with childbearing families care for families from many different cultures and ethnic groups. To provide culturally competent care, the nurse must assess the beliefs and practices of patients. When working with childbearing families, a nurse considers all aspects of culture including communication, space, time orientation, and family roles.

Communication often creates the most challenging obstacle for nurses working with patients from diverse cultural groups. Communication is not merely the exchange of words. Instead, it involves (1) understanding the individual's language, including subtle variations in meaning and distinctive dialects; (2) appreciating individual differences in interpersonal style; and (3) accurately interpreting the volume of speech as well as the meanings of touch and gestures. For example, members of some cultural groups tend to speak more loudly when they are excited, with great emotion and with vigorous and animated gestures; this is true whether their excitement is related to positive or negative events or emotions. It is important, therefore, for the nurse to avoid rushing to judgment regarding a person's intent when the patient is speaking, especially in a language not understood by the nurse. Instead, the nurse should withhold an interpretation of what has been expressed until it is possible to clarify the patient's intent. The nurse needs to enlist the assistance of a person who can help verify with the patient the true intent and meaning of the communication (see Critical Thinking Case Study).

Inconsistencies between the language of patients and the language of providers present a significant barrier to effective health care. For example, there are many dialects of Spanish that vary by geographic location. Because of the diversity of cultures and languages within the U.S. and Canadian populations, health care agencies are increasingly seeking the services of **interpreters** (of oral communication from one language to another) or **translators** (of written words from one language to another) to bridge these gaps and fulfill their obligation for culturally and linguistically appropriate health care (Box 2-2). Finding the best possible interpreter in the circumstance is critically important as well. Ideally, interpreters should have the same native language and be of the same religion or have the same country of origin as the patient. Interpreters should have specific health-related language skills and experience and help bridge the language and cultural barriers between the patient and the health care provider. The person interpreting also should be mature enough to be trusted with private information. However, because the nature of nursing care is not always predictable and because nursing care that is provided in a home or community setting does not always allow expert, experienced, or mature adult interpreters, ideal interpretive services sometimes are impossible to find when they are needed. In crisis or emergency situations or when family members are having extreme stress or emotional upset, it may be necessary to use relatives, neighbors, or children as interpreters. If this situation occurs, the nurse must ensure that the patient is in agreement and comfortable with using the available interpreter to assist.

When using an interpreter, the nurse respects the family by creating an atmosphere of respect and privacy. Questions should be addressed to the woman and not to the interpreter. Even though an interpreter will of necessity be exposed to sensitive and privileged information about the family, the nurse should take care to ensure that confidentiality is maintained. A quiet location free from interruptions is ideal for interpretive services to take place. Culturally and linguistically appropriate educational materials that are easy to read, with appropriate text and graphics, should be available to assist the woman and her family in understanding health care information. To ensure understanding and avoid liability issues, it is important to make certain that the material has been translated by someone who is trained appropriately.

Personal Space

Cultural traditions define the appropriate **personal space** for various social interactions. Although the need for personal space varies from person to person and with the situation, the actual physical dimensions of comfort zones differ from culture to culture. Actions such as touching, placing the woman in proximity to others, taking away personal possessions, and making decisions for the woman can decrease personal security and heighten anxiety. Conversely, respecting the need for distance allows the woman to maintain control over personal space and support personal autonomy, thereby increasing her sense of security. Nurses must touch patients. However, they frequently do so without any awareness of the emotional distress they may be causing patients.

Time Orientation

Time orientation is a fundamental way in which culture affects health behaviors. People in cultural groups may be relatively more oriented to past, present, or future. Those who focus on the past strive to maintain tradition or the status quo and have little motivation for formulating future goals. In contrast, individuals who focus primarily on the present neither plan for the future nor consider the

BOX 2-2 WORKING WITH AN INTERPRETER

Step 1: Before the Interview

A. Outline your statements and questions. List the key pieces of information you want/need to know.
B. Learn something about the culture so that you can converse informally with the interpreter.

Step 2: Meeting with the Interpreter

A. Introduce yourself to the interpreter and converse informally. This is the time to find out how well he or she speaks English. No matter how proficient or what age the interpreter is, be respectful. Some ways to show respect are to ask a cultural question to acknowledge that you can learn from the interpreter, or you could learn one word or phrase from the interpreter.
B. Emphasize that you do want the patient to ask questions, because some cultures consider this inappropriate behavior.
C. Make sure the interpreter is comfortable with the technical terms you need to use. If not, take some time to explain them.

Step 3: During the Interview

A. Ask your questions and explain your statements (see Step 1).
B. Make sure that the interpreter understands which parts of the interview are most important. You usually have limited time with the interpreter, and you want to have adequate time at the end for patient questions.
C. Try to get a "feel" for how much is "getting through." No matter what the language is, if in relating information to the patient, the interpreter uses far fewer or far more words than you do, something else is going on.
D. Stop now and then and ask the interpreter, "How is it going?" You may not get a totally accurate answer, but you will have emphasized to the interpreter your strong desire to focus on the task at hand. If there are language problems, (1) speak slowly; (2) use gestures (e.g., fingers to count or point to body parts); and (3) use pictures.
E. Ask the interpreter to elicit questions. This may be difficult, but it is worth the effort.
F. Identify cultural issues that may conflict with your requests or instructions.
G. Use the interpreter to help problem solve or at least give insight into possibilities for solutions.

Step 4: After the Interview

A. Speak to the interpreter and try to get an idea of what went well and what could be improved. This will help you be more effective in the future with this or another interpreter.
B. Make notes on what you learned for your future reference or to help a colleague.

Remember

Your interview is a *collaboration* between you and the interpreter. *Listen* as well as speak.

Notes:

1. The interpreter may be a child, grandchild, or sibling of the patient. Be sensitive to the fact that the child is playing an adult role.
2. Be sensitive to cultural and situational differences (e.g., an interview with someone from urban Germany will likely be different from an interview with someone from a transitional refugee camp).
3. Younger females telling older males what to do may be a problem for both a female nurse and a female interpreter. This is not the time to pioneer new gender relations. Be aware that in some cultures it is difficult for a woman to talk about some topics with a husband or a father present.

Courtesy Elizabeth Whalley, PhD, San Francisco State University.

experiences of the past. These individuals do not necessarily adhere to strict schedules and are often described as "living for the moment" or "marching to their own drummer." Individuals oriented to the future maintain a focus on achieving long-term goals.

The time orientation of the childbearing family may affect nursing care. For example, talking to a family about bringing the infant to the clinic for follow-up examinations (events in the future) may be difficult for the family who is focused on the present concerns of day-to-day survival. Because a family with a future-oriented sense of time plans far in advance, thinking about the long-term consequences of present actions, they may be more likely to return as scheduled for follow-up visits. Despite the differences in time orientation, each family can be equally concerned for the well-being of its newborn.

Family Roles

Family roles involve the expectations and behaviors associated with a member's position in the larger family system (e.g., mother, father, grandparent). Social class and cultural norms also affect these roles, with distinct expectations for men and women clearly determined by social norms. For example, culture may influence whether a man actively participates in pregnancy and childbirth, yet maternity care practitioners working in the Western health care system expect fathers to be involved. This can create a significant conflict between the nurse and the role expectations of very traditional Mexican or Arab families, who usually view the birthing experience as a female affair (see Cultural Competence box). The way that health care practitioners manage such a family's care molds its experience and perception of the Western health care system.

In maternity nursing, the nurse supports and nurtures the beliefs that promote physical or emotional adaptation to childbearing. However, if certain beliefs might be harmful, the nurse should carefully explore them with the woman and use them in the re-education

CULTURAL COMPETENCE

Questions to Ask to Elicit Cultural Expectations About Childbearing

1. What do you and your family think you should do to remain healthy during pregnancy?
2. What can you do to improve your health and the health of your baby?
3. What foods will help make a healthy baby?
4. Who do you want with you during your labor?
5. What can your labor support person do to help you be most comfortable during labor?
6. What actions are important for you and your family after the baby's birth?
7. What do you and your family expect from the nurse(s) caring for you?
8. How will family members participate in your pregnancy, childbirth, and parenting?

BOX 2-3 STRATEGIES FOR CARE DELIVERY AND PROVIDING CULTURALLY APPROPRIATE CARE

Strategies for Care Delivery	Providing Culturally Appropriate Care
• Break down the language barriers. • Explain your rationale and reasons for suggestions. • Integrate folk and Western treatments. • Enlist the family caregiver and others. • Get consent from the right person. • Provide language-appropriate materials.	• Ask about traditional beliefs, such as the role of hot and cold. • Be sensitive regarding interpreters and language barriers. • Ask about important dietary practices, particularly those related to events such as childbirth. • Ask about group practices and beliefs. • Ask about a woman's fears and those of her family regarding an unfamiliar care setting.

From Mattson S: Providing culturally competent care: strategies and approaches for perinatal clients, *AWHONN Lifelines* 4(5):37–39, 2000.

and modification process. Strategies for care delivery and providing appropriate care are presented in Box 2-3.

Table 2-2 provides examples of some cultural beliefs and practices surrounding childbearing. The cultural beliefs and customs in the table are categorized on the basis of distinct cultural traditions and are not practiced by all members of the cultural group in every part of the country. Women from these cultural and ethnic groups may adhere to a few, all, or none of the practices listed. In using this table as a guide, the nurse should take care to avoid making stereotypic assumptions about any person based on sociocultural-spiritual affiliations. Nurses should exercise sensitivity in working with every family, being careful to assess the ways in which they apply their own mixture of cultural traditions.

DEVELOPING CULTURAL COMPETENCE

Cultural competence has many names and definitions, all of which have subtle shades of difference but which are essentially the same: multiculturalism, cultural sensitivity, and intercultural effectiveness. Cultural competence involves acknowledging, respecting, and appreciating ethnic, cultural, and linguistic diversity. Culturally competent professionals act in ways that meet the needs of the patient and are respectful of ways and traditions that may be very different from their own. In today's society it is of critical importance that nurses develop more than technical skill. At every level of preparation and throughout their professional lives, nurses must engage in a continual process of developing and refining attitudes and behaviors that will promote culturally competent care (Giger, 2013).

Key components of culturally competent care include:

- Recognizing that disparity exists between one's own culture and that of the patient
- Educating and promoting healthy behaviors in a cultural context that has meaning for patients
- Taking abstract knowledge about other cultures and applying it in a practical way so that the quality of service improves and policies are enacted that meet the needs of all patients
- Communicating respectfulness for a wide range of differences, including patient use of nontraditional healing practices and alternative therapies
- Recognizing the importance of culturally different communication styles, problem-solving techniques, concepts of space and time, and desires to be involved with care decisions
- Anticipating the need to address varying degrees of language ability and literacy, as well as barriers to care and compliance with treatment

FIG 2-6 Physicians, nurses, and interpreters during a medical mission in Honduras. (Courtesy Shannon Perry, Phoenix, AZ.)

In addition to issues of preserving and promoting human dignity, the development of cultural competence is of equal importance in terms of health outcomes. Nurses who relate effectively with patients are able to motivate them in the direction of health-promoting behaviors. Provider competence to address language barriers facilitates appropriate tailoring of health messages and preventive health teaching. Cross-cultural experiences also present an opportunity for the health care professional to expand cultural sensitivity, awareness, and skills (Fig. 2-6).

COMMUNITY HEALTH PROMOTION

Best practices in community-based health initiatives involve understanding of community relationships and resources as well as participation of community leaders. The emphasis on community-based **health promotion** has grown in recent years, with recognition that many health issues require the collaborative efforts of a diverse community network to achieve public health goals. These efforts are particularly relevant in relation to maternal-newborn health, which is affected by multiple public health issues: lack of health insurance; recent economic challenges that include job loss; teen pregnancy; substance abuse; and the consequences of no or inadequate prenatal care.

Levels of Preventive Care

In community-based health promotion, three **levels of prevention** of disease exist. Primary prevention involves promoting healthy lifestyles through immunizations, encouraging exercise, and healthy nutrition. Secondary prevention involves targeting populations at risk for certain diseases. For example, women are encouraged to have

TABLE 2-2 TRADITIONAL* CULTURAL BELIEFS AND PRACTICES: CHILDBEARING AND PARENTING

Hispanic

(Based primarily on knowledge of Mexican-Americans; members of the Hispanic community have their origins in Spain, Cuba, Central and South America, Mexico, Puerto Rico, and other Spanish-speaking countries.)

Pregnancy

Pregnancy desired soon after marriage
Late prenatal care
Expectant mother influenced strongly by mother or mother-in-law
Cool air in motion considered dangerous during pregnancy
Unsatisfied food cravings thought to cause a birthmark
Some pica observed in the eating of ashes or dirt (not common)
Milk avoided because it causes large babies and difficult births
Many predictions about sex of baby
May be unacceptable and frightening to have pelvic examination by male health care provider
Use of herbs to treat common complaints of pregnancy
Drinking chamomile tea thought to ensure effective labor
May wear ribbon or band around pregnant belly in belief that baby will be born healthy

Labor

Use of *partera* or lay midwife preferred in some places; may prefer presence of mother rather than husband
After birth of baby, mother's legs brought together to prevent air from entering uterus
Loud behavior in labor

Postpartum

Diet may be restricted after birth; for first 2 days only boiled milk and toasted tortillas permitted (special foods to restore warmth to body)
Bedrest for 3 days after birth
Keep warm
Delay bathing
Mother's head and feet protected from cold air; bathing permitted after 14 days
Mother often cared for by her own mother
Forty-day restriction on sexual intercourse
Mother may want baby's first wet diaper to wipe her face in belief that it aids in making "mask of pregnancy" go away

Newborn

Breastfeeding begun after third day; colostrum may be considered "filthy" or "spoiled" or just not enough nourishment
Olive oil or castor oil given to stimulate passage of meconium
Male infant not circumcised
Female infant's ears pierced
Belly band used to prevent umbilical hernia
Religious medal worn by mother during pregnancy; placed around infant's neck
Infant protected from *mal ojo* ("evil eye")
Various remedies used to treat *mal ojo* and fallen fontanel (depressed fontanel)

African-American

(Members of the African-American community, many of whom are descendants of slaves, have different origins. Today a number of black Americans have emigrated from Africa, the West Indies, the Dominican Republic, Haiti, and Jamaica.)

Pregnancy

Acceptance of pregnancy depends on economic status
Pregnancy thought to be state of "wellness," which is often the reason for delay in seeking prenatal care, especially by lower-income African-Americans
Old wives' tales include beliefs that having a picture taken during pregnancy will cause stillbirth and reaching up will cause cord to strangle baby
Craving for certain foods, including chicken and greens, and nonfood substances such as clay, starch, and dirt
Pregnancy may be viewed by African-American men as a sign of their virility
Self-treatment for various discomforts of pregnancy, including constipation, nausea, vomiting, headache, and heartburn

Labor

Use of "Granny midwife" in certain parts of United States
Varied emotional responses: some cry out, some display stoic behavior to avoid calling attention to selves
Woman may arrive at hospital in far-advanced labor
Emotional support often provided by other women, especially the woman's own mother

Postpartum

Vaginal bleeding seen as sign of sickness; tub baths and shampooing of hair prohibited
Sassafras tea thought to have healing power
Eating liver thought to cause heavier vaginal bleeding because of its high "blood" content

Newborn

Feeding very important:
  "Good" baby thought to eat well
  Early introduction of solid foods
  May breastfeed or bottle-feed; breastfeeding may be considered embarrassing
Parents fearful of spoiling baby
Commonly call baby by nicknames
May use excessive clothing to keep baby warm
Belly band used to prevent umbilical hernia
Abundant use of oil on baby's scalp and skin
Strong feeling of family, community, and religion

TABLE 2-2 TRADITIONAL CULTURAL BELIEFS AND PRACTICES: CHILDBEARING AND PARENTING—cont'd

Asian-American

(Typically refers to groups from China, Korea, the Philippines, Japan, Southeast Asia [particularly Thailand], Indochina, and Vietnam.)

Pregnancy

- Pregnancy considered time when mother "has happiness in her body"
- Pregnancy seen as natural process
- Strong preference for female health care provider
- Belief in theory of hot and cold
- May omit soy sauce in diet to prevent dark-skinned baby
- Prefer soup made with ginseng root as general strength tonic
- Milk usually excluded from diet because it causes stomach distress
- Inactivity or sleeping late may cause difficult birth

Labor

- Mother attended by other women, especially her own mother
- Father does not actively participate
- Labor in silence
- Cesarean birth not desired

Postpartum

- Must protect self from *yin* (cold forces) for 30 days
- Ambulation limited
- Shower and bathing prohibited
- Warm room
- Diet:
  - Warm fluids
  - Some women are vegetarians
  - Korean mother served seaweed soup with rice
  - Chinese diet high in hot foods
  - Chinese mother avoids fruits and vegetables

Newborn

- Concept of family important and valued
- Father is head of household; wife plays a subordinate role
- Birth of boy preferred
- May delay naming child
- Some groups (e.g., Vietnamese) believe colostrum is dirty; therefore they may delay breastfeeding until milk comes in

European-American

(Members of the European-American [Caucasian] community have their origins in countries such as Ireland, Great Britain, Germany, Italy, and France.)

Pregnancy

- Pregnancy viewed as a condition that requires medical attention to ensure health
- Emphasis on early prenatal care
- Variety of childbirth education programs available, and participation encouraged
- Technology driven
- Emphasis on nutritional science
- Involvement of the father valued
- Written sources of information valued

Labor

- Birth is a public concern
- Technology dominated
- Birthing process in institutional setting valued
- Involvement of father expected
- Physician seen as head of team

Postpartum

- Emphasis or focus on early bonding
- Medical interventions for dealing with discomfort
- Early ambulation and activity emphasized
- Self-management valued

Newborn

- Increased popularity of breastfeeding
- Breastfeeding begins as soon as possible after childbirth

Parenting

- Motherhood and transition to parenting seen as stressful time
- Nuclear family valued, although single-parenting and other forms of parenting more acceptable than in the past
- Women often deal with multiple roles
- Early return to prenatal activities

Native American

(Many different tribes exist within the Native-American culture; viewpoints vary according to tribal customs and beliefs.)

Pregnancy

- Pregnancy considered a normal, natural process
- Late prenatal care
- Avoid heavy lifting
- Herb teas encouraged

Labor

- Prefers female attendant, although husband, mother, or father may assist with birth
- Birth may be attended by whole family
- Herbs may be used to promote uterine activity
- Birth may occur in squatting position

Postpartum

- Herbal teas to stop bleeding

Newborn

- Infant not fed colostrum
- Use of herbs to increase flow of milk
- Use of cradle boards for infant
- Babies not handled often

Data from Amaro H: Women in the Mexican-American community: religion, culture, and reproductive attitudes and experiences, *J Comp Psychol* 16(1):6–19, 1994; Bar-Yam N: Learning about culture: a guide for birth practitioners, *Int J Childbirth Educ* 9(2):8–10, 1994; Galanti G: *Caring for patients from different cultures: case studies from American hospitals,* ed 2, Philadelphia, 1997, University of Pennsylvania Press; D'Avanzo C: *Mosby's pocket guide to cultural health assessment*, ed 4, St Louis, 2008, Mosby; Mattson S: Culturally sensitive prenatal care for Southeastern Asians, *J Obstet Gynecol Neonatal Nurs* 24(4):335–341, 1995; Spector R: *Cultural diversity in health and illness*, ed 8, Upper Saddle River, NJ, 2013, Prentice-Hall; Williams R: Issues in women's health care. In Johnson B, editor: *Psychiatric mental health nursing: adaptation and growth,* Philadelphia, 1989, JB Lippincott.

NOTE: Most of these cultural beliefs and customs reflect the traditional culture and are not universally practiced. These lists are not intended to stereotype patients but, rather, to serve as guidelines while discussing meaningful cultural beliefs with a woman and her family. Examples of other cultural beliefs and practices are found throughout this text.

*Variations in some beliefs and practices exist within subcultures of each group.

mammograms; men are encouraged to have prostate screening. Tertiary prevention focuses on rehabilitation of an individual to health as optimal as is possible in the presence of a disease or injury. For example, a person who has experienced a stroke has an optimal expectation of being able to function at his or her fullest potential. As nurses, we do what we can to ensure that this occurs.

During pregnancy, primarily primary and secondary prevention are relevant. The goal is to maintain a healthy pregnancy by preventing illness and by screening those at risk for potential illnesses or complications that could arise during pregnancy. In pregnancy, primary prevention might involve providing the influenza vaccine to women, whereas secondary prevention might involve performing an amniocentesis for a woman older than 35 years.

Promoting Family Health

Functioning within the social, cultural, environmental, and economic context of the community, the family becomes an integral component of community health-promotion efforts. For childbearing families, health promotion is focused primarily on early intervention through prenatal care and prevention of complications during the perinatal period. Often this early exposure to health information sets the stage for a successful birth and positive outcomes for mother and baby. The nurse's role in this process is focused on collaboration with the family, identifying risk factors, and providing health information to facilitate positive health behaviors. Involving expectant mothers and fathers in identification of their learning needs is an essential first step to securing their participation in the health-promotion process.

A wide variety of strategies have been used to engage families and groups in health-promoting activities or community health programs. Some are more successful than others. Generally, participant engagement in the planning process and empowerment to create internal solutions are considered key factors in effective interventions. Many communities have organized coalitions to address specific health-promotion agendas related to sharing information, educating community members, or advocating for health policies around maternal and child health issues. The benefits of partnership with faith-based organizations for community health improvement have been demonstrated in health-promotion efforts aimed at lifestyle choices, health education, and maternal-child health outcomes.

Prepared childbirth classes are a well-established mechanism for increasing awareness of healthy behaviors during pregnancy and preparing parents for the care of themselves and their newborn during the postpartum period. Mass media efforts such as those presented by the March of Dimes "Baby Your Baby" advertisements are clear consumer-friendly messages designed to reach a large target audience. Other venues include public health education in newspapers and magazines and health department programs such as the Special Supplemental Nutrition Program for Women, Infants, and Children (WIC), which offers a variety of health education and written information to mothers.

ASSESSING THE COMMUNITY

A **community assessment** is a tool that is used to assess the health and well-being of a community. One can define community either geographically or as having a common characteristic. For example, one can do a community assessment of people who live in a particular neighborhood or of women who have developed preterm labor. In doing the community assessment, risk factors for certain diseases, patterns of illness, cultural beliefs, religious beliefs, transportation systems, and support systems are just a few factors that are assessed to determine how these components relate to certain patterns of illness.

In a **community health assessment,** data are collected, analyzed, and used to educate and mobilize communities, develop priorities, garner resources, and plan actions to improve public health. Many models and frameworks of community assessment are available, but the actual process often depends on the extent and nature of the assessment to be performed, the time and resources available, and the way the information is to be used (http://assessnow.info/resources/models-of-community-health-assessment/view).

Data Collection and Sources of Community Health Data

Important measures of community health, for example, are **access to care,** level of provider services available, availability of transportation, and family support. Consideration of a variety of these factors helps one assess areas that may affect care so that nurses can introduce alternatives to meet the needs of patients. For example, if a woman has to work Monday through Friday, from 8 AM to 5 PM, the nurse can facilitate an after-hours appointment.

The most critical community indicators of perinatal health relate to access to care; maternal mortality; infant mortality; low birth weight; first-trimester prenatal care; and rates for mammography, Papanicolaou smears, and other similar screening tests. Nurses can use these indicators as a reflection of access, quality, and continuity of health care in a community. For women and infants, access to a consistent source of care is critical. Those with a regular source of care are more likely to use preventive services and have more positive pregnancy outcomes, but many women lack access to a usual source of care or rely primarily on emergency services.

Access to health care relates not only to the availability of health department services, hospitals, public clinics, clinic hours, or other sources of care but also to accessibility of care. In many areas where facilities and providers are available, geographic and transportation barriers render the care inaccessible for certain populations. This is particularly true in rural areas or other remote locations. Other barriers to care should also be evaluated including cultural and language barriers and lack of providers or specialty care. There is a growing trend in the United States to have walk-in clinics in grocery stores, an easily accessible location.

Health departments at the city, county, and state level are a valuable resource for annual reports of births and deaths. Local health departments also compile extensive statistics about the birth complications, causes of death, and leading causes of morbidity and mortality for each age-group. Local and state health data are compiled and reported through the Centers for Disease Control and Prevention (CDC) (www.cdc.gov) to the National Center for Health Statistics (NCHS) (www.cdc.gov/nchs). The National Health Survey published annually from this source describes national health trends. However, national data are only as accurate and reliable as the local data on which they are based, so caution is needed in interpreting the data and applying it to specific population groups.

The U.S. census provides data on population size, age ranges, sex, racial and ethnic distribution, socioeconomic status, educational level, employment, and housing characteristics. Summary data are available for most large metropolitan areas, arranged by zip code and census tract, which usually corresponds to a neighborhood comprising approximately 3000 to 6000 people. Looking at individual census tracts within a community helps identify subpopulations or aggregates whose needs may differ from those of the

larger community. For example, women at high risk for inadequate prenatal care according to age, race, and ethnic or cultural group can be readily identified and outreach activities appropriately targeted.

Other sources of useful information are hospitals and voluntary health agencies. The March of Dimes Foundation, for example, has supported perinatal needs assessments in many communities across the United States (www.modimes.org). Other community health resources include health care providers or administrators, government officials, religious leaders, and representatives of voluntary health agencies. Community or county health councils exist in many areas, with oversight of specific health initiatives or programs for that region. These key informants often provide a unique perspective that may not be accessible through other sources. Community gatekeepers who address the social and health care needs of the population are also critical links to population-specific health information.

Professional associations and publications are rich and readily accessible sources of information for all nurses. Professional associations publish standards and position papers that are useful. In addition to nursing and public health journals, behavioral and social science literature offers diverse perspectives on community health status for specific populations and subgroups. The Internet has increased the availability and accessibility of national, state, and local health data as well. However, the use of Internet-based resources for health information requires caution because data reliability and validity are difficult to verify. Guidelines for evaluation of Internet health resources can be found on the "Health on the Net" website (www.hon.ch).

Data collection methods may be either qualitative (e.g., by discussion, interview, observation) or quantitative (e.g., number, mean, standard deviation, percent of data collected) and may include visual surveys that can be completed by walking through a community, participant observation, interviews, focus groups, and analysis of existing data. Potential patients and health care consumers may be asked to participate in focus groups or community forums to present their views on needed community services and programs. Formal surveys, conducted by mail, telephone, the Internet, or face-to-face interviews, can be a valuable source of information not available from national databases or other secondary sources. Several drawbacks exist with this method—surveys are generally expensive to develop and time-consuming to administer. In addition to the cost of such surveys, poor response rates often preclude a sufficiently representative response on which to base nursing interventions.

A **walking survey** is generally conducted by a walk-through observation of the community (Box 2-4), taking note of specific characteristics of the population, economic and social environment, transportation, health care services, and other resources. With this type of data collection, information is gathered based on what the data collector observes and is clearly objective data. **Participant observation** is another useful assessment method in which the nurse actively participates in the community to understand the community more fully and to validate observations. As part of the assessment process, nurses working in multiethnic and multicultural groups need an in-depth assessment of culturally based health behaviors.

Analysis and synthesis of data obtained during the assessment process help generate a comprehensive picture of the community's health status, needs, and problem areas, as well as its strengths and resources for addressing these concerns. The goal of this process is to assign priorities to community health needs and to develop a plan of action for correcting them. A comparison of community health data with state and national statistics can help identify appropriate target populations and develop interventions to improve health outcomes.

BOX 2-4 COMMUNITY WALK-THROUGH

As you observe the community, take note of the following:

- **Physical environment**—Older neighborhood or newer subdivision? Sidewalks, streets, and buildings in good or poor repair? Billboards and signs? What are they advertising? Are lawns kept up? Is there trash in the streets? Parks or playgrounds? Parking lots? Empty lots? Industries?
- **People in the area**—Old, young, homeless, children; predominant ethnicity, language? Is the population homogeneous? What signs do you see of different cultural groups?
- **Stores and services available**—Restaurants: chain, local, ethnic? Grocery stores: neighborhood or chain? Department stores, gas stations, real estate or insurance offices, travel agencies, pawn shops, liquor stores, discount or thrift stores, newspaper stands?
- **Social**—Clubs, bars, fraternal organizations (e.g., Elks, American Legion), museums?
- **Religious**—Churches, synagogues, mosques? What denominations? Do you see evidence of their use other than on religious/holy days?
- **Health services**—Drugstores, physicians' offices, clinics, dentists, mental health services, veterinarians, urgent care facilities, hospitals, shelters, nursing homes, home health agencies, public health services, traditional healers (e.g., herbalists, palmists)?
- **Transportation**—Cars, buses, taxis, light rail, sidewalks, bicycle paths, access for disabled persons?
- **Education**—Schools, before- and after-school programs, child care, libraries, bookstores? What is the reputation of the schools?
- **Government**—What is the governance structure? Is there a mayor? City council? Are meetings open to the public? Are there signs of political activity (e.g., posters, campaign signs)?
- **Safety**—How safe is the community? What is the crime rate? What types of crimes are committed? Are police visible? Is there a fire station?
- **Evaluation of the community based on your observations**—What is your impression of the community? Is the environment pleasing? Are services and transportation adequate? How difficult is it for residents to obtain needed services (i.e., how far do they have to travel)? Would you want to live in this community? Why or why not?

Vulnerable Populations in the Community

Assessment of population health includes indicators related to diverse groups and cultures, particularly disenfranchised or **"vulnerable"** community members. Vulnerability in terms of health status and health outcomes may take many forms, including sociocultural, economic, and environmental risk factors that contribute to disparities in health. Health disparities are conditions that disproportionately affect certain racial, ethnic, or other groups. African-Americans, Hispanic-Americans, Native Americans, Pacific Islanders, and Asian-Americans are all considered vulnerable populations because they are more likely to have poor health and die prematurely (see Chapter 1).

Women

Women make up 51% of the U.S. population, representing a very diverse and largely at-risk, group in relation to health (U.S. Census Bureau, 2011). Although women assume leadership for health care

decision making in most families, they also face significant challenges in accessing the health care system and meeting their own health needs and those of family members. Although there is no single contributing factor, the primary sources of health disparities for women fall into the areas of gender, socioeconomic status, and race or ethnicity. Significant gaps exist in the quality of care for women when compared with men.

The *National Report Card on Women's Health* describes significant deficiencies in women's health (National Women's Law Center [NWLC], 2010). States' performance in relation to 26 graded indicators was assessed; all but 3 were rated as *unsatisfactory* in relation to women's health status and policies influencing women's health. Key indicators focused on access to services, use of preventive health care and health promotion-activities, the occurrence of certain health conditions, and an assessment of the community's effect on women's health. This report suggested that one of the primary factors compromising women's health is lack of access to acceptable-quality health care, which may manifest itself in many forms: lack of health insurance, living in a medically underserved area, or an inability to obtain needed services, particularly basic services such as prenatal care. With the enactment of the Patient Protection and Affordable Care Act, many of the policy goals will be realized as the Act is implemented (NWLC, 2010).

Although many women report that they are in good to excellent health, statistics reveal significant disparities in health status of women from all age-groups and racial and ethnic backgrounds. Low levels of educational attainment (high school or lower) are also associated with lack of resources and difficulty navigating the health care system. This is particularly true of women of ethnic and racial minorities, whose limited English proficiency may compromise provider access and quality of care.

Racial and Ethnic Minorities

In addition to social, economic, and cultural barriers to optimal health, women who are in racial and ethnic minorities experience a disproportionate burden of disease, disability, and premature death. Significant health disparities continue to exist in adult women's health and the health of their infants. Although positive trends are evident, disparities persist among racial and ethnic groups in early prenatal care, an important factor in achieving healthy pregnancy outcomes.

Minority women, many of whom live in poverty, also have higher rates of chronic disease including heart disease, cancer, hepatitis, and acquired immunodeficiency syndrome (AIDS), as well as mental health issues. Women with underlying health conditions are at especially high risk for poor obstetric outcomes for themselves and their infants. They have high rates of preterm labor and gestational hypertension and often have intrauterine growth restriction resulting in the birth of infants who are small for gestational age. These are the women for whom the community-based perinatal nurse will be providing care, and their needs are complex, demanding high levels of expertise and skill.

Adolescent Girls

The adolescent population in the United States is generally considered healthy. However, adolescents participate in riskier behaviors and their health is often compromised as a result. Although adolescents are concerned about becoming pregnant, they still engage in unprotected sex. Adolescents also use a variety of sources for health information—the media, friends, and sex education—yet they are very misinformed, particularly about sexually transmitted infections (STIs) and human immunodeficiency virus (HIV) transmission. These findings have significant implications for perinatal outcomes and emphasize the importance of aggressive prevention programs and community outreach related to sexuality, teen pregnancy, and substance abuse.

It is crucial that nurses engage adolescents in health education programs that will encourage them to make informed decisions about their sexual health. It is also vital that nurses be a resource to these young women.

Older Women

Although women have a longer life expectancy than men, they are more likely to have chronic illnesses, less likely to use preventive services, and ultimately spend more on health care. As nurses, it is important that we engage this population at all levels of prevention, from primary to tertiary.

Incarcerated Women

The number of incarcerated women in the United States has continued to climb in recent years, increasing at a significantly greater rate than for men. In 2010 there were 113,000 women incarcerated in state and federal facilities, with the highest number of these being non-Hispanic black women (Sipes, 2012). Many of these women report a history of sexual and physical abuse.

Because their relationship histories are often unstable and because they often lack the support of family, incarcerated women or those with a history of repeated incarceration frequently have difficulty providing emotional stability, secure housing, and health-promotion role modeling for their children.

The lifestyle choices of this group, including risky sexual relationships, illicit drug use, and smoking, place them at high risk for STIs, HIV, and AIDS; other chronic and communicable diseases; and complicated pregnancies.

Immigrant, Refugee, and Migrant Women

As of 2010 nearly 40 million or 13% of the population in the United States were foreign born (Grieco, Acosta, del al Cruz, et al., 2012). This accounts for a rapidly growing diverse population for which nurses will be providing care.

An **immigrant** is an individual who moves from one country to another in an effort to take up legal residency, whereas a refugee is an individual who is forced to leave his or her home country, often in search of a safer and more stable living environment. Both populations are often challenged with not being able to easily access health care because they are not U.S. citizens. These women often do not seek medical care for fear of deportation. Access to care is further limited by health care policies that restrict Medicaid eligibility for these groups.

Along with their profound resilience and determination, **refugees** and immigrants have brought rich diversity to the United States in several important dimensions including cultural heritage and customs, economic productivity, and enhanced national vitality. In general, refugees are more likely to live in poverty than are immigrants. Over time, measures of health and well-being actually decline for the immigrant population as they become part of American society. Many of the conditions or illnesses that they acquire contribute to the persistence of disparities in maternal and neonatal health outcomes for both immigrants and refugees.

Migrant workers are those who work outside their home country or migrate within their own country seeking seasonal work. Migrant laborers and their families face many problems, including financial instability, child labor, poor housing, lack of education, language and cultural barriers, and limited access to health and social services.

COMMUNITY FOCUS

Community Activity

- Visit the Health Resources and Services Administration (HRSA) website at www.communityhealth.hrsa.gov. What is the definition of a health center by the HRSA? What populations do they serve? What are the different types of health centers?
- Locate a health center in your community at the HRSA website. What types of services do they provide? Do they provide primary and preventive health services? Is care provided regardless of the patient's ability to pay?
- Visit your State Center for Health Statistics (SCHS) website. Evaluate the health status of women and infants in your county. Vital statistics include live births, physician versus midwife attended, out-of-wedlock births, cesarean births, low birth weight, maternal smoking, and fetal/infant mortality.

Poor dental health, diabetes, hypertension, malnutrition, tuberculosis, skin diseases, and parasitic infections are common health issues among migrant populations. Primary health care services are largely provided by a number of migrant health centers, of which there are more than 400 throughout the United States. In 2011 more than 862,808 seasonal and migrant farm workers and their families were served (U.S. Department of Health and Human Services [USDHHS], 2011). Routine prenatal care, as well as screening and treatment for hypertension and diabetes, is provided. Community health nurses frequently encounter the challenges of providing culturally and linguistically appropriate care while facing numerous health issues.

Numerous reproductive health issues exist for migrant women, including less consistent use of contraception and increased rates of STIs. Migrants are less likely to receive early prenatal care and have a greater incidence of inadequate weight gain during pregnancy than do other poor women (see Community Focus box).

Rural Versus Urban Community Settings

Approximately 16% of the U.S. population live in a rural area (Rural Assistance Center, 2011). Generally, rural residents are older, less educated, and in poorer health than their urban counterparts. Rural communities are disproportionately affected by poverty and poor access to health care services. Fewer physicians choose to practice in rural areas. Lack of insurance presents an additional factor for poor health in rural areas.

Rural women are especially vulnerable to financial and transportation barriers to health care. Although women in rural counties report only fair to poor health, they pay considerably more for their health care. In rural communities, women have less access to prenatal care, which contributes to higher rates of adverse pregnancy outcomes including higher rates of preterm birth, low birth weight, and infant mortality. The disproportionate distribution of poverty and of variations in race/ethnicity, age, education, and availability and access to medical resources may be the link to infant mortality in rural areas.

Homeless Women

Homelessness among women is an increasing social and health issue in the United States. Although exact numbers are unknown because of the difficulty in tracking individuals without a permanent address, it is estimated that more than 636,000 people were homeless in 2011 (Homelessness in America, 2012). Single women make up 13% of the homeless population and are often on the street to escape domestic violence (Dray, 2012). Families with children make up the fastest-growing group of the homeless. In these families, one in five children experienced food insecurity (did not have enough to eat) in 2010 (National Coalition for the Homeless, 2011).

Health issues among the homeless are numerous and result primarily from a lack of preventive care and a lack of resources in general. Health problems include chronic illness, infectious diseases, asthma, circulatory problems, diabetes, substance abuse, and mental illness. Lifestyle factors and the vulnerability resulting from being homeless contribute to health problems. Women are at increased risk for illness and injury; many have been victims of domestic abuse, assault, and rape. Although little is known about pregnancy in this population, women do become pregnant while homeless. In addition to risk factors related to inadequate nutrition, inadequate weight gain, anemia, bleeding problems, and preterm birth, homeless women face multiple barriers to prenatal care: transportation, distance, and wait times. Most of these women underutilize available prenatal services. The unsafe environment and high risk lifestyles often result in adverse perinatal outcomes (American College of Obstetricians and Gynecologists [ACOG], 2010; Richards, Merrill, and Baksh, 2011). The United States has initiated programs to address these problems. For example, the U.S. Interagency Council on Homelessness and its 19 member agencies launched *Opening Doors,* the federal strategic plan to prevent and end homelessness in 2010 and updated it in 2011 (Opening Doors, 2012).

Implications for Nursing

Working in the community or in the home with the full spectrum of family organizational styles, vulnerable populations, and cultural groups presents challenges for nurses. Whether it involves perinatal care focused on women and their newborns or women's health care directed toward treatment and prevention of other health conditions such as communicable diseases and sexually transmitted infections, nursing must exhibit a high degree of professionalism. Cultural sensitivity, compassion, and a critical awareness of family dynamics and social stressors that will affect health-related decision making are critical components in developing an effective plan of care.

Although the long-term consequences of contemporary immigration for American society are unclear, the successful incorporation of immigrant families depends on the resources, benefits, and policies that ensure their healthy development and successful social adjustment. Culturally competent health care and involvement of the immigrant community in health care programs are recommended strategies for improving the access to and effectiveness of health care for this population.

The use of camp volunteers has been effective in assisting families living in migrant worker camps to obtain prenatal, postpartum, and infant care. Working in partnership with health care professionals such as nurses, lay camp aides have been used effectively for outreach and health education; however, more strategies are needed to link traditional practices with the formal health care system. Guidance and information about other health resources are available to health care providers through the National Center for Farmworker Health, Inc. (www.ncfh.org) and the Migrant Clinicians Network (www.migrantclinician.org).

Nurses working with homeless women and families are challenged to treat them with dignity and respect to establish a **therapeutic relationship. Case management** is recommended to coordinate the services and disciplines that may be involved in meeting the complex needs of these families. Whenever possible, general screening and preventive health services must be provided

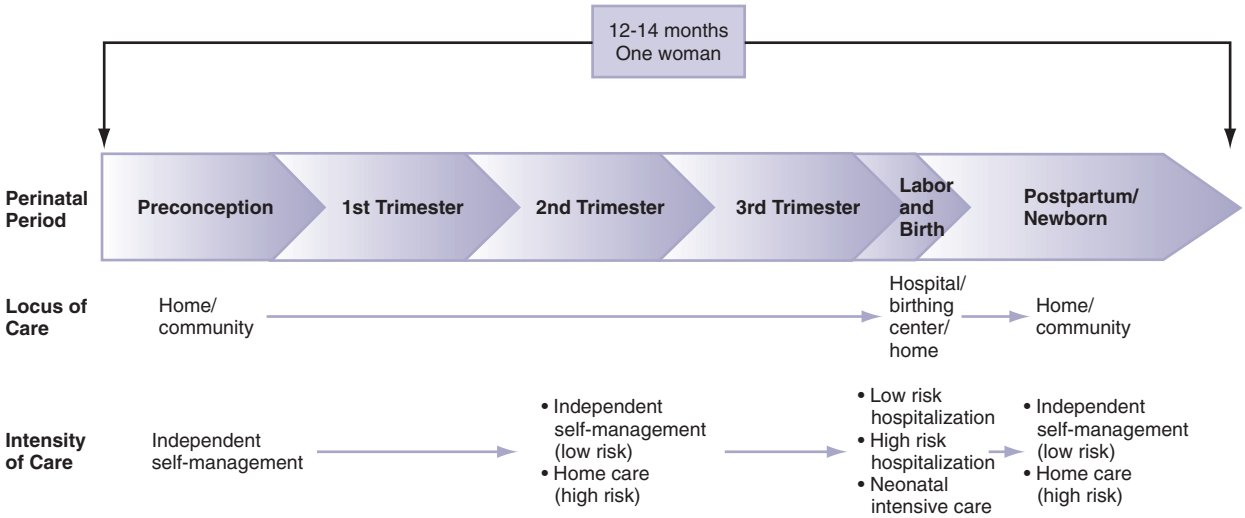

FIG 2-7 Perinatal continuum of care.

when the woman seeks treatment, because this may be the only opportunity to provide health information and intervention. Building on existing **coping** strategies and strengths, the health care provider helps the woman and her family reconnect with a social support system. Nurses also have an important role in advocating for funding to support health care services to the homeless and to improve access to preventive care for all homeless populations.

HOME CARE IN THE COMMUNITY

Modern home care nursing has its foundation in public health nursing, which provided comprehensive care to sick and well patients in their own homes. Specialized maternity home care nursing services began in the 1980s when public health maternity nursing services were limited and services had not kept pace with the changing practices of high risk obstetrics and emerging technology. Lengthy antepartum hospitalizations for such conditions as preterm labor and gestational hypertension created nursing care challenges for staff members of inpatient units.

Many women expressed their concern about the negative effect of antepartum hospitalizations on the family. Although clinical indications showed that a new nursing care approach was needed, home health care did not become a viable alternative until third-party payers (i.e., public or private organizations or employer groups that pay for health care) pushed for cost containment in maternity services.

In the current health care system, home care is an important component of health care delivery along the perinatal continuum of care (Fig. 2-7). The growing demand for home care is based on several factors:

- Interest in family birthing alternatives
- Shortened hospital stays
- New technologies that facilitate home-based assessments and treatments
- Reimbursement by third-party payers

As health care costs continue to rise and millions of American families lack health insurance, there is greater demand for innovative, cost-effective methods of health care delivery in the community. Large health care systems are developing clinically integrated health care delivery networks whose goals are (1) improved coordination of care and care outcomes; (2) better communication among health care providers; (3) increased patient, payer, and provider satisfaction; and (4) reduced cost. The integration of clinical services changes the focus of care to a continuum of services that are increasingly community based.

FIG 2-8 Home care nurse visits with a woman in preterm labor at home on bedrest. (Courtesy Shannon Perry, Phoenix, AZ.)

Communication and Technology Applications

As maternity care continues to consist of frequent and brief contacts with health care providers throughout the prenatal and postpartum periods, services that link maternity patients throughout the perinatal continuum of care have assumed increasing importance. These services include critical pathways, telephonic nursing assessments, discharge planning, specialized education programs, parent support groups, home visiting programs, nurse advice lines, and perinatal home care (Fig. 2-8). Hospitals may provide cross-training for hospital-based nurses to make postpartum home visits or to staff outpatient centers for postpartum follow-up.

Telephonic nursing care through services such as warm lines, nurse advice lines, and telephonic nursing assessments is a valuable means of managing health care problems and bridging the gaps

among acute, outpatient, and home care services. Providers are using the Internet to communicate with patients who have an Internet service provider (ISP). Nursing care that occurs by telephone is interactive and responsive to immediate health care questions about particular health care needs. Warm lines are telephone lines that are offered as a community service to provide new parents with support, encouragement, and basic parenting education. Nurse advice lines, or toll-free nurse consultation services, often are supported by third-party payers or health maintenance organizations/managed care organizations (HMOs/MCOs) and are designed to provide answers to medical questions. Nurse care managers are prepared to guide callers through urgent health care situations, suggest treatment options, and provide health education. Telephonic nursing assessments or nurse consultation, assessment, and health education that take place during a telephone conversation can be added to the plan of care in conjunction with skilled nursing visits, or they may comprise a separate nursing contact for the woman. Telephonic nursing assessments are commonly used after a postpartum home care visit to reassess a woman's knowledge about the signs and symptoms of adequate hydration in breastfeeding or, after initiating home phototherapy, to assess the caregiver's knowledge regarding problems with equipment.

Guidelines for Nursing Practice

The Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN, 2009) defines **home care** as the provision of technical, psychologic, and other therapeutic support in the woman's home rather than in an institution. The scope of nursing care delivered in the home is necessarily limited to practices deemed safe and appropriate to be carried out in an environment that is physically separated from a health care institution and its resources. Nursing practice at home is consistent with federal and state regulations that direct home care practice. The nurse demonstrates practice competence through formalized orientation and ongoing clinical education and performance evaluation in the respective home care agency. Standards for practice from key specialty organizations such as AWHONN, the National Association of Neonatal Nurses (NANN), the ACOG, the American Academy of Pediatrics (AAP), and the Intravenous Nursing Society (INS) provide the basis for clinical protocols and pathways and organizational programs in home care practice. The Joint Commission (www.jointcommission.org) provides criteria for home care operations based on Centers for Medicare & Medicaid Services (CMS) regulations (cms.hhs.gov).

A wide range of professional health care services and products can be delivered or used in the home by means of technology and telecommunication. For example, telehealth and telemedicine make it possible for patients in the home to be interviewed and assessed by a specialist located hundreds of miles away. Home health care can be viewed as an extension of in-hospital care. Essentially, the primary difference between health care in a hospital and home care is the absence of the continuous presence of professional health care providers in a patient's home. Generally, but not always, home health care entails intermittent care by a professional who visits the patient's home for a particular reason and/or provides care onsite for fewer than 4 hours at a time. The home health care agency maintains on-call professional staff to assist home care patients who have questions about their care and for emergencies, such as equipment failure.

Perinatal Services

Home care perinatal services may be provided by hospital-based programs, independent proprietary (for-profit) agencies, or nonprofit home care agencies and by official or tax-supported agencies. Innovative programs may be supported by research grants for a period of years, but ultimately they must be sponsored by an agency with long-term funding. Home visits have advantages and disadvantages. The pregnant woman can maintain bedrest if indicated, and vulnerable neonates are not exposed to the weather or external sources of infection. The nurse can observe and interact with family members in their most natural and secure environment. Adequacy of resources and safety factors can be assessed. Teaching can be tailored to the actual home conditions, and other family members can be included. A home visit is less expensive than a day's hospitalization, but a 60- to 90-minute visit requires 2.5 to 3 hours of nursing time, including travel and documentation. Areas of challenge include limited availability of nurses with expertise in maternity care and concerns about the nurse's physical safety in the community. One alternative that is less expensive is contacting women via telephone.

Visits for outreach and health promotion are an integral part of community (or public) health nursing. In countries with national health systems, a nurse or midwife may see all women during pregnancy and after birth. In the United States, visits of this sort have been provided mainly to low-income families without health insurance and Medicaid recipients who use the clinics provided by local health departments. Until recently, private insurers did not reimburse for health-promotion visits. MCOs now recognize that **anticipatory guidance** can be cost-effective, but home visitation programs for the most part still target specific, high risk populations, such as adolescents and women at risk for preterm labor.

Home care agencies are subject to regulation by governmental and professional organizations and provide interdisciplinary services including social work, nutrition, and occupational and physical therapy. Increasingly, their caseloads are made up of women who require high-technology care, such as infusions or home monitoring. Although the home health nurse develops the care plan, all care must be ordered by a physician. In addition, interventions must meet the insurer's criteria for reimbursement and services are limited to registered patients. Preconception care and low risk antepartum care can usually be provided more efficiently in offices and are not currently reimbursable. High risk antepartum care can be provided by home care agencies; for example, women with hyperemesis gravidarum who require parenteral nutrition may be treated at home. Conditions requiring bedrest, such as preterm labor and hypertension, are other common indications for home care. Other conditions often managed with home care may include cardiac disease, substance abuse, and diabetes in pregnancy.

Insurers may reimburse for at least one postpartum visit to families after early discharge or in the presence of high risk factors. Phototherapy for treatment of neonatal hyperbilirubinemia can be used at home, allowing the mother and infant to be discharged to home together. Many other neonates who require long-term high-technology care are also managed with home care.

Patient Selection and Referral

The office or hospital-based nurse is often the key person in making effective referrals to home care. When considering a referral to home care, these factors are evaluated:

- Health status of mother and fetus or infant: Is the condition serious enough to warrant home care, and is it stable enough for intermittent observation to be sufficient?
- Availability of professionals to provide the needed services within the woman's community.

- Family resources, including psychosocial, social, and economic resources: Will the family be able to provide care between nursing visits? Are relationships supportive? Is third-party reimbursement available, or can it be negotiated with the insurer? Could a voluntary or tax-supported community agency provide needed care without payment?
- Cost-effectiveness: Is it more reasonable for the woman to receive these services at home or to go to a local outpatient facility to receive them?

Community referrals should not be limited to women with physiologic complications of pregnancy that require medical treatment. Women at risk (e.g., young adolescents, families with a history of abuse, members of vulnerable population groups, developmentally disabled individuals) may need follow-up care at home. As we move more and more into an interdisciplinary health care society, it is crucial that nurses communicate with social workers to tap into valuable community resources that women can use in their own communities after being discharged.

Standardized forms simplify the referral process and ensure that all needed information will be forwarded to the home health agency. The nursing assessment should include the woman's physical and psychologic status, her level of knowledge about self-management activities, her willingness to learn, the availability of caregivers and social support in the home, and her level of comfort with home care. If the referral is for a mother-and-infant home care visit, the nursing assessment should include newborn data.

High-technology home care requires additional information to be collected from the chart and consultation with the referring physician and other members of the health care team before a home care referral is made. These additional data include the medical diagnosis, medical prognosis, prescribed therapies, medication history, drug-dosing information, potential ancillary supplies, type of infusion and access device, and the available systems of social support for the woman and family. The nursing assessment and therapy data provide baseline information for the home care nurse and other health care providers involved in the care plan.

Whenever a referral is called in to a home health care agency, a member of the nursing or admissions staff determines the agency's ability to accept the woman for service. The use of telecommunication modalities such as fax machines, cellular phones, electronic files, and the Internet to transmit information has eliminated delays in initiating home care services, even in more remote rural areas.

CARE MANAGEMENT

Preparing for the Home Visit

The home care nurse reviews the available clinical data, demographic information, and completed care plan form and consults with the home care pharmacist or other health care team members who have previously contacted the woman to determine the goals of the visit. At this point, the nurse uses the medical diagnosis and the location of the case on the perinatal continuum as a starting point to organize the woman's care. The nurse reviews agency policies and procedures, professional literature about diagnosis, and community resources as part of the pre-visit preparation work (Box 2-5).

Before going on a home visit, the nurse schedules a time for the visit with the woman. It is essential that the nurse obtain clear driving directions at this time as well.

The nurse identifies herself or himself by name, title, and agency. She or he then explains who referred the woman to the agency for home care and the purpose of the home care visits. The nurse briefly explains what will occur during the visit and approximately how long the visit will last. The woman should be asked to restrain any pets during the visit. Last, the nurse asks about health supplies that may be needed for the woman's care.

First Home Care Visit

Making the first home care visit can be stressful for the nurse and the woman. The home care nurse is faced with an unknown environment controlled by the woman and her family. The woman and her family also experience feelings about the unknown, such as anxiety about the way the nurse will treat them or what the nurse will do during the visit. The challenge for the home care nurse is to establish a positive nurse-patient relationship and provide the prescribed home care services within the time provided for the initial home visit.

Implementing the following will generally make the home visit more comfortable for both the nurse and the woman: the nurse wears identification, introduces herself upon entering the home, clearly states the purpose of the visit, obtains written consent for the visit, provides privacy as desired by the woman, provides culturally sensitive care, and encourages the woman and family to become actively involved in the care provided. One of the most important roles of the home care nurse is modeling health-related behaviors for the woman and others who are in the home during the visit.

ASSESSMENT AND NURSING DIAGNOSES

The primary goals of the assessment phase are to develop a trusting relationship and collect data by various methods to obtain a comprehensive patient profile. It may not be feasible or appropriate to collect in-depth information about all areas of assessment during the first visit. However, in many instances the nurse may be limited to one visit and must obtain information pertinent to the current situation in that hour.

The major areas of the assessment are demographics, medical history, general health history, medication **history,** psychosocial assessment (Box 2-6), home and community environment, and physical assessment. Information can be obtained from patient records sent to the home care agency at the time of referral or from the pre-visit interview. These data will be used to develop the nursing care plan and complete the plan of care, which is required for many licensed home health care agencies.

Each plan of care has a different emphasis in the home environment. For example, women receiving infusion therapy for hyperemesis gravidarum need a safe place to store medications and infusion supplies that is out of reach of small children living in the home. The home care nurse should incorporate the agency policies and procedures for the storage and handling of infusion supplies into her walk-through inspection. During the walk-through, the home care nurse looks at the potential storage areas that are dry and clean and where the temperature can be maintained. The home care nurse should include an inspection of work areas such as countertops, tabletops, sinks, and trash areas that the woman or caregiver may use for mixing medications, changing infusion tubing, handling supplies, or disposing of used equipment and supplies.

The homes of women using electronic home health care equipment, such as phototherapy equipment or infusion pumps, require physical inspection of any electrical outlets, electrical cords, and extension cords that will be used. Homes with faulty electrical wiring may place the woman at risk for being involved in an electrical fire; faulty wiring may require inspection and repair by a

BOX 2-5 PROTOCOL FOR PERINATAL HOME VISITS

Pre-visit Interventions

1. Contact the family to arrange details for home visit.
   a. Identify self, credentials, and agency role.
   b. Review purpose of home visit follow-up.
   c. Schedule convenient time for visit.
   d. Confirm address and route to family home.
2. Review and clarify appropriate data.
   a. Review all available assessment data for mother and fetus or infant (i.e., referral forms, hospital discharge summaries, identified learning needs of the family).
   b. Review records of any previous nursing contacts.
   c. Contact other professional caregivers as necessary to clarify data (e.g., obstetrician, nurse-midwife, pediatrician, referring nurse).
3. Identify community resources and teaching materials appropriate to meet those needs already identified.
4. Plan the visit, and prepare a bag with equipment, supplies, and materials necessary for assessments of mother and fetus or infant, actual care anticipated, and teaching.

In-Home Interventions: Establishing a Relationship

1. Reintroduce yourself, and establish the purpose of the visit for mother, infant, and family; offer the family the opportunity to clarify their expectations of the contact.
2. Spend a brief time socially interacting with the family to become acquainted and establish a trusting relationship.

In-Home Interventions: Working with the Family

1. Conduct a systematic assessment of the mother and the fetus or newborn to determine their physiologic adjustment and any existing complications (see Fig. 2-8).
2. Throughout the visit, collect data to assess the emotional adjustment of individual family members to the pregnancy or birth and lifestyle changes. Note any evidence of family-newborn bonding and sibling rivalry; note relationships among mother, father, children, and grandparents.
3. Determine the adequacy of the support system.
   a. To what extent does someone help with cooking, cleaning, and other home-management tasks?
   b. To what extent is help being provided in caring for the newborn and any other children?
   c. Are support persons encouraging the new mother to care for herself and get adequate rest?
   d. Who is providing helpful information? Emotional support?
4. Throughout the visit, observe the home environment for adequacy of resources.
   a. Space: privacy, safe play of children, sleeping
   b. Overall cleanliness and state of repair
   c. Number of steps pregnant woman/new mother must climb
   d. Adequacy of cooking arrangements
   e. Adequacy of refrigeration and other food storage areas
   f. Adequacy of bathing, toilet, and laundry facilities
   g. Arrangements in home for newborn: sleeping, bathing, formula preparation (if needed), layette items, and diapers
5. Throughout the visit, observe the home environment for overall state of repair and existence of safety hazards.
   a. Storage of medications, household cleaners, and other substances hazardous to children
   b. Presence of peeling paint on furniture, walls, or pipes
   c. Factors that contribute to falls, such as dim lighting, broken steps, scatter rugs
   d. Presence of vermin
   e. Use of crib or playpen that fails to meet safety guidelines
   f. Existence of emergency plan in case of fire; fire alarm or extinguisher
6. Provide care to the mother, the newborn, or both as prescribed by their respective primary care provider or in accord with agency protocol.
7. Provide teaching on the basis of previously identified needs.
8. Refer the family to appropriate community agencies or resources, such as warm lines and support groups.
9. Ensure that the woman knows potential problems to watch for and who to call if they occur.
10. Ensure that used disposable items have been handled appropriately and that reusable items are cleaned and repacked appropriately in the nurse's bag.

In-Home Interventions: Ending the Visit

1. Summarize the activities and main points of the visit.
2. Clarify future expectations, including the schedule of the next visit.
3. Review the teaching plan and provide major points in writing.
4. Provide information about reaching the nurse or agency if needed before the next scheduled visit.

Post-visit Interventions

1. Document the visit thoroughly, using the necessary agency forms to serve as a legal record of the visit and to allow third-party reimbursement, as possible.
2. Initiate the plan of care on which the next encounter with the woman and/or family will be based.
3. Communicate appropriately (e.g., by telephone, letter, progress notes, or referral form) with the primary care provider, other health care professionals, or referral agencies on behalf of the woman and family.

BOX 2-6 PSYCHOSOCIAL ASSESSMENT

Language

- Identify the primary language spoken in the home.
- Assess whether there are any language barriers to receiving support.

Community Resources/Access to Care

- Identify primary and secondary means of transportation.
- Identify community agencies family uses for health care and support.
- Assess cultural and psychosocial barriers to receiving care.

Social Support

- Determine the people living with the pregnant woman.
- Identify who assists with household chores.
- Identify who assists with child care and parenting activities.
- Identify who the pregnant woman turns to for problems or during a crisis.

Interpersonal Relationships

- Identify the way decisions are made in the family.
- Identify the family's perception of the need for home care.
- Identify roles of adults in caring for family members.

Caregiver

- Identify the primary caregiver for home care treatments.
- Identify other caregivers and their roles.
- Assess the caregiver's knowledge of treatments and the care process.
- Identify potential strain from the caregiver role.
- Identify the level of satisfaction with the caregiver role.

Stress and Coping

- Identify what the woman perceives as lifestyle changes and their effect on her and her family.
- Identify the changes she and her family have made to adjust to her health condition and home health care treatments.

professional electrician before electronic devices are used. Findings from the assessment are incorporated into the plan of care.

The nursing plan of care is developed in collaboration with the woman, based on her health care needs. Home care nurses working in home health care agencies regulated by the CMS use a plan of care that includes patient demographics, the health care provider's orders, home care goals, and the woman's level of functioning. This document is initiated at the time of referral to the home care agency and must be updated every 60 days or as specified by state regulations. The frequency of the skilled nursing visit may vary with the individual plan of care and reimbursement criteria established by the third-party payers.

Nursing Considerations

There are several areas of concern when caring for a woman in the home. In home care, the woman or family members are responsible for administration of medications in the absence of the nurse. A careful medication history should be obtained to see if the woman is taking her medications correctly and understands their desired action and potential side effects. It is important that women and

NURSING CARE PLAN

Community and Home Care

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
Readiness for Enhanced Family Coping related to family growth and development in new community	The family will identify at least three community groups that can serve as appropriate resources for an expectant family with small children.	Assess family structure and availability of significant others, friends, or family members to assist family with new baby and siblings	To provide database for further interventions
		Encourage family to enlist assistance of individuals who are available to help family at birth of new baby	To provide physical and emotional support
		Using therapeutic communication, assist family to assess coping strategies used in the past for new situations	To provide clarification and promote empowerment of family in new situations
		Suggest strategies to find resources available in community	To assist family during pregnancy, with new baby, and with small siblings
		Give information regarding community workshops, classes, or support groups	To promote networking, community bonding, and support
Deficient Community Health related to resettlement of refugees in the community	The community will develop programs to meet the needs of new members of the community.	Conduct needs assessment of community	To identify priority needs for new members of community
		Initiate health education programs based on topics identified in needs assessment	To meet needs of members of community
		Prepare patient education materials in a variety of languages	To enhance understanding of community members
		Identify risks in community (e.g., environmental hazards, drug sales)	To provide target for community improvement
		With community leaders, develop plan to cope with and reduce environmental hazards	To improve public health and safety
		Develop monitoring or surveillance system	To ensure that progress will continue and new problems will be identified
Ineffective Community Coping related to presence of gangs and lack of community programs to redirect activities of youth	The health status of the community will improve.	Initiate health screening programs for community members	To identify effects of environmental hazards in community
		Work with politicians and policy makers to develop community	To provide safe environment with means of economic survival for community members
		Initiate programs such as Block Watch, Safe Houses, and Neighborhood Watch	To enhance safety of environment
		Work with community leaders to develop or clean up playgrounds	To provide safe place for children to play
		With community leaders, develop community grassroots initiatives	To enable community members to take ownership in community
		Identify sites of lead exposure	To decrease potential for lead poisoning in children
		Participate in immunization or vaccination clinics	To reduce risk in community of infectious diseases
		Develop community education programs on drugs, alcohol, and tobacco	To reduce exposure of young people to these products

caregivers have a clear understanding of medication regimens and are notified when medications change in any way. Even more important is ensuring that the woman and her caregivers fully understand the information that they are provided by health care providers.

It is also important that nurses are aware of how to use and educate women on the use of all home care equipment such as infusion pumps and phototherapy lights. Nurses also have to be skilled at performing various procedures such as venipuncture and administration of intravenous medications or fluids. In addition to teaching about medications and equipment, nurses must be sure that women know how to respond in emergency situations. Women need to be able to have 24-hour access to resources in the community in emergency situations. Women and family members are also encouraged to learn how to perform **cardiopulmonary resuscitation** (CPR), especially for infants.

Additional patient and family education in home care includes information about the specific high risk condition(s) involved, implications for pregnancy outcome, and measures for self-monitoring. Verbal explanations should be supplemented with clearly written instructions. General information to promote well-being, such as about nutrition and common discomforts of pregnancy, should also be included. The need for preparation for childbirth can be addressed by using books or videos and supplemented by individual teaching at home. Coping with bedrest or other limitation of activity is a problem for many women with high risk pregnancies. The nurse can share strategies that others have used, help with time management, and provide information about support services. Teaching about infant care or the special needs of the preterm infant may be appropriate during the prenatal period.

Clear documentation of assessments, problems identified, treatments and interventions performed, and the woman's response is essential. Third-party payers base reimbursement on the nurse's written record of providing skilled nursing care and assessments that support the woman's continuing need for those services. The nurse must promptly inform the health care provider by telephone, facsimile, or electronic file of any significant changes. When new orders are transmitted by telephone, a written copy must be sent for the physician's signature.

Finally, as soon as home care has been provided, it is essential that the nurse document assessment findings, care provided, recommendations for change, and any patient or family teaching. Detailed documentation is necessary to justify the need for the home visit and is often crucial in obtaining reimbursement from insurance companies. The nursing care plan summarizes details to be included in caring for a woman in the home (see Nursing Care Plan).

SAFETY ALERT

In caring for the home care patient, Occupational Safety and Health Administration (OSHA) guidelines should be followed. The use of strict handwashing techniques, personal protective equipment (PPE), and proper equipment is essential in preventing the spread of disease to the care provider, the woman, and her family.

KEY POINTS

- The family is a social network that acts as an important support system for its members.
- Family theories provide nurses with useful guidelines for understanding family function.
- Family socioeconomics, response to stress, and culture are key factors influencing family health.
- The economic, religious, kinship, and political structures are embedded in the reproductive beliefs and practices of a culture.
- Nurses must develop cultural competence and integrate it into the nursing plan of care.
- Of necessity, most changes aimed at improving community health involve partnerships among community residents and health care workers.
- Methods of collecting data useful to the nurse working in the community include walking surveys, analysis of existing data, informant interviews, and participant observation.
- Vulnerable populations are groups who are at higher risk for developing physical, mental, or social health problems.
- Social and economic factors affect the scope of perinatal nursing practice.
- Perinatal home care is a unique nursing practice that incorporates knowledge from community health nursing, acute care nursing, family therapy, health promotion, and patient education.
- Perinatal home care nurses should incorporate personal safety and infection control practices in the nursing plan of care.
- Telephonic nurse advice lines, telephonic nursing assessments, and warm lines are low-cost health care services that facilitate continuous patient education, support, and health care decision making even though health care is delivered in multiple sites.

CHAPTER

3

Assessment and Health Promotion

Ellen Olshansky

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify the structures and functions of the female reproductive system.
- Describe the menstrual cycle in relation to hormonal, ovarian, and endometrial responses.
- Identify the phases of the sexual response cycle.
- Identify facilitators and barriers for women to access care in the health care system.
- Analyze financial, cultural, gender, and communication barriers that may affect a woman's decision to seek and follow through with health-promoting activities.
- Describe the need for health promotion across the woman's life span.
- Analyze conditions and factors that increase health risks for women across the life span, including life stage, substance abuse, eating disorders, medical/health conditions, pregnancy, and intimate partner violence.
- Describe components of taking a woman's history and performing a physical examination.
- Review patient teaching of breast self-examination.
- Describe how the history and physical examination can be adapted for women with special needs.
- Outline the health-screening schedules for women across the life span.
- Identify the correct procedure for assisting with and collecting Papanicolaou test specimens.

Care of the well woman is focused on health promotion and illness prevention, recognizing that a woman is a bio-psycho-social-spiritual being, requiring a holistic approach to nursing care. To encourage appropriate health-promotion activities, it is important to conduct systematic health assessments and screenings. This chapter presents an overview of the nurse's role in encouraging health promotion and illness prevention in women. It provides guidelines for how to conduct a complete history and physical examination. This chapter also includes a schedule of screening tests recommended for women at different stages of their lives. As background to understanding assessment, a review of female anatomy and physiology as well as the menstrual cycle is presented. Facilitators and barriers to women to enter the health care system and risk factors for women's health across the life cycle are described. Anticipatory guidance suggestions, including nutrition and stress management, are included. Violence against women, particularly intimate partner violence (IPV) and battering of women, is discussed because it is often in the health care setting that the woman is able to acknowledge being in an abusive relationship. Examples of health-promotion efforts in the community are presented in an effort to emphasize community health approaches to care, especially since much of well woman care occurs in the community.

FEMALE REPRODUCTIVE SYSTEM

The female reproductive system consists of external structures visible from the pubis to the perineum and internal structures located in the pelvic cavity. The external and internal female reproductive structures develop and mature in response to estrogen and progesterone. This process starts in fetal life and continues through puberty and the childbearing years. Reproductive structures atrophy with age or in response to a decrease in ovarian hormone production. A complex nerve and blood supply supports the functions of these structures. The appearance of the external genitalia varies greatly among women. Heredity, age, race, and the number of children a woman has borne influence the size, shape, and color of her external organs.

External Structures

The external genital organs, or vulva, include all structures visible externally from the pubis to the perineum. These include the mons

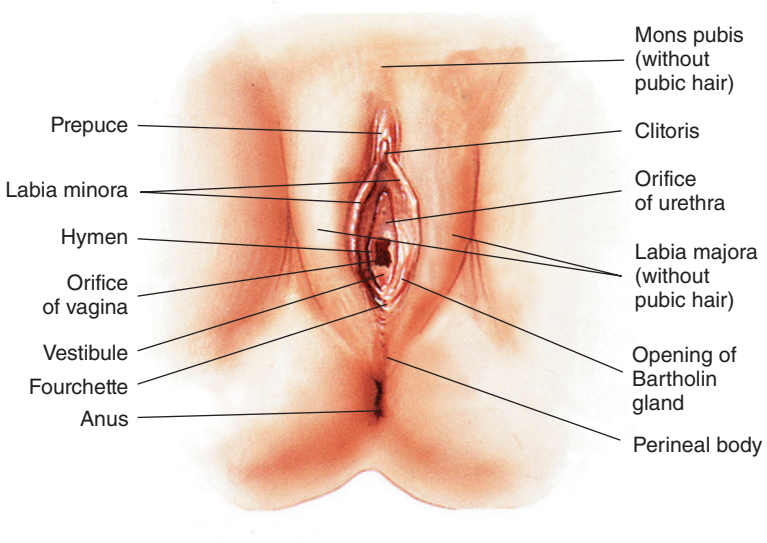

FIG 3-1 External female genitalia.

pubis, labia majora, labia minora, clitoris, vestibular glands, vaginal vestibule, vaginal orifice, and urethral opening. The external genital organs are illustrated in Fig. 3-1.

The mons pubis is a fatty pad that lies over the anterior surface of the symphysis pubis. In the postpubertal female, the mons is covered with coarse, curly hair. The labia majora are two rounded folds of fatty tissue covered with skin that extend downward and backward from the mons pubis. The labia are highly vascular structures that develop hair on the outer surfaces after puberty. They protect the inner vulvar structures. The labia minora are two flat, reddish folds of tissue visible when the labia majora are separated. There are no hair follicles on the labia minora, but many sebaceous follicles and a few sweat glands are present. The interior of the labia minora comprises connective tissue and smooth muscle and is supplied with extremely sensitive nerve endings. Anteriorly, the labia minora fuse to form the **prepuce** (the hoodlike covering of the clitoris) and the frenulum (the fold of tissue under the clitoris). The labia minora join to form a thin, flat tissue called the *fourchette* underneath the vaginal opening at midline. The clitoris is located underneath the prepuce. It is a small structure composed of erectile tissue with numerous sensory nerve endings. During sexual arousal, the clitoris increases in size.

The vaginal vestibule is an almond-shaped area enclosed by the labia minora that contains openings to the urethra, Skene glands, vagina, and Bartholin glands. The urethra is not a reproductive organ but is discussed here because of its location. It usually is found about 2.5 cm below the clitoris. Skene glands are located on each side of the urethra and produce mucus, which aids in lubrication of the vagina. The vaginal opening is in the lower portion of the vestibule and varies in shape and size. The hymen, a connective tissue membrane that surrounds the vaginal opening, can be perforated during strenuous exercise, insertion of tampons, masturbation, and vaginal intercourse. Bartholin glands lie under the constrictor muscles of the vagina and are located posteriorly on the sides of the vaginal opening, although the ductal opening usually is not visible. During sexual arousal, the glands secrete clear mucus to lubricate the vaginal introitus.

The area between the fourchette and the anus is the perineum, a skin-covered muscular area that covers the pelvic structures. The perineum forms the base of the perineal body, a wedge-shaped mass that serves as an anchor for the muscles, fascia, and ligaments of the pelvis. The muscles and ligaments form a sling that supports the pelvic organs.

Internal Structures

The internal structures include the vagina, uterus, fallopian tubes, and ovaries. The description of these structures follows.

The vagina is a fibromuscular, collapsible, tubular structure that lies between the bladder and rectum and extends from the vulva to the uterus. During the reproductive years, the mucosal lining is arranged in transverse folds called *rugae.* These rugae allow the vagina to expand during childbirth. Estrogen deprivation that occurs after childbirth, during lactation, and at menopause causes dryness and thinning of the vaginal walls and smoothing of the rugae. The vagina, particularly the lower segment, has few sensory nerve endings. Vaginal secretions are slightly acidic (pH 4 to 5) so that vaginal susceptibility to infections is limited. The vagina serves as a passageway for menstrual flow, as a female organ of copulation, and as a part of the birth canal for vaginal childbirth. The uterine cervix projects into a blind vault at the upper end of the vagina. Anterior, posterior, and lateral pockets called **fornices** (singular: *fornix*) surround the cervix. The internal pelvic organs can be palpated through the thin walls of these fornices.

The uterus is a muscular organ shaped like an upside-down pear that sits midline in the pelvic cavity between the bladder and rectum and above the vagina. Four pairs of ligaments support the uterus: cardinal, uterosacral, round, and broad. Single anterior and posterior ligaments also support the uterus. The cul-de-sac of Douglas is a deep pouch, or recess, posterior to the cervix formed by the posterior ligament.

The uterus is divided into two major parts: an upper triangular portion called the *corpus* and a lower cylindric portion called the *cervix* (Fig. 3-2). The fundus is the dome-shaped top of the uterus and is the site at which the uterine tubes (fallopian tubes) enter the uterus. The isthmus, or lower uterine segment, is a short, constricted portion that separates the corpus from the cervix.

The uterus serves for reception, implantation, retention, and nutrition of the fertilized ovum and later of the fetus during

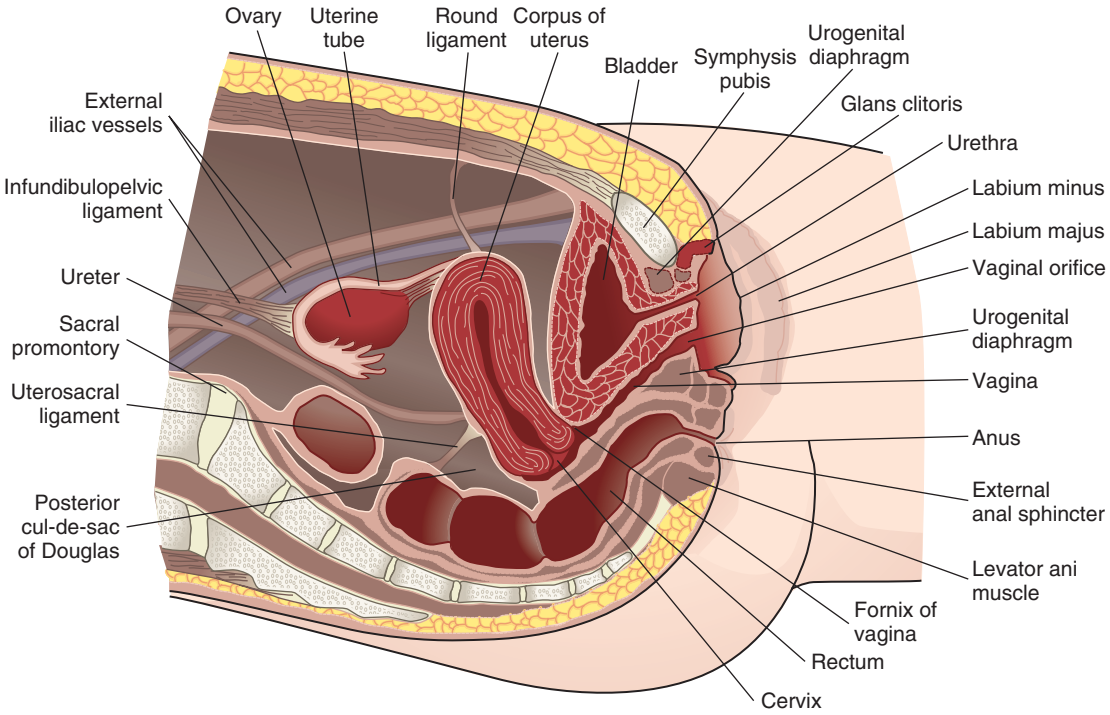

FIG 3-2 Midsagittal view of female pelvic organs with woman lying supine.

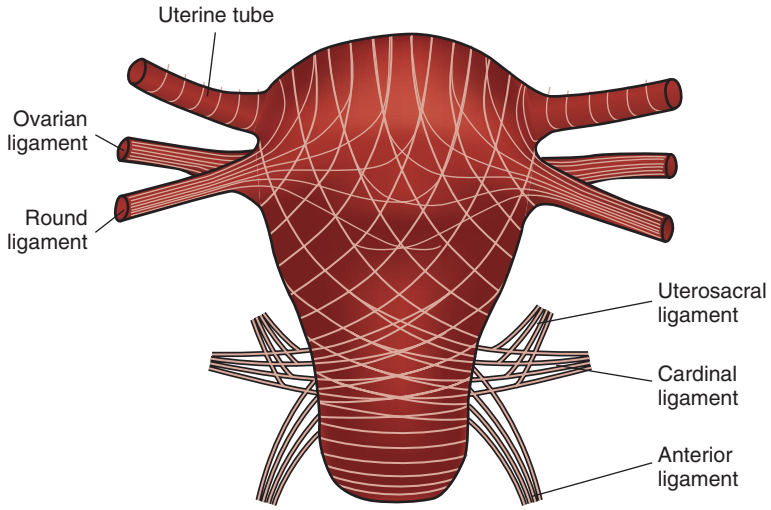

FIG 3-3 Schematic arrangement of directions of muscle fibers. Note that uterine muscle fibers are continuous with supportive ligaments of uterus.

pregnancy and for expulsion of the fetus during childbirth. It is also responsible for cyclic menstruation.

The uterine wall is made up of three layers: the **endometrium,** the myometrium, and part of the peritoneum. The endometrium is a highly vascular lining made up of three layers, the outer two of which are shed during menstruation. The myometrium is made up of layers of smooth muscles that extend in three different directions (longitudinal, transverse, and oblique) (Fig. 3-3). Longitudinal fibers of the outer myometrial layer are found mostly in the fundus, and this arrangement assists in expelling the fetus during the birth process. The middle layer contains fibers from all three directions, which form a figure-eight pattern encircling large blood vessels. These fibers assist in ligating blood vessels after childbirth and control blood loss. Most of the circular fibers of the inner myometrial layer are around the site where the uterine tubes enter the uterus and around the internal cervical os (opening). These fibers help keep the cervix closed during pregnancy and prevent menstrual blood from flowing back into the uterine tubes during menstruation.

The cervix is made up of mostly fibrous connective tissues and elastic tissue, making it possible for the cervix to stretch during vaginal childbirth. The opening between the uterine cavity and the canal that connects the uterine cavity to the vagina (endocervical canal) is the internal os. The narrowed opening between the endocervix and the vagina is the external os, a small circular opening in

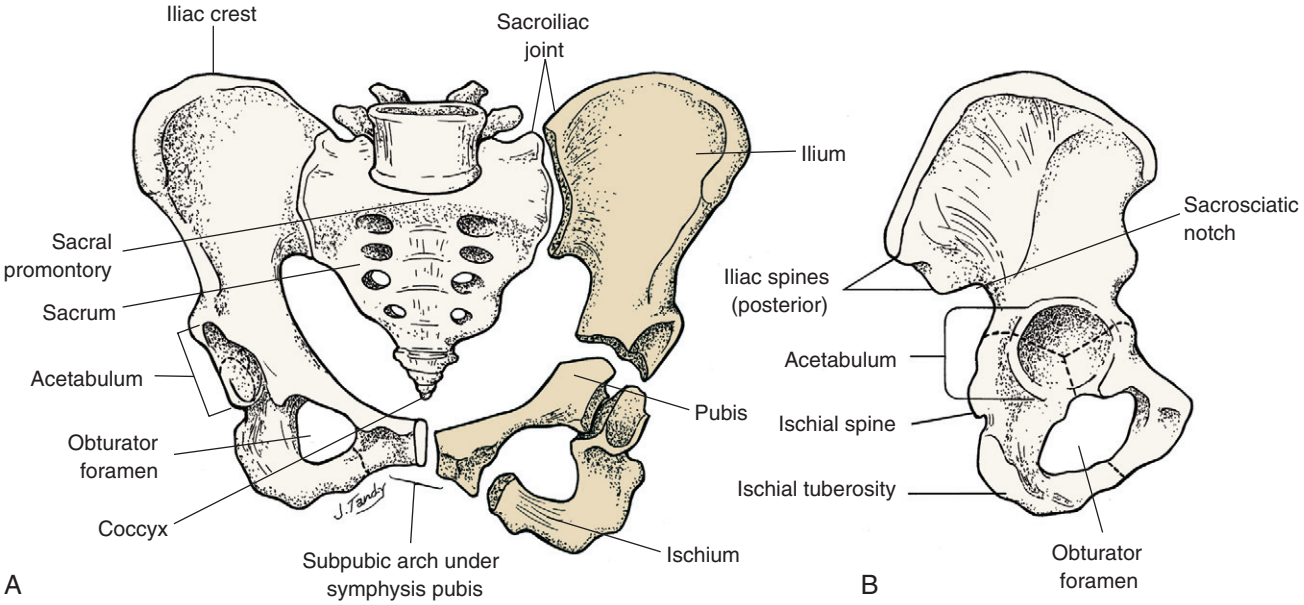

FIG 3-4 Adult female bony pelvis. **A,** Anterior view. **B,** External view of innominate bone (fused).

women who have never been pregnant. The cervix feels firm (like the end of a nose) with a dimple in the center that marks the external os.

The outer cervix is covered with a layer of squamous epithelium. The mucosa of the cervical canal is covered with columnar epithelium and contains numerous glands that secrete mucus in response to ovarian hormones. The squamo-columnar junction, where the two types of cells meet, is usually located just inside the cervical os. This junction is also called the *transformation zone* and is the most common site for neoplastic changes. Cells from this site are scraped for the Papanicolaou (Pap) test (see later discussion).

The uterine tubes (fallopian tubes) attach to the uterine fundus. The tubes are supported by the broad ligaments and range from 8 to 14 cm in length. The tubes are divided into four sections: the interstitial portion is closest to the uterus; the isthmus and the ampulla are the middle portions; and the infundibulum is closest to the ovary. The uterine tubes provide a passage between the ovaries and the uterus for the movement of the ovum. The infundibulum has fimbriated (fringed) ends, which pull the ovum into the tube. The ovum is pushed along the tubes to the uterus by rhythmic contractions of muscles of the tubes and by the current produced by the movement of the cilia that line the tubes. The ovum is usually fertilized by the sperm in the ampulla portion of one of the tubes.

The ovaries are almond-shaped organs located on each side of the uterus below and behind the uterine tubes. During the reproductive years, they are approximately 3 cm long, 2 cm wide, and 1 cm thick; they diminish in size after menopause. Before menarche, each ovary has a smooth surface; after menarche, they are nodular because of repeated ruptures of follicles at ovulation. The two functions of the ovaries are ovulation and hormone production. **Ovulation** is the release of a mature ovum from the ovary at intervals (usually monthly). Estrogen, progesterone, and androgen are the hormones produced by the ovaries.

The Bony Pelvis

The bony pelvis serves three primary purposes: protection of the pelvic structures, accommodation of the growing fetus during pregnancy, and anchorage of the pelvic support structures. The two innominate (hip) bones (consisting of ilium, ischium, and pubis), the sacrum, and the coccyx make up the four bones of the pelvis (Fig. 3-4). Cartilage and ligaments form the symphysis pubis, sacrococcygeal joint, and two sacroiliac joints that separate the pelvic bones.

The pelvis is divided into two parts: the false pelvis and the true pelvis (Fig. 3-5). The false pelvis is the upper portion above the pelvic brim or inlet. The true pelvis is the lower, curved, bony canal, which includes the inlet, the cavity, and the outlet through which the fetus passes during vaginal birth. The upper portion of the outlet is at the level of the ischial spines, and the lower portion is at the

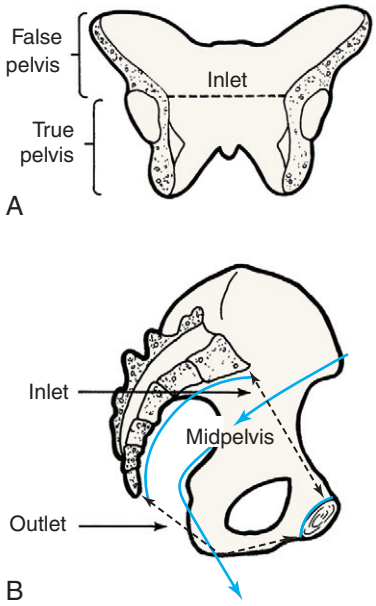

FIG 3-5 Female pelvis. **A,** Cavity of false pelvis is shallow. **B,** Cavity of true pelvis is irregularly curved canal *(arrows)*.

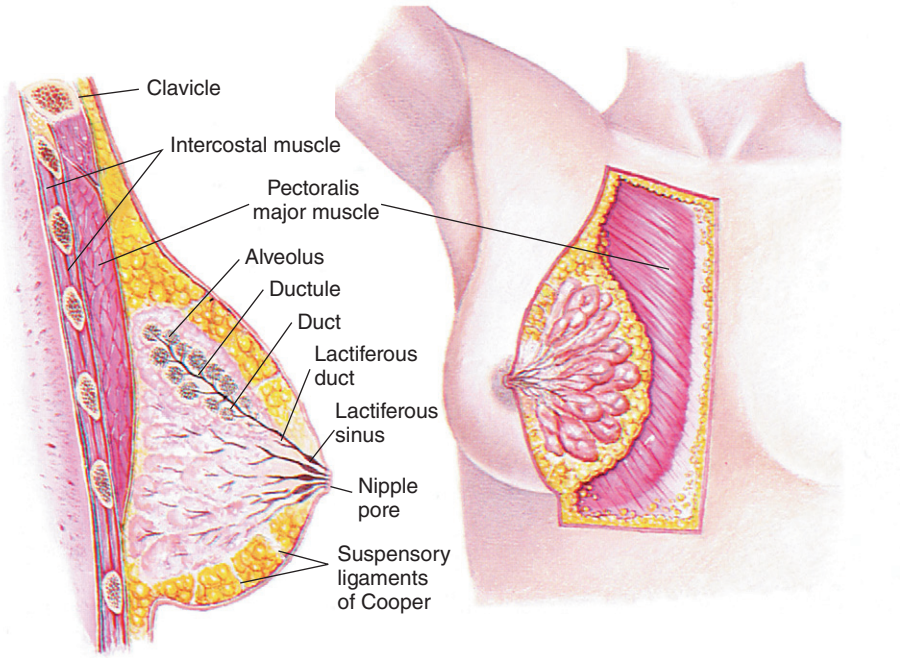

FIG 3-6 Anatomy of the breast showing position and major structures. (Adapted from Seidel H, Ball J, Dains J, et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

level of the ischial tuberosities and the pubic arch. Variations that occur in the size and shape of the pelvis are usually related to age, race, and sex. Pelvic ossification is complete at about 20 years of age.

Breasts

The breasts are paired mammary glands located between the second and sixth ribs (Fig. 3-6). About two thirds of the breast overlies the pectoralis muscle, between the sternum and midaxillary line, with an extension to the *tail of Spence*. The lower one third of the breast overlies the serratus anterior muscle. The breasts are attached to the muscles by connective tissue or fascia.

The breasts of the healthy, mature woman are approximately equal in size and shape but often are not absolutely symmetric. The size and shape vary with the woman's age, heredity, and nutrition. However, the contour should be smooth with no retractions, dimpling, or masses. Estrogen stimulates growth of the breast by inducing fat deposition in the breasts, development of stromal tissue (i.e., increase in its amount and elasticity), and growth of the extensive ductile system. Estrogen also increases the vascularity of breast tissue.

Once ovulation begins in puberty, progesterone levels increase. The increase in progesterone causes maturation of mammary gland tissue, specifically the lobules and acinar structures. During adolescence, fat deposition and growth of fibrous tissue contribute to the increase in the size of the glands. Full development of the breasts is not achieved until after the end of the first pregnancy or in the early period of lactation.

Findings from several studies using ultrasound imaging to investigate the anatomy of the breast reported differences from previous descriptions (Geddes, 2007; Love and Barsky, 2004; Ramsay, Kent, Hartmann, et al., 2005). The following description incorporates these findings. Each mammary gland is made of a number of lobes that are divided into lobules. Lobules are clusters of acini. An acinus is a saclike terminal part of a compound gland emptying through a narrow lumen or duct. The acini are lined with epithelial cells that secrete colostrum and milk. Just below the epithelium is the myoepithelium (*myo*, or muscle), which contracts to expel milk from the acini.

The ducts from the clusters of acini that form the lobules merge to form larger ducts draining the lobes. Ducts from the lobes converge in a single nipple (mammary papilla) surrounded by an areola. The anatomy of the ducts is similar for each breast but varies among women. Protective fatty tissue surrounds the glandular structures and ducts. *Cooper's ligaments,* or fibrous suspensory, separate and support the glandular structures and ducts. Cooper's ligaments provide support to the mammary glands while permitting their mobility on the chest wall (see Fig. 3-6). The round nipple is usually slightly elevated above the breast. On each breast the nipple projects slightly upward and laterally. It contains 4 to 20 openings from the milk ducts. The nipple is surrounded by fibromuscular tissue and covered by wrinkled skin (the areola). Except during pregnancy and lactation, there is usually no discharge from the nipple.

The nipple and surrounding areola are usually more deeply pigmented than the skin of the breast. The rough appearance of the areola is caused by sebaceous glands, Montgomery tubercles, directly beneath the skin. These glands secrete a fatty substance thought to lubricate the nipple. Smooth muscle fibers in the areola contract to stiffen the nipple to make it easier for the breastfeeding infant to grasp.

The vascular supply to the mammary gland is abundant. In the nonpregnant state there is no obvious vascular pattern in the skin. The normal skin is smooth without tightness or shininess. The skin covering the breasts contains an extensive superficial lymphatic network that serves the entire chest wall and is continuous with the superficial lymphatics of the neck and abdomen. The lymphatics form a rich network in the deeper portions of the breasts. The primary deep lymphatic pathway drains laterally toward the axillae.

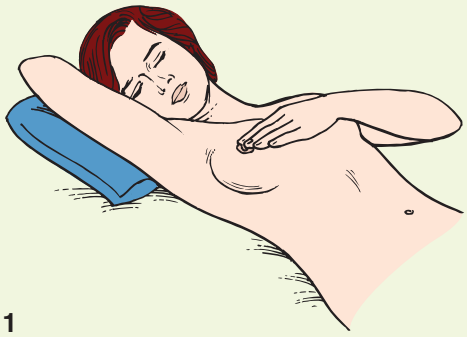
GUIDELINES

Breast Self-Examination

If you choose to perform a breast self-examination, the best time is when breasts are not tender or swollen.

How to examine your breasts:

1. Lie down and put a pillow under your right shoulder. Place your right arm behind your head (Fig. 1).



1

2. Use the finger pads of your three middle fingers on your left hand to feel for lumps or thickening. Your finger pads are the top third of each finger. Use circular motions of the finger pads to feel the breast tissue.
3. Press firmly enough to know how your breast feels. Use light pressure to feel the tissue just under the skin, medium pressure for a little deeper, and firm pressure to feel the breast tissue close to the chest and ribs. A firm ridge in the lower curve of the breast is normal.
4. Move around the breast in a set way, such as using an up-and-down or vertical line pattern (Fig. 2). Go up to the collar bone and down to the ribs and from your underarm on the side to the middle of your chest. Use the same technique every time. It will help you to make sure that you have gone over the entire breast area and to remember how your breast feels.

2

5. Now examine your left breast using the finger pads of your right hand.
6. You may want to check your breasts while standing in front of a mirror. See if there are any changes in the way your breasts look: dimpling of the skin, changes in the nipple, or redness or swelling.
7. Checking the area between the breast and the underarm and the underarm itself is important. Examine the area above the breast to the collarbone and to the shoulder while you are standing or sitting up with your arms slightly raised.
8. If you find any changes, see your health care provider right away.

Adapted from American Cancer Society: *Breast awareness and self-exam,* 2013, www.cancer.org.

Besides their function of lactation, breasts function as organs for sexual arousal in the mature adult female.

The breasts change in size and nodularity in response to cyclic ovarian changes throughout reproductive life. Increasing levels of both estrogen and progesterone in the 3 to 4 days before menstruation increase the vascularity of the breasts, induce growth of the ducts and acini, and promote water retention. The epithelial cells lining the ducts proliferate in number, the ducts dilate, and the lobules distend. The acini become enlarged and secretory, and lipid (fat) is deposited within their epithelial cell lining. As a result, breast swelling, tenderness, and discomfort are common symptoms just before the onset of menstruation. After menstruation, cellular proliferation begins to regress, acini begin to decrease in size, and retained water is lost. After breasts have undergone changes numerous times in response to the ovarian cycle, the proliferation and involution **(regression)** are not uniform throughout the breast. In time, after repeated hormonal stimulation, small, persistent areas of nodulations may develop. This normal physiologic change must be remembered when breast tissue is examined. Nodules may develop just before and during menstruation, when the breast is most active. The physiologic alternations in breast size and activity reach their minimum level about 5 to 7 days after menstruation stops. Therefore breast self-examination (BSE) (systematic palpation of breasts to detect signs of breast cancer or other changes) is best carried out during this phase of the menstrual cycle (see Guidelines box). Although monthly BSE used to be recommended to all women, the current guidelines recommend BSE as an option (American Cancer Society, 2012b), mostly because they believe that many unnecessary biopsies and other procedures result. However, breastcancer.org (2012) continues to recommend that all women perform BSE monthly (see the Critical Thinking Case Study).

MENSTRUATION

Menarche and Puberty

Although young girls secrete small, rather constant amounts of estrogen, a marked increase occurs between 8 and 11 years of age. The term **menarche** denotes first menstruation. **Puberty** is a broader term that denotes the entire transitional stage between childhood and sexual maturity. Increasing amounts and variations in gonadotropin and estrogen secretion develop into a cyclic pattern at least a year before menarche. In North America this occurs in most girls at about 13 years of age.

Initially, menstrual periods are irregular, unpredictable, painless, and anovulatory (no ovum is released from the ovary). After 1 or more years, a hypothalamic-pituitary rhythm develops and the ovary produces adequate cyclic estrogen to make a mature ovum. Ovulatory (ovum released from the ovary) periods tend to be regular, with estrogen dominating the first half of the cycle and progesterone dominating the second half of the cycle.

Although pregnancy can occur in exceptional cases of true precocious puberty, most pregnancies in young girls occur after the normally timed menarche. All young adolescents of both sexes

CRITICAL THINKING CASE STUDY

Breast Self-Examination

Jessie is a 21-year-old college student who has come to the Student Health Clinic for contraception advice. During her consultation with the nurse, Jessie asks about doing breast self-examination. She said her roommate said she really needs to do them every month. What advice or counseling would you give Jessie?

1. Evidence—Is there sufficient evidence to draw conclusions about what intervention is needed?
2. Assumptions—Describe underlying assumptions about the following issues:
   a. Risk factor assessment for breast cancer
   b. Screening for breast cancer
   c. Breast self-examination practices
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

would benefit from knowing that pregnancy can occur at any time after the onset of menses.

Menstrual Cycle

Menstruation is the periodic uterine bleeding that begins approximately 14 days after ovulation. It is controlled by a feedback system of three cycles: endometrial, hypothalamic-pituitary, and ovarian. The average length of a menstrual cycle is 28 days, but variations are normal. The first day of bleeding is designated as day 1 of the menstrual cycle, or menses (Fig. 3-7). The average duration of menstrual flow is 5 days (with a range of 3 to 6 days) and the average blood loss is 50 mL (with a range of 20 to 80 mL), but these vary greatly.

For about 50% of women, menstrual blood does not appear to clot. The menstrual blood clots within the uterus, but the clot usually liquefies before being discharged from the uterus. Uterine discharge includes mucus and epithelial cells in addition to blood.

The menstrual cycle is a complex interplay of events that occur simultaneously in the endometrium, the hypothalamus, the pituitary glands, and the ovaries. The menstrual cycle prepares the uterus for pregnancy. When pregnancy does not occur, menstruation follows. A woman's age, physical and emotional status, and environment influence the regularity of her menstrual cycles.

Endometrial Cycle

The four phases of the endometrial cycle are (1) the menstrual phase, (2) the proliferative phase, (3) the secretory phase, and (4) the ischemic phase (see Fig. 3-7). During the menstrual phase, shedding of the functional two thirds of the endometrium (the compact and spongy layers) is initiated by periodic vasoconstriction in the upper layers of the endometrium. The basal layer is always retained, and regeneration begins near the end of the cycle from cells derived from the remaining glandular remnants or stromal cells in this layer.

The proliferative phase is a period of rapid growth lasting from about the fifth day to the time of ovulation. The endometrial surface is completely restored in approximately 4 days, or slightly before bleeding ceases. From this point on, an eightfold to tenfold thickening occurs, with a leveling off of growth at ovulation. The proliferative phase depends on estrogen stimulation derived from ovarian follicles.

The secretory phase extends from the day of ovulation to about 3 days before the next menstrual period. After ovulation, large amounts of progesterone are produced. An edematous, vascular, functional endometrium is now apparent. At the end of the secretory phase, the fully matured secretory endometrium reaches the thickness of heavy, soft velvet. It becomes luxuriant with blood and glandular secretions—a suitable protective and nutritive bed for a fertilized ovum.

Implantation of the fertilized ovum generally occurs about 7 to 10 days after ovulation. If fertilization and implantation do not occur, the **corpus luteum,** which secretes estrogen and progesterone, regresses. With the rapid decrease in progesterone and estrogen levels, the spiral arteries go into spasm. During the ischemic phase, the blood supply to the functional endometrium is blocked and necrosis develops. The functional layer separates from the basal layer, and menstrual bleeding begins, marking day 1 of the next cycle (see Fig. 3-7).

Hypothalamic-Pituitary Cycle

Toward the end of the normal menstrual cycle, blood levels of estrogen and progesterone decrease. Low blood levels of these ovarian hormones stimulate the hypothalamus to secrete gonadotropin-releasing hormone (GnRH). In turn, GnRH stimulates anterior pituitary secretion of follicle-stimulating hormone (FSH). FSH stimulates development of ovarian **graafian follicles** and their production of estrogen. Estrogen levels begin to decrease, and hypothalamic GnRH triggers the anterior pituitary to release luteinizing hormone (LH). A marked surge of LH and a smaller peak of estrogen (day 12) (see Fig. 3-7) precede the expulsion of the ovum from the graafian follicle by about 24 to 36 hours. LH peaks at about day 13 or 14 of a 28-day cycle. If fertilization and implantation of the ovum have not occurred by this time, regression of the corpus luteum follows. Levels of progesterone and estrogen decline, menstruation occurs, and the hypothalamus is once again stimulated to secrete GnRH. This process is called the *hypothalamic-pituitary cycle.*

Ovarian Cycle

The primitive graafian follicles contain immature oocytes (primordial ova). Before ovulation, from 1 to 30 follicles begin to mature in each ovary under the influence of FSH and estrogen. The preovulatory surge of LH affects a selected follicle. The oocyte matures, *ovulation* occurs, and the empty follicle begins its transformation into the corpus luteum. This follicular phase (preovulatory phase) (see Fig. 3-7) of the ovarian cycle varies in length from woman to woman. Almost all variations in ovarian cycle length are the result of variations in the length of the follicular phase. On rare occasions (i.e., 1 in 100 menstrual cycles), more than one follicle is selected and more than one oocyte matures and undergoes ovulation.

After ovulation, estrogen levels drop. For 90% of women, only a small amount of withdrawal bleeding occurs, and it goes unnoticed. In 10% of women, there is sufficient bleeding for it to be visible, resulting in what is termed midcycle bleeding.

The luteal phase begins immediately after ovulation and ends with the start of menstruation. This postovulatory phase of the ovarian cycle usually requires 14 days (range 13 to 15 days). The corpus luteum reaches its peak of functional activity 8 days after ovulation, secreting the steroids *estrogen* and *progesterone.* Coincident with this time of peak luteal functioning, the fertilized ovum is implanted in the endometrium. If no implantation occurs, the

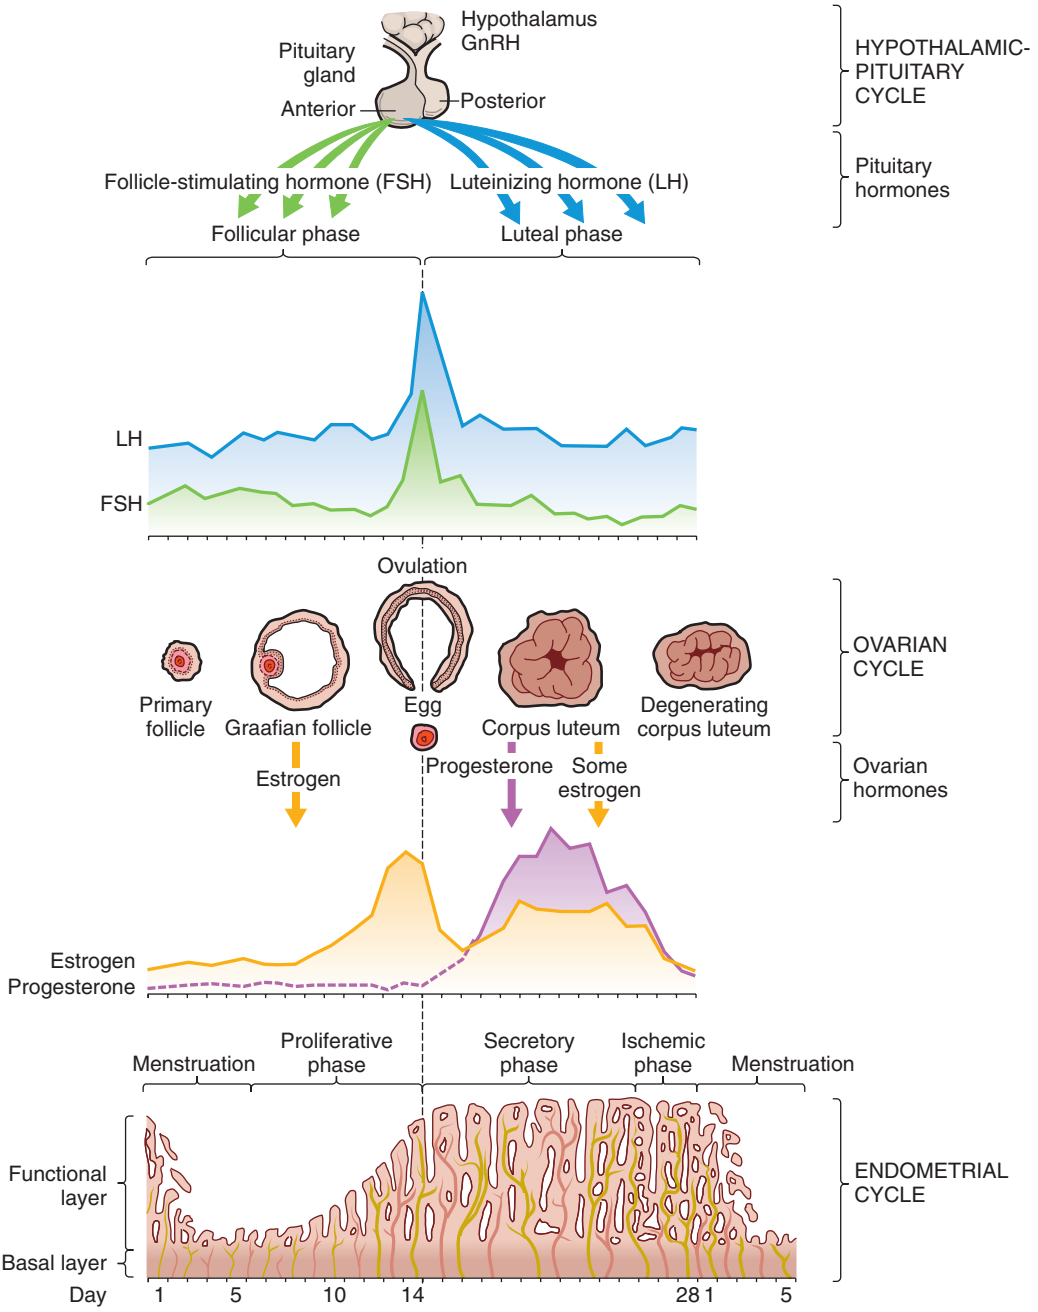


FIG 3-7 Menstrual cycle: hypothalamic-pituitary, ovarian, and endometrial. *GnRH,* Gonadotropin-releasing hormone.

corpus luteum regresses and steroid levels drop. Two weeks after ovulation, if fertilization and implantation do not occur, the functional layer of the uterine endometrium is shed through menstruation.

Other Cyclic Changes

When the hypothalamic-pituitary-ovarian axis functions properly, other tissues undergo predictable responses. Before ovulation, the woman's **basal body temperature** is often less than 37° C (98.6° F); after ovulation, with increasing progesterone levels, her basal body temperature rises. Changes in the cervix and cervical mucus follow a generally predictable pattern. Preovulatory and postovulatory mucus is viscous (thick) so that sperm penetration is discouraged. At the time of ovulation, cervical mucus is thin and clear. It looks, feels, and stretches like egg white. This stretchable quality is termed **spinnbarkeit.** Some women have localized lower abdominal pain called **mittelschmerz** that coincides with ovulation. Some spotting may occur.

Prostaglandins

Prostaglandins (PGs) are oxygenated fatty acids classified as *hormones.* The different kinds of PGs are distinguished by letters (PGE and PGF), numbers (PGE_2), and letters of the Greek alphabet ($PGF_{2\alpha}$).

PGs are produced in most organs of the body, including the uterus. Menstrual blood is a potent PG source. PGs are metabolized quickly by most tissues. They are biologically active in minute amounts in the cardiovascular, gastrointestinal, respiratory, urogenital, and nervous systems. They also exert a marked effect on metabolism, particularly on glycolysis. PGs play an important role in many physiologic, pathologic, and pharmacologic reactions. $PGF_{2\alpha}$, PGE_4, and PGE_2 are most commonly used in reproductive medicine.

PGs affect smooth muscle contractility and modulation of hormonal activity. Indirect evidence indicates that PGs have an effect on ovulation, fertility, changes in the cervix and cervical mucus that affect receptivity to sperm, tubal and uterine motility, sloughing of endometrium (menstruation), onset of miscarriage and induced abortion, and onset of labor (term and preterm).

After exerting biologic actions, newly synthesized PGs are rapidly metabolized by tissues in such organs as the lungs, kidneys, and liver.

PGs may play a key role in ovulation. If PG levels do not rise along with the surge of LH, the ovum remains trapped within the graafian follicle. After ovulation, PGs may influence production of estrogen and progesterone by the corpus luteum.

The introduction of PGs into the vagina or the uterine cavity (from ejaculated semen) increases the motility of uterine musculature, which may assist the transport of sperm through the uterus and into the oviduct.

PGs produced by the woman cause regression of the corpus luteum and regression and sloughing of the endometrium, resulting in menstruation. PGs increase myometrial response to oxytocic stimulation, enhance uterine contractions, and cause cervical dilation. They may be a factor in the initiation of labor, the maintenance of labor, or both. They may also be involved in dysmenorrhea (see Chapter 4) and preeclampsia/eclampsia (see Chapter 12).

Climacteric and Menopause

The **climacteric** is a transitional phase during which ovarian function and hormone production decline. This phase spans the years from the onset of premenopausal ovarian decline to the postmenopausal time when symptoms stop. **Menopause** (from Latin *mensis*, month, and Greek *pauses*, to cease) refers only to the last menstrual period. However, unlike menarche, menopause can be dated with certainty only 1 year after menstruation ceases. The average age at natural menopause is 51.4 years, with an age range of 35 to 60 years. *Perimenopause* is a period preceding menopause that lasts about 4 years. During this time, ovarian function declines. Ova slowly diminish, and menstrual cycles may be anovulatory, resulting in irregular bleeding. The ovary stops producing estrogen, and eventually menses no longer occur.

SEXUAL RESPONSE

The hypothalamus and anterior pituitary glands in females regulate the production of FSH and LH. The target tissue for these hormones is the ovary, which produces ova and secretes estrogen and progesterone. A feedback mechanism between hormone secretion from the ovaries, the hypothalamus, and the anterior pituitary aids in the control of the production of sex cells and steroid sex hormone secretion.

Although the first outward appearance of maturing sexual development occurs at an earlier age in females, both females and males achieve physical maturity at approximately 17 years of age; however, individual development varies greatly. Anatomic and reproductive differences notwithstanding, women and men are more alike than different in their physiologic response to sexual excitement and orgasm. For example, the glans clitoris and the glans penis are embryonic homologs. Little difference exists between female and male sexual response; the physical response is essentially the same whether stimulated by coitus, fantasy, or masturbation. Physiologic sexual response can be analyzed in terms of two processes: vasocongestion and myotonia.

Sexual stimulation results in increase in circulation to circumvaginal blood vessels (lubrication in the female), causing engorgement and distention of the genitals. Venous congestion is localized primarily in the genitalia, but it also occurs to a lesser degree in the breasts and other parts of the body. Arousal is characterized by myotonia (increased muscular tension), resulting in voluntary and involuntary rhythmic contractions. Examples of sexually stimulated myotonia are pelvic thrusting, facial grimacing, and spasms of the hands and feet (carpopedal spasms).

The sexual response cycle is classically divided into four phases: excitement, plateau, orgasmic, and resolution, according to the seminal work of Masters and Johnson (1966). The four phases occur progressively, with no sharp dividing line between any two phases. The time, intensity, and duration for cyclic completion also vary for individuals and situations. Other researchers have suggested different models to explain sexual response. Leeman and Rogers (2012) emphasize the need to address sexuality and possible sexual difficulties with women in the postpartum period. Specific issues related to this period (and prior procedures such as episiotomy) must be considered in counseling to promote healthy sexuality during the postpartum period. Despite these alternate models of sexual response, it is still common to describe the classic four stages in which specific body changes take place in sequence, and this description is useful in educating and talking with women who may have concerns about possible sexual dysfunction. Table 3-1 compares male and female body changes during each of the four phases of the sexual response cycle.

BARRIERS TO ENTERING THE HEALTH CARE SYSTEM

Financial Issues

Access to care varies greatly, depending on type and size of the system, source of payment for services, private versus public programs, availability of and accessibility to providers, individual preferences, and insurance coverage or ability to pay. The existing system continues to be oriented to treatment of acute or episodic conditions rather than to the promotion of health and comprehensive care, despite the fact that people are discharged earlier from hospitals, requiring more care in homes and community settings.

In the United States, disparity among races and socioeconomic classes affects many facets of life including health. Limited finances is associated with lack of access to care, delay in seeking care, few prevention activities, and little accurate information about health and the health care system. Women use health care services more often than men but are more likely than men to have difficulty in financing the services. Many poor women have traditionally been underinsured or uninsured, but rules about health insurance and who and what are covered are undergoing a transition with the Affordable Care Act (healthcare.gov, 2012). People will not be denied insurance because of pre-existing

TABLE 3-1 FOUR PHASES OF SEXUAL RESPONSE

REACTIONS COMMON TO BOTH SEXES	FEMALE REACTIONS	MALE REACTIONS
Excitement Phase		
Heart rate and blood pressure increase. Nipples become erect. Myotonia begins.	Clitoris increases in diameter and swells. External genitalia become congested and darken. Vaginal lubrication occurs; upper two thirds of vagina lengthens and extends. Cervix and uterus pull upward. Breast size increases.	Erection of the penis begins; penis increases in length and diameter. Scrotal skin becomes congested and thickens. Testes begin to increase in size and elevate toward the body.
Plateau Phase		
Heart rate and blood pressure continue to increase. Respirations increase. Myotonia becomes pronounced; grimacing occurs.	Clitoral head retracts under the clitoral hood. Lower one third of vagina becomes engorged. Skin color changes occur—red flush may be observed across breasts, abdomen, or other surfaces.	Head of penis may enlarge slightly. Scrotum continues to grow tense and thicken. Testes continue to elevate and enlarge. Preorgasmic emission of two or three drops of fluid appears on the head of the penis.
Orgasmic Phase		
Heart rate, blood pressure, and respirations increase to maximum levels. Involuntary muscle spasms occur. External rectal sphincter contracts.	Strong rhythmic contractions are felt in the clitoris, vagina, and uterus. Sensations of warmth spread through the pelvic area.	Testes elevate to maximum level. Point of "inevitability" occurs just before ejaculation and an awareness of fluid in the urethra. Rhythmic contractions occur in the penis. Ejaculation of semen occurs.
Resolution Phase		
Heart rate, blood pressure, and respirations return to normal. Nipple erection subsides. Myotonia subsides.	Engorgement in external genitalia and vagina resolves. Uterus descends to normal position. Cervix dips into seminal pool. Breast size decreases. Skin flush disappears.	Fifty percent of erection is lost immediately with ejaculation; penis gradually returns to normal size. Testes and scrotum return to normal size. Refractory period (time needed for erection to occur again) varies according to age and general physical condition.

conditions, and various preventive health services will be covered under health insurance. However this legislation is far from decided and its impact on the American people will not be known for years.

With a greater focus on preventive health care services and with 32 million formerly uninsured patients having access to health care, nurses, advanced practice nurses, including nurse practitioners, midwives, and clinical nurse specialists, are critical to the provision of high quality, safe, effective, and accessible health care (see the Community Focus box).

Cultural Issues

We live in a multicultural society with constantly changing demographics, and for nursing care of women to be optimal, cultural differences must be addressed with great sensitivity and competency. Nurses are in excellent positions to be responsible for providing culturally sensitive and competent health care (Escallier, Fullterton, and Messina, 2011). A variety of reasons are given to explain some of the differences in accessing care when financial barriers are adjusted. Some women experience racial discrimination or disrespectful, disillusioning, or discouraging encounters with community service providers such as social services and health care providers. Many women do not seek care from the health care system because of lack of trust (Yang, Matthews, and Hillemeier, 2011). A lack of cross-cultural communication also presents problems. Desired health outcomes are best achieved when the health care provider has knowledge of and understanding about the culture, language, values, priorities, and health beliefs of those in various ethnic groups. Conversely, members of these various groups should understand the health goals to be achieved and the methods proposed to do so. Language differences

COMMUNITY FOCUS

Role of Nurses in Women's Health Promotion and Illness Prevention

Registered nurses work with women to promote wellness by:

- Teaching
- Encouraging
- Motivating
- Integrating various modalities of care ("integrative nurse coaching")
- Collaborating with other health care practitioners
- Providing care in the community, working with individuals, families, communities
- Working to influence health policy

Advanced practice nurses work with women to promote wellness by:

- Providing comprehensive primary care
- Coordinating care in communities (from hospitals to home to communities)
- Working with social service resources for patients in the community

can produce profound barriers between patients and providers. Even with an interpreter, misinformation can occur on both sides of the communication.

Providers must consider culturally based differences that could affect the treatment of diverse groups of women, and the women themselves must share practices and beliefs that could influence their responses to treatment or willingness to adhere to treatment. For example, women in some cultures value privacy to such an extent that they are reluctant to disrobe and, as a result, avoid physical examination unless absolutely necessary. Other women rely on their husbands to make major decisions, including those affecting the woman's health. Religious beliefs may dictate a plan of care, as with birth control measures or blood transfusions. Some cultural groups prefer folk medicine, homeopathy, or prayer to traditional Western medicine; and others attempt combinations of some or all practices. Nurses can integrate into their own practice various holistic approaches to care, in accordance with Dossey's (2010) *Theory of Integral Nursing*. It is critically important to be sensitive to cultural differences and at the same time not stereotype and assume that a woman has certain beliefs because of her ethnic background. Although the amount of health information on the Internet is increasing, information in languages other than English is limited and not all information on the Internet is accurate, making health literacy an important issue in culturally competent care.

Gender Issues

Gender influences provider-patient communication and may influence access to health care in general. Researchers have reported significant male-female differences in receipt of major diagnostic and therapeutic interventions, especially with cardiac and kidney problems. Women tend to use primary care services more often than do men and, some believe, more effectively. The gender of the provider plays a role. The concept of "gender concordance," in which the patient's gender matches the health care provider's gender, was found to be important for women seeking Pap tests (McAlearney, Oliveri, Post, et al., 2011). McAlearney et al. found that women were more comfortable having a Pap test performed by a female physician and having a female nurse present.

Sexual orientation may produce another barrier. Nurses need to understand the specific health care needs and issues related to sexual orientation (Brennan, Barnsteiner, de Leon Siantz, et al., 2012). Some lesbians may not disclose their sexual orientation to health care providers because they feel they may be at risk for hostility, inadequate health care, or breach of confidentiality. In many health care settings, heterosexuality is assumed, and the setting may be one in which the woman does not feel welcome (magazines, brochures, and environment reflect heterosexual couples, or the health care provider shows discomfort interacting with the woman). Lesbians themselves may hold beliefs that are incorrect (e.g., that they have immunity to human immunodeficiency virus [HIV], sexually transmitted infections [STIs], and certain cancers [e.g., cervical]). The perceived lack of risk can result in lesbians avoiding health care, as well as in health care providers giving incorrect advice or not providing appropriate screening for these women. Not all gynecologic cancers are related to sexual activity; lesbians who have never had children may be more at risk for breast, ovarian, and endometrial cancer. Their risk for heart disease, cancer of the lung, and colon cancer is not different from that of the heterosexual woman. To offset stereotypes, it is necessary for providers to develop an approach that does not assume that all patients are heterosexual. More content related to this issue needs to be included in nursing curricula.

CARING FOR THE WELL WOMAN ACROSS THE LIFE SPAN: THE NEED FOR HEALTH PROMOTION AND DISEASE PREVENTION

Maintaining optimal health is a goal for all women. Essential components of health maintenance are the identification of unrecognized problems and potential risks and the education and health promotion needed to reduce them. Current trends in the health care of women have expanded beyond a reproductive focus. A holistic approach to women's health care goes beyond simple reproductive needs and includes a woman's health needs throughout her lifetime, with attention to physical, mental/emotional, social, and spiritual health. Women's health is considered to be part of the primary health care delivery system with assessment and screening focusing on a multisystem evaluation that emphasizes the maintenance and enhancement of wellness. Prevention of cardiovascular disease, promotion of mental health, and prevention of cancers beyond just reproductive-related cancers are all components of well-woman care. It is important to consider all aspects of women's health, particularly in light of the fact that the leading causes of death in women in the United States include more than just reproductive health conditions (Box 3-1).

Even when focusing on reproductive health, it is critical to take a holistic approach to the health of women. This is especially important for women in their childbearing years because conditions that increase a woman's health risks are related not only to her well-being but also to the well-being of both mother and baby in the event of a pregnancy. Prenatal care is an example of prevention that is practiced after conception. However, prevention and health maintenance are needed before conception because many of the mother's risks can be identified and eliminated, or at least modified.

As a female progresses through developmental ages and stages, she is faced with conditions that are age related. An overview of conditions and circumstances that increase health risks in women across the life span is presented in the next section.

Adolescents

All teens undergo progressive development of sex characteristics. They experience the developmental tasks of adolescence such as establishing identity and sexual orientation, emancipating from family, and establishing career goals. Some of these processes can produce great stress for the adolescent, and the health care provider

BOX 3-1 TOP 10 LEADING CAUSES OF DEATH IN WOMEN IN THE UNITED STATES

1. Heart disease
2. Malignant neoplasm (cancer)
3. Cardiovascular disease (stroke)
4. Chronic lower respiratory disease
5. Alzheimer's disease
6. Unintentional injury
7. Diabetes mellitus
8. Influenza and pneumonia
9. Nephritis
10. Septicemia

Data from U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau: *Women's health USA*, 2011, Rockville, MD; U.S. Department of Health and Human Services, 2009, mchb.hrsa.gov/whusa11.

should treat her very carefully. Female teenagers who enter the health care system usually do so for screening or because of a problem such as episodic illness or accidents. Previous guidelines recommended that young women should be screened with Pap tests at age 18 or when they become sexually active. Guidelines suggest that Pap tests begin at age 21, but controversy exists about the evidence to support these new guidelines, with some health care providers providing evidence for earlier testing (Zhao, Kalpos-Novak, and Austin, 2011). Gynecologic problems are often associated with menses (either bleeding irregularities or dysmenorrhea), vaginitis or leukorrhea, STIs, contraception, or pregnancy. The adolescent is also at risk for use of street drugs, for eating disorders, and for stress, depression, and anxiety.

Many women first enter the health care delivery system for a Pap test or for contraception. Visits to the nurse may be their only contact with the system unless they become ill. Some women postpone examination until a specific need arises such as pregnancy, infertility, pain, abnormal bleeding, or vaginal discharge. Recently the availability of the human papillomavirus (HPV) vaccine has created another reason for young women to enter the health care system (Saraiya, Rosser, and Cooper, 2012).

Teenage Pregnancy

Most young women begin having sex in the mid- to late teens. At age 15, 13% of teens have had sex, but by age 19, 70% of teens have had sexual intercourse (Guttmacher Institute, 2012). A sexually active teen who does not use contraception has a 90% chance of pregnancy within 1 year. The United States has the highest teen pregnancy rate in the industrialized world. By age 20, one third of all American girls get pregnant; most of these pregnancies are unintended (CDC, 2012).

Effective educational programs about sex and family life are imperative to control the rate of teen pregnancy and STIs (Box 3-2). The nurse can provide information regarding the need for child spacing, methods of family planning that are consistent with religious and personal preferences, non-contraceptive benefits of certain methods, the appropriate use of methods selected, and the protection of future fertility when so desired.

Pregnancy in the teenager who is 16 years of age or younger often introduces additional stress into an already stressful developmental period. The emotional level of such teens is commonly characterized by impulsiveness and self-centered behavior, and they often place primary importance on the beliefs and actions of their peers. In attempts to establish a personal and independent identity, many teens do not realize the consequence of their behavior; their thinking processes do not include planning for the future.

Teenagers usually lack the financial resources to support a pregnancy and may not have the maturity to avoid teratogens or have prenatal care and instruction or follow-up care. Children of teen mothers may be at risk for abuse or neglect because of the teen's inadequate knowledge of growth, development, and parenting. Implementation of specialized adolescent programs in schools, communities, and health care systems is demonstrating continued success in reducing the birthrate in teens.

BOX 3-2 CONTRACEPTIVE HEALTH PROMOTION

- Child spacing and quality maternity care improve perinatal outcomes and health in general of mother and children.
- Achieving desired family size enables a better sharing of all resources, with attendant increases in education, health care, and other positive societal parameters.
- Contraceptives themselves may positively affect future health. For example, use of condoms may prevent acquisition of HIV infection; combined OCs may provide some protection against later development of cancer of ovary and endometrium; barrier methods decrease transmission of STIs, which can develop into pelvic inflammatory disease with resultant infertility or sterility and thus affect future childbearing capacity.

HIV, Human immunodeficiency virus; *OCs,* oral contraceptives; *STIs,* sexually transmitted infections.

Young and Middle Adulthood

Because women ages 20 to 40 years have a need for contraception, pelvic and breast screening, and pregnancy care, they may prefer to use their gynecologic or obstetric provider as their primary care provider. During these years the woman may be "juggling" family, home, and career responsibilities, with resulting increases in stress-related conditions. Health maintenance includes not only pelvic and breast screening but also promotion of a healthy lifestyle (i.e., good nutrition, regular exercise, no smoking, moderate or no alcohol consumption, sufficient rest, stress reduction, and referral for medical conditions and other specific problems). Common conditions requiring well-woman care include vaginitis, urinary tract infections, menstrual variations, obesity, sexual and relationship issues, and pregnancy.

Parenthood After Age 35

The woman older than 35 years does not have a different physical response to a pregnancy per se but, rather, has had health status changes as a result of time and the aging process. These changes may be responsible for age-related pregnancy conditions. For example, a woman with type 2 diabetes may not have had expression of her diabetes at age 22 years but may have full-blown disease at age 38 years. Other chronic or debilitating diseases or conditions increase in severity with time, and these in turn may predispose to increased risks during pregnancy. Of significance to women in this age-group is the risk for certain genetic anomalies (e.g., Down syndrome). The opportunity for genetic counseling should be available to all (see Chapter 6).

Late Reproductive Age

Women of later reproductive age are often experiencing change and reordering personal priorities. In general, the goals of education, career, marriage, and family have been achieved and now the woman has increased time and opportunity for new interests and activities. Divorce rates are high at this age, and children leaving home may produce an "empty nest syndrome," resulting in increased levels of depression. Chronic diseases also become more apparent. Most problems for the well woman are associated with perimenopause (e.g., bleeding irregularities and vasomotor symptoms). Health maintenance screening continues to be of importance because some conditions such as breast disease or ovarian cancer occur more often during this stage.

APPROACHES TO CARE AT SPECIFIC STAGES OF A WOMAN'S LIFE

There are certain specific approaches to care of women at different stages of their lives. Several of these approaches are described in the next section.

Preconception Counseling and Care

Preconception health promotion provides women and their partners with information that is needed to make decisions about their reproductive future. **Preconception care** guides couples on how to avoid unintended pregnancies, identify and manage risk factors in their lives and their environment, and identify healthy behaviors that promote the well-being of the woman and her potential fetus. It has been estimated that 31% of pregnant women experience some complications of pregnancy, including mental health issues (mostly depression) and factors that lead to the need for cesarean birth (HealthyPeople.gov, 2012b). In addition, 12% of births result in preterm infants and 8.2% result in low-birth-weight infants (HealthyPeople.gov, 2012a).

Activities that promote healthy mothers and babies must be initiated before the period of critical fetal organ development, which is between 17 and 56 days after fertilization. By the end of the eighth week after conception and certainly by the end of the first trimester, any major structural anomalies in the fetus are already present. Because many women do not realize that they are pregnant and do not seek prenatal care until well into the first trimester, the rapidly growing fetus may be exposed to many types of intrauterine environmental hazards during this most vulnerable developmental phase. These hazards include drugs, viruses, and chemicals. In many instances, counseling can promote behavior modification before damage is done or the woman can make an informed decision about her willingness to accept potential hazards.

Preconception care is important for women who have had a problem with a previous pregnancy (e.g., miscarriage or preterm birth). Although causes are not always identifiable, in many cases problems can be discovered and treated and do not recur in subsequent pregnancies. Preconception care is also important to minimize fetal malformations. For example, the offspring of women who have type 1 diabetes mellitus have significantly more congenital anomalies than do children of mothers without diabetes. The rate of malformation is greatly reduced when the insulin-dependent woman with diabetes has excellent blood glucose control at the time she becomes pregnant and maintains **euglycemia** (normal blood sugar level) throughout the period of organ development in the fetus. The incidence of neural tube defects such as spina bifida and anencephaly is decreased significantly with the intake of 400 mcg of supplemental folic acid.

The components of preconception care such as health promotion, risk assessment, and interventions are outlined in Box 3-3.

Pregnancy

A woman's entry into health care is often associated with pregnancy, for either diagnosis or actual prenatal care. Early entry into prenatal care (i.e., within the first 12 weeks) allows for identification of the woman at risk for complications and initiation of measures to prevent problems or treat them if they arise. The U.S. Department of Health and Human Services (2012) has emphasized the importance of early and consistent prenatal care to improve outcomes for both mother and infant. Major goals of prenatal care are listed in Box 3-4 and should be addressed in the first visit. Extensive discussion of pregnancy is found in Unit 3.

Fertility Control and Infertility

More than half of the pregnancies in the United States each year are unintended (Taylor, Levi, and Simmonds, 2010), and the majority of these occur in women who either do not use contraception or who experienced a contraceptive failure. Education is the key to encouraging women to make family planning choices based on preference and actual benefit-to-risk ratios. Providers can influence the user's motivation and ability to use the method correctly (see Chapter 5).

Women also enter the health care system because of their desire to become pregnant. Approximately 15% of couples in the United

BOX 3-3 COMPONENTS OF PRECONCEPTION CARE

Health Promotion: General Teaching

- Nutrition
  - Healthy diet, including folic acid
  - Optimal weight
- Exercise and rest
- Avoidance of substance abuse (tobacco, alcohol, "recreational" drugs)
- Use of risk-reducing sex practices
- Attending to family and social needs

Risk Factor Assessment

- Chronic diseases
  - Diabetes, heart disease, hypertension, asthma, thyroid disease, kidney disease, anemia, mental illness
- Infectious diseases
  - HIV/AIDS, other sexually transmitted infections, vaccine-preventable diseases (e.g., rubella, hepatitis B, HPV)
- Reproductive history
  - Contraception
  - Pregnancies—unplanned pregnancy, pregnancy outcomes
  - Infertility
- Genetic or inherited conditions (e.g., sickle cell anemia, Down syndrome, cystic fibrosis)
- Medications and medical treatment
  - Prescription medications (especially those contraindicated in pregnancy), over-the-counter medication use, radiation exposure
- Personal behaviors and exposures
  - Smoking, alcohol consumption, illicit drug use
  - Overweight or underweight; eating disorders
  - Folic acid supplement use
  - Spouse or partner and family situation, including intimate partner violence
  - Availability of family or other support systems
  - Readiness for pregnancy (e.g., age, life goals, stress)
- Environmental (home, workplace) conditions
  - Safety hazards
  - Toxic chemicals
  - Radiation

Interventions

- Anticipatory guidance or teaching
  - Treatment of medical conditions and results
  - Medications

- Referral to and use of:
  - Family planning services
  - Family and social needs management

AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus. *HPV,* human papillomavirus.

BOX 3-4 MAJOR GOALS OF PRENATAL CARE

- Define health status of mother and fetus.
- Determine the gestational age of the fetus, and monitor fetal development.
- Identify the woman at risk for complications, and minimize the risk whenever possible.
- Provide appropriate education and counseling.

States have some degree of infertility. Many couples have delayed starting their families until they are in their 30s or 40s, which allows more time to be exposed to factors that affect fertility negatively (including age-related infertility for the woman). In addition, STIs, which can predispose to decreased fertility, are becoming more common and many women and men are in workplaces and home settings where they may be exposed to reproductive environmental hazards.

Infertility can cause emotional pain for many couples, and the inability to produce offspring sometimes results in feelings of failure and places inordinate stress on the couple's relationship. Much time, money, and emotional investment can be used for testing and treatment in efforts to build a family.

Steps toward prevention of infertility should be undertaken as part of ongoing routine health care, and information about how women may prevent some causes of infertility is especially appropriate in preconception counseling. Primary care providers can undertake initial evaluation and counseling before couples are referred to specialists. For additional information about infertility, see Chapter 5.

Menstrual Problems

Irregularities or problems with the menstrual period are among the most common concerns of women and often cause them to seek help from the health care system. Common menstrual disorders include amenorrhea, dysmenorrhea, premenstrual syndrome, endometriosis, and menorrhagia or metrorrhagia. Simple explanation and counseling may handle the concern; however, history and examination must be completed, as well as laboratory or diagnostic tests, if indicated. Questions should never be considered inconsequential, and age-specific reading materials are recommended, especially for teenagers. See Chapter 4 for an in-depth discussion of menstrual problems.

Perimenopause

The body responds to this natural transition in a number of ways, most of which are caused by the decrease in estrogen. Most women seeking health care during the perimenopausal period do so because of irregular bleeding. Others are concerned about vasomotor symptoms (hot flashes and flushes). Although fertility is greatly reduced during this period, women are urged to maintain some method of birth control because pregnancies still can occur. All women need to have factual information, the dispelling of myths, a thorough examination, and periodic health screenings thereafter.

IDENTIFICATION OF RISK FACTORS TO WOMEN'S HEALTH

In caring for women at all stages of life, it is important to understand the various and complex risk factors that can affect a woman's health. This section describes these risk factors. A thorough and systematic health history can elicit information about risk factors that exist for each woman.

Social, Cultural, and Genetic Factors

Differences exist among people from different socioeconomic levels and ethnic groups with respect to risk for illness and distribution of disease and death. Some diseases are more common among people of selected ethnicity (e.g., sickle cell anemia in African-Americans, Tay-Sachs disease in Ashkenazi Jews, adult lactase deficiency in Chinese, β-thalassemia in Mediterranean people, and cystic fibrosis in northern Europeans). Cultural and religious influences also increase health risks because the woman and her family may have life and societal values and a view of health and illness that dictate practices different from those expected in the Judeo-Christian Western model. These may include food taboos or frequencies, methods of hygiene, effects of climate, care-seeking behaviors, willingness to undergo screening and diagnostic procedures, and conflicts in values.

Socioeconomic status affects birth outcomes. The rates of perinatal and maternal deaths, preterm births, and low-birth-weight babies are considerably higher in disadvantaged populations (Hogue and Silver, 2011). Social consequences for poor women as single parents are great because many mothers with few skills are caught in the bind of insufficient income to afford child care. These families generate fewer and fewer resources and increase their risks for health problems. Multiple roles for women in general produce overload, conflict, and stress, resulting in higher risks for psychologic illness.

Substance Use and Abuse

Use of illicit drugs and inappropriate use of prescription drugs continue to increase and are found in all ages, races, ethnic groups, and socioeconomic levels. Addiction to substances is seen as a biopsychosocial disease, with several factors leading to risk. These include biogenetic predisposition, lack of resilience to stressful life experiences, and poor social support. Women are less likely than men to abuse drugs, but the rate in women is increasing significantly. Substance-abusing pregnant women create severe problems for themselves and their offspring, including interference with optimal growth and development and addiction. In many instances the use of substances is identified through screening programs in prenatal clinics and obstetric units.

Because of the risks to the unborn children and financial concerns, pregnant women who abuse substances can now face criminal charges under expanded interpretations of child abuse and drug trafficking statutes (Guttmacher Institute, 2010). Fifteen states define substance abuse in pregnancy to be child abuse, with 3 states defining it as reason for civil commitment. Suspected drug abuse in pregnant women is reason for reporting by health care professionals in 14 states, and prenatal drug exposure testing is required in 4 states if health care providers suspect substance abuse. Although some policymakers have proposed that pregnant women who abuse substances should be jailed or placed under house arrest, no states actually criminalize prenatal drug abuse. However, some states do commit women to psychiatric hospitals (Guttmacher Institute, 2010). Screening for substance abuse in pregnancy and encouraging prenatal care, counseling, and treatment will be of greater benefit to the mother and child than will prosecution.

Prescription Drug Use

Psychotherapeutic medications such as stimulants, sleeping pills, tranquilizers, and pain relievers are used by an estimated 2% of

American women. Such medications can bring relief from undesirable conditions such as insomnia, anxiety, and pain. Because the medications have mind-altering capacity, misuse can produce psychologic and physical dependency in the same manner as illicit drugs. Risk-to-benefit ratios should be considered when such medications are used for more than a very short period. Depression and anxiety are the most common mental health problems in women (depression used to be considered the most common, but recently it is noted that depression occurs comorbidly with anxiety). Many kinds of medications are used to treat depression and anxiety. All of these psychotherapeutic drugs can have some effect on the fetus and must be monitored very carefully.

Illicit Drug Use

Marijuana. Marijuana is a substance derived from the cannabis plant. It is usually rolled into a cigarette and smoked, but it also may be mixed into food and eaten. Marijuana produces distorted perceptions, difficulty with problem solving as well as with thinking and memory, altered state of awareness, relaxation, mild euphoria, and reduced inhibition (National Institute on Drug Abuse, 2012a). Marijuana readily crosses the placenta and causes increased carbon monoxide levels in the mother's blood, which reduces the oxygen supply to the fetus. Research findings regarding the effects of marijuana demonstrate adverse outcomes on the fetus and infant (Hayatbakhsh, Flenady, Gibbons, et al., 2012).

Cocaine. Cocaine is a powerful central nervous system stimulant that is addictive because of the tremendous sense of euphoria that it creates. It can be snorted, smoked, or injected. Crack or rock cocaine is a form of the drug that is exceedingly potent and even more highly addictive. (Some say that an individual is "hooked" after the first use or at least after two or three "hits"). After ingestion of cocaine, an intensely pleasurable high results that is followed by an uncomfortable low; this increases the urge to repeat the drug.

Predisposing factors and problems associated with cocaine use in pregnancy are polydrug use; poor nutrition; poverty; STIs; hepatitis B infection; dysfunctional family systems; employment difficulties; stress; anger; poor self-esteem; and previous or present physical, emotional, and sexual abuse. Cocaine use is especially concentrated among poor women of color.

Cocaine affects all of the major body systems. Among other complications, it produces cardiovascular stress (including tachycardia and hypertension) that can lead to heart attack or stroke, liver disease, central nervous system simulation that can cause seizures, and even perforation of the nasal septum. Needle-borne diseases such as hepatitis B and acquired immunodeficiency syndrome (AIDS) are common among cocaine users. If the user is pregnant, there is an increased incidence of miscarriage, preterm labor, small-for-gestational age babies, abruption of placenta, and stillbirth. Anomalies have been reported.

One of the promising treatments for cocaine abuse in pregnancy is acupuncture. A component of traditional Chinese medicine, acupuncture is used to redirect energy flow (chi) within the body, reduce cravings, and enhance well-being. Acupuncture has been studied and shown to be effective in detoxification in people addicted to many different drugs (Schaub and Burt, 2013).

Opiates. The opiates include opium, heroin, meperidine, morphine, codeine, and methadone. Heroin is one of the most commonly abused drugs of this class. It is usually taken by intravenous injection but can be smoked or "snorted." The signs and symptoms of heroin use are euphoria, relaxation, relief from pain, "nodding out" (apathy, detachment from reality, impaired judgment, and drowsiness), constricted pupils, nausea, constipation, slurred speech, and respiratory depression.

The incidence of heroin use among pregnant women is unknown because women with a dependency on heroin often use multiple drugs. Women who use opiates during pregnancy have a 6-times higher risk for problem outcomes (Keegan, Parva, Finnegan, et al., 2010). The recommended treatment is methadone maintenance, ideally done by stabilizing the treatment before as well as during pregnancy (Peles, Schreiber, Bloch, et al., 2012). This treatment must be closely monitored because, in pregnancy, methadone is metabolized more rapidly, leading to withdrawal symptoms in less than 24 hours in many women. Withdrawal symptoms can include fetal hyperactivity and, if severe, preterm labor or fetal death. Women may resort to heroin to alleviate the uncomfortable symptoms.

Methamphetamine. Methamphetamine is a relatively cheap and highly addictive stimulant. Over the past few years, use of this dangerous drug has decreased. In 2006 it was estimated that there were 731,000 methamphetamine users per month, decreasing in 2008 to 314,000 users per month (National Institute on Drug Abuse, 2012b). Methamphetamine makes many users feel hypersexual and uninhibited, leading to more sex and less protection from pregnancy and STIs.

The active metabolite of methamphetamine is amphetamine, a central nervous system stimulant known as both "speed" and "meth." The crystalline form, which is smoked, is known as "ice." Methamphetamine causes a person to experience an elevated mood state and pleasure as well as increased energy and creates addiction within a short period. It can lead to cardiac problems, including irregular heartbeat and hypertension and, over time, can create cognitive and mental as well as dental problems (Medline Plus, 2012). Most of the effects of amphetamines are similar to those of cocaine. Although fewer maternal and neonatal complications have been attributed to this class of substances than to cocaine, the rates of preterm births and intrauterine growth restriction with smaller head circumference are higher in methamphetamine-exposed pregnant women than in pregnant women who abuse other substances.

Phencyclidine. Phencyclidine (PCP) is a synthetic drug known by various names ("peace pill," "elephant," "angel dust," "hog"). At least 1% of 12th graders in the United States have abused PCP (National Institute on Drug Abuse, 2012c). PCP causes a person to experience dissociative symptoms that include distorted perceptions and detached feelings, delusions, hallucinations, extreme anxiety, and disordered thinking (National Institute on Drug Abuse, 2012c). Because some effects mimic the signs and symptoms of schizophrenia, a user may be admitted to a psychiatric unit. The major concerns regarding PCP use in pregnant women are its association with polydrug abuse and the neurobehavioral effects on the neonate.

Other Illicit Drugs. A number of street drugs pose risk to users. A few are derived from organic materials, but more and more are produced synthetically in laboratories. Sedatives such as "downers," "yellow jackets," or "red devils" are used to come off of "highs." Hallucinogens alter perceptions and body function. PCP ("angel dust") and lysergic acid diethylamide (LSD) produce vivid changes in sensation, often with agitation, euphoria, paranoia, and a tendency toward antisocial behavior. Their use may lead to flashbacks, chronic psychosis, and violent behavior. Hallucinogens taken during pregnancy may have negative neurobehavioral effects on the newborn.

Alcohol Consumption

Women ages 35 to 49 have the highest rates of chronic alcoholism, but women ages 21 to 34 have the highest rates of specific alcohol-related problems. About one third of alcoholics are women, and many relate the onset of their drinking problem to stressful events. Women who are problem drinkers are often depressed, have more motor vehicle injuries, and have a higher incidence of attempted suicide than do women in the general population. They are also at risk for alcohol-related liver damage. Early case finding and treatment are important in alcoholism for both the ill individual and family members.

Prenatal alcohol exposure has been found to increase the chance of birth defects significantly, with one study reporting a fourfold increase (O'Leary, Nassar, Kurinczuk, et al., 2011). Although fetal alcohol syndrome (FAS) is a known consequence of prenatal alcohol intake, studies also indicate that other consequences include increased risk for miscarriage, stillbirth, preterm birth, and sudden infant death syndrome (SIDS). Clearly, alcohol consumption during pregnancy has wide-reaching effects (Bailey and Sokol, 2011). A 2020 national health objective is to have 98.3% of pregnant women abstain from alcohol use (HealthyPeople.gov, 2012c.)

Alcohol use during pregnancy can lead to fetal alcohol spectrum disorder (FASD), which includes FAS, fetal alcohol effects, and alcohol-related neurologic developmental disabilities. Approximately 40,000 babies per year are born with FASD; however, recent research reveals that multivitamin supplement use during pregnancy may lessen the effects of prenatal alcohol exposure in the children of women who are unable or unwilling to curtail their alcohol abuse when pregnant (Avalos, Kaskutas, Block, et al., 2011). Low birth weight, intellectual disability, behavioral problems, and learning and physical problems are some of the symptoms of FAS babies (see Chapter 25). Severe facial deformities of FAS occur at day 20 of conception when women may not even suspect that they are pregnant.

Cigarette Smoking

Tobacco use is the leading cause of preventable death and illness. Smoking is linked to cardiovascular disease, various types of cancers (especially lung and cervical), chronic lung disease, and negative pregnancy outcomes. Premature death is estimated to occur in 443,000 people annually because of either smoking or being exposed to secondhand smoke, and 8.6 million people are estimated to be seriously ill as a result of smoking. However, it is also estimated that 46.6 million adults in the United States smoke; 17.3% of women are smokers (Centers for Disease Control and Prevention, 2011). Tobacco contains nicotine, which is an addictive substance that creates physical and psychologic dependence. Smoking in pregnancy is known to cause a decrease in placental perfusion and is one cause of low birth weight in infants.

Cigarette smoking impairs fertility in both women and men, may reduce the age for menopause, and increases the risk for osteoporosis after menopause. Passive, or secondhand, smoke (environmental tobacco smoke) contains similar hazards and presents additional problems for the smoker and harm for the nonsmoker. Box 3-5 describes an intervention, referred to as the "Five A's" to encourage smoking cessation.

Caffeine

Caffeine is found in society's most popular drinks: coffee, tea, and soft drinks. It is a stimulant that can affect mood and interrupt body functions by producing anxiety and sleep interruptions. Heart dysrhythmias may be made worse by caffeine, and there can be interactions with certain medications such as lithium. Birth defects have not been related to caffeine consumption; however, high intake has been related to a slight decrease in birth weight and may also increase risk for miscarriage. The March of Dimes (2010) recommends that until more is known about the effects of caffeine during pregnancy, especially in regard to miscarriage, that pregnant women limit their caffeine intake to no more that 200 mg/day (an 8-ounce cup of brewed coffee has approximately 137 mg of caffeine).

BOX 3-5 INTERVENTIONS FOR SMOKING CESSATION: THE FIVE A'S

Ask
- What was her age when she started smoking?
- How many cigarettes does she smoke a day? When was her last cigarette?
- Has she tried to quit?
- Does she want to quit?

Advise
- Give her information about the effects of smoking on pregnancy and her fetus, on her own future health, and on the members of her household.

Assess
- What were her reasons for not being able to quit before, or what made her start again?
- Does she have anyone who can help her?
- Does anyone else smoke at home?
- Does she have friends or family who have quit successfully?

Assist
- Provide support; give self-help materials.
- Encourage her to set a quit date.
- Refer to a smoking cessation program, or provide information about nicotine replacement products (not recommended during pregnancy) if she is interested.
- Teach and encourage use of stress-reduction activities.
- Provide for follow-up with a phone call, letter, or clinic visit.

Arrange Follow-Up
- Arrange to follow the woman to find out about smoking-cessation status.
- Make a phone call around the time of her quit date. Assess her status at every prenatal visit.
- Congratulate her on her success, or provide support for her if she relapses.
- Referral to intensive treatment may be necessary.

From Fiore MC, Jaen CR, Baker TB, et al: *Treating tobacco use and dependence: 2008 update: Clinical Practice Guideline,* Rockville, MD, 2008, US Department of Health and Human Services, Public Health Service, http://www.surgeongeneral.gov/tobacco/treating_tobacco_use08.pdf (pg. 39).

Nutrition Problems and Eating Disorders

Good nutrition is essential for optimal health. A well-balanced diet helps prevent illness and also is used to treat certain health problems. Conversely, poor eating habits, eating disorders, and obesity are linked to disease and debility. *Dietary Guidelines for Americans* (U.S. Department of Agriculture, 2010) provides evidence-based recommendations to promote health and reduce risks for chronic diseases

through diet and physical activity. This guide contains resources for health professionals and consumers on dietary guidelines. Recently the Food Guide Pyramid has been replaced by MyPlate, a guide to healthy eating recommended by the *Dietary Guidelines for Americans* (HealthyPeople.gov, 2012b).

In addition to specific guidelines for healthy eating, environmental factors play an important role in nutrition. Dubowitz, Ghosh-Dastidar, Eibner, et al. (2012) presented data from the Women's Health Initiative Clinical Trial (WHI CT) that indicated availability of healthy food was correlated with decreased obesity in women. These data suggest that social conditions and access to nutritious food are important contributors to women's health.

Nutritional Deficiencies

Overt disease caused by a lack of certain nutrients is rarely seen in the United States. However, insufficient amounts or imbalances of nutrients do pose problems for individuals and families. Overweight or underweight status, malabsorption, listlessness, fatigue, frequent colds and other minor infections, constipation, dull hair and nails, and dental caries are examples of problems that can be related to nutrition and indicate the need for further nutritional assessment. Poor nutrition, especially related to obesity and high fat and cholesterol intake, may lead to more serious conditions and contribute to 4 of the 10 leading causes of death in the United States: heart diseases, malignant neoplasms, cerebrovascular diseases, and diabetes.

Other dietary extremes also produce risk. For example, insufficient amounts of calcium can lead to osteoporosis, too much sodium can aggravate hypertension, and megadoses of vitamins can cause adverse effects in several body systems. Fad weight-loss programs and yo-yo dieting (repeated and cyclic weight gain and weight loss) result in nutritional imbalances and, in some instances, medical problems. Such diets and programs are not appropriate for weight maintenance. Adolescent pregnancy produces special nutritional requirements because the metabolic needs of pregnancy are superimposed on the teen's own needs for growth and maturation at a time when eating habits are not ideal. Neural tube defects are more common in infants born to women with a diet poor in folate. In their childbearing years, women should ingest at least 0.4 mg (400 mcg) of folic acid daily in additional to consuming a diet rich in folate-containing foods.

Obesity

During the past 20 years, obesity has increased dramatically in the United States. More than one third of women in the United States are obese (body mass index [BMI] of 30 or greater), with adults ages 40 to 59 having the highest prevalence. The BMI is defined as a measure of an adult's weight in relation to his or her height, specifically the adult's weight in kilograms divided by the square of his or her height in meters (Box 3-6). It is estimated that one third of adults and one sixth of children and adolescents are in the obese range (HealthyPeople.gov, 2012b). Overweight and obesity are known risk factors for premature death, diabetes, heart disease, stroke, hypertension, type 2 diabetes, gallbladder disease, diverticular disease, some anemias, oral disease, constipation, osteoarthritis, gout, osteoporosis, respiratory dysfunction, sleep apnea, and some types of cancer (uterine, breast, colorectal, kidney, and gallbladder) (American Cancer Society, 2012a). In addition, obesity is associated with high cholesterol, menstrual irregularities, hirsutism (excess body/facial hair), stress incontinence, depression, complications of pregnancy, increased surgical risk, and shortened life span. Pregnant women who are morbidly obese are at increased risk for hypertension, diabetes, gallbladder disease, postterm pregnancy, and musculoskeletal problems.

BOX 3-6 IDEAL BODY WEIGHT WITH BODY MASS INDEX

BMI 18.5 or less—Underweight
BMI 18.5 to 24.9—Normal weight
BMI 25.0 to 29.9—Overweight
BMI 30.0 to 34.5—Obese
BMI 35.0 to 40—Very obese

Eating Disorders

Anorexia nervosa and bulimia are two forms of eating disorders, although there are additional forms, such as subclinical eating disorders. Some women, especially adolescents, do not have symptoms that lend themselves to a diagnosis of anorexia nervosa or bulimia. These women are diagnosed as having a subclinical eating disorder, which is usually associated with disorders of mood and anxiety and requires accurate diagnosis and prompt treatment (Touchette, Henegar, Godart, et al., 2011). Recent research suggests that eating disorders are often associated with difficulties in intimate relationships, and interpersonal psychotherapy has been considered as an approach to treatment of women with eating disorders (Murphy, Straebler, Basden, et al., 2012).

It is important to assess for and treat women with eating disorders early because they are at increased risk for serious physical problems as well as diminished quality of life (Vallance, Latner, and Gleaves, 2011). Eating disorders during pregnancy are also associated with increased risk to the pregnant woman and her fetus (Pasternak, Weintraub, Shoham-Vardi, et al., 2012).

Anorexia Nervosa. Some women have a distorted view of their bodies and, no matter what their weight, perceive themselves to be much too heavy. As a result, they undertake strict and severe diets and rigorous extreme exercise. This chronic eating disorder is known as **anorexia nervosa.** Women can carry this condition to the point of starvation, with resulting endocrine and metabolic abnormalities. If not corrected, significant complications of dysrhythmias, amenorrhea, cardiomyopathy, and heart failure occur and, in the extreme, can lead to death. The condition commonly begins during adolescence in young women who have some degree of personality disorder. They gradually lose weight over several months, have amenorrhea, and are abnormally concerned with body image. A coexisting depression usually accompanies anorexia.

There are no specific tests to diagnose anorexia nervosa. A medical history, physical examination, and screening tests help identify women at risk for eating disorders. Several tools are available to use in primary care settings. The SCOFF questionnaire, developed by Morgan, Reid, and Lacey (1999) is easy to administer and can help the nurse decide whether an eating disorder is likely and whether the woman needs further assessment and possibly psychiatric and medical intervention. More recently, Hautala, Junnila, Alin, et al. (2009) provided further evidence for the validity and usefulness of the SCOFF. See Box 3-7 for a description of the SCOFF.

Bulimia Nervosa. **Bulimia** refers to secret, uncontrolled binge eating alternating with methods to prevent weight gain: self-induced vomiting, laxatives or diuretics, strict diets, fasting, and rigorous exercise. During a binge episode, a large number of calories are consumed, usually consisting of sweets and "junk foods." Binges

BOX 3-7 SCREENING FOR EATING DISORDERS: SCOFF QUESTIONS

Each question scores 1 point. A score of 2 or more indicates the person may have anorexia nervosa or bulimia.

1. Do you make yourself Sick (i.e., induce vomiting) because you feel too full?
2. Do you worry about loss of Control over the amount you eat?
3. Have you recently lost more than One stone (6.4 kg [14 lbs]) in a 3-month period?
4. Do you think you are too Fat even if others think you are too thin?
5. Does Food dominate your life?

From Morgan J, Reid F, Lacey J: The SCOFF questionnaire: assessment of a new screening tool for eating disorders, *BMJ* 319(7223):1467–1468, 1999.

FIG 3-8 Exercise should be part of one's regular health routine. A cycle class is fun and provides moderate to vigorous exercise. (Courtesy Shari Rivera Sharpe, Chapel Hill, NC.)

occur at least twice per week. Bulimia usually begins in early adulthood (ages 18 to 25 years) and is found primarily in females. Complications can include dehydration and electrolyte imbalance, gastrointestinal abnormalities, and cardiac dysrhythmias. Bulimia is somewhat similar to anorexia in that it is an eating disorder and usually involves some degree of depression (Skinner, Haines, Austin, et al., 2012). Unlike those with anorexia, individuals with bulimia may feel shame or disgust about their disorder and tend to seek help earlier. The SCOFF screening assessment also can be used to assess patients with bulimia (see Box 3-7).

Lack of Exercise

Exercise contributes to good health by lowering risks for a variety of conditions that are influenced by obesity and a sedentary lifestyle. It is effective in the prevention of cardiovascular disease and in the management of chronic conditions such as hypertension, arthritis, diabetes, respiratory disorders, and osteoporosis (Fig. 3-8). Exercise also contributes to stress reduction and weight maintenance. Women report that engaging in regular exercise improves their body image and self-esteem and acts as a mood enhancer. Aerobic exercise produces cardiovascular involvement because an increased amount of oxygen is delivered to working muscles. Anaerobic exercise such as weight training improves individual muscle mass without stress on the cardiovascular system. Because women are concerned about both cardiovascular and bone health, weight-bearing aerobic exercises such as walking, running, racket sport, and dancing are preferred. However, excessive or strenuous exercise can lead to hormone imbalances, resulting in amenorrhea and its consequences. Physical injury is also a potential risk.

One particular exercise that is important for women is *Kegel exercise*, or pelvic muscle exercise. This exercise is used to strengthen the muscles that support the pelvic floor and should be practiced regularly. Instructions for this exercise are in presented in the Guidelines box.

Physical activity and exercise counseling for persons of all ages should be undertaken at schools, work sites, and primary care settings. Specific recommendations include 20 to 30 minutes of moderate activity at least 3 times per week. Few Americans exercise this often, and physical inactivity increases with age, especially during adolescence and early adulthood. Even small increases in activity can be beneficial. During pregnancy, an ongoing exercise regimen can be continued but intensity and duration should be decreased. Sedentary women should obtain medical clearance to initiate exercise during pregnancy and should begin with low-intensity and low-impact workouts.

Stress

The modern woman faces increasing levels of stress and, as a result, is prone to a variety of stress-induced complaints and illnesses. Stress often occurs because of multiple roles in which coping with job and financial responsibilities conflicts with parenting and duties at home. To add to this burden, women are socialized to be caregivers, which is emotionally draining, creating additional stress. They also may find themselves in positions of minimal power that do not allow them control over their everyday environments. Some stress is normal and contributes to positive outcomes. Many women thrive in busy surroundings. However, excessive or high levels of ongoing stress trigger physical reactions such as rapid heart rate, elevated blood pressure, slowed digestion, release of additional neurotransmitters and hormones, muscle tenseness, and a weakened immune system. Consequently, constant stress can contribute to clinical illnesses such as flare-ups of arthritis or asthma, frequent colds or infections, gastrointestinal upsets, cardiovascular problems, and infertility. Box 3-8 lists symptoms that may be related to chronic or extreme stress. Psychologic symptoms such as anxiety, irritability, eating disorders, depression, insomnia, and substance abuse have also been associated with stress.

Because it is neither possible nor desirable to avoid all stress, women must learn how to manage it. The nurse should assess each woman for signs of stress, using therapeutic communication skills to determine risk factors and the woman's ability to function. Some women must be referred for counseling or other mental health therapy. Women are twice as likely as men to suffer from depression, anxiety, or panic attacks. Nurses must be alert to the symptoms of serious mental disorders such as depression and anxiety and make referrals to mental health practitioners when necessary. Women experiencing major life changes such as separation and divorce, bereavement, serious illness, and unemployment also need special attention.

Many centers offer support groups to help women prevent or manage stress. Social support and good coping skills can improve a woman's self-esteem and give her a sense of mastery. Anticipatory guidance for developmental or expected situational crises can help her plan strategies for dealing with potentially stressful events. Role playing, relaxation techniques, biofeedback, meditation,

GUIDELINES

Kegel Exercises

Description and Rationale

Kegel exercises, or pelvic muscle exercise, is a technique used to strengthen the muscles that support the pelvic floor. This exercise involves regularly tightening (contracting) and relaxing the muscles that support the bladder and urethra. By strengthening these pelvic muscles, a woman can prevent or reduce accidental urine loss.

Technique

The woman needs to learn how to target the muscles for training and how to contract them correctly. One suggestion for teaching is to have the woman pretend she is trying to prevent the passage of intestinal gas. Have her use this tightening motion on the muscles around her vagina and the upper pelvis. She should feel these muscles drawing inward and upward. Other suggested techniques are to have the woman pretend she is trying to stop the flow of urine in midstream or to have her think about how her vagina is able to contract around and move up the length of the penis during intercourse.

The woman should avoid straining or bearing-down motions while performing the exercise. She should be taught how bearing down feels by having her take a breath, hold it, and push down with her abdominal muscles as though she were trying to have a bowel movement. Then the woman can be taught how to avoid straining down by exhaling gently and keeping her mouth open each time she contracts her pelvic muscles.

Specific Instructions

1. Each contraction should be as intense as possible without contracting the abdomen, thighs, or buttocks.
2. Contractions should be held for at least 10 seconds. The woman may have to start with as little as 2 seconds per contraction until her muscles get stronger.
3. The woman should rest for 10 seconds or more between contractions so that the muscles have time to recover and each contraction can be as strong as the woman can make it.
4. The woman should feel the pulling up over the three muscle layers so that the contraction reaches the highest level of her pelvis.

Data from Sampselle C: Behavior interventions in young and middle-aged women: Simple interventions to combat a complex problem, *American Journal of Nursing* 103(Suppl):9–19, 2003; Sampselle C: Behavioral interventions for urinary incontinence in women: Evidence for practice, *Journal of Midwifery & Women's Health* 45(2):94–103, 2000; Sampselle C, Wyman J, Thomas K, et al: Continence for women: a test of AWHONN's evidence-based protocol, *Journal of Obstetric, Gynecologic, and Neonatal Nursing* 29(1):312–317, 2000.

desensitization, imagery, assertiveness training, yoga, diet, exercise, and weight control are all techniques nurses can include in their repertoire of helping skills.

Depression, Anxiety, and Other Mental Health Conditions

Women experience depression and/or anxiety frequently. In addition, depression is sometimes described as a co-traveler because it is exists comorbidly with other physical conditions. Depression and/or anxiety create difficulties for quality of life and, at the extreme, create a risk for suicide. Recent research (Berecki-Gisolf, McKenzie, Dobson, et al., 2012) suggests that women with comorbid anxiety and depression are at greater risk for developing cardiac disease. In addition to depression and anxiety, women experience other mental health disorders, such as bipolar disease.

BOX 3-8 STRESS SYMPTOMS

Physical

- Perspiration/sweaty hands
- Increased heart rate
- Trembling
- Nervous tics
- Dryness of throat and mouth
- Tiring easily
- Urinating frequently
- Sleeping problems
- Diarrhea, indigestion, vomiting
- Butterflies in stomach
- Headaches
- Premenstrual tension
- Pain in neck and lower back
- Loss of appetite or overeating
- Susceptibility to illness

Behavioral

- Stuttering and other speech difficulties
- Crying for no apparent reason
- Acting impulsively
- Startling easily
- Laughing in a high-pitched and nervous tone of voice
- Grinding teeth
- Increasing smoking
- Increasing use of drugs and alcohol
- Being accident prone

Psychologic

- Feeling anxious
- Feeling scared
- Feeling irritable
- Feeling moody
- Having low self-esteem
- Being afraid of failure
- Being unable to concentrate
- Embarrassing easily
- Worrying about the future
- Being preoccupied with thoughts or tasks
- Forgetful

Adapted from State University of New York Counseling Center: *Stress management*, Buffalo, NY, 2002, University of Buffalo, State University of New York.

Sleep Disorders

Many women suffer from sleep disorders, including difficulty initiating sleep or staying asleep and experiencing nonrestorative sleep (Zender and Olshansky, 2009). Restless leg syndrome may be a cause of sleep disorders or a comorbid condition. Sleep disorders are correlated with physical and mental health problems, including depression, pain, and fibromyalgia. Mong, Baker, Mahoney, et al. (2011) presented a review of studies conducted on gender differences related to sleep, suggesting that, while further research is needed, women experience insomnia significantly more than do men. It is important that the nurse talk with the woman about her sleep patterns and discuss ways to improve sleep, such as avoiding alcohol before going to sleep and sleeping in a regular pattern.

Environmental and Workplace Hazards

Environmental hazards in the home, the workplace, and the community can contribute to poor health at all ages. Categories and examples of health-damaging hazards include the following: (1) pathogenic agents (viruses, bacteria, fungi, parasites); (2) natural and synthetic chemicals (natural toxins from animals, insects, and plants; consumer and industrial products such as pesticides and hydrocarbon gases; medical and diagnostic devices; tobacco; fuels; and drug and alcohol abuse); (3) radiation (radon, heat waves, sound waves); (4) food substances (added

components that are not necessary for nutrition); and (5) physical objects (moving vehicles, machinery, weapons, water, and building materials).

Environmental hazards can affect fertility, fetal development, live birth, and the child's future mental and physical development. Children are at special risk for poisoning from lead found in paint and soil. Everyone is at risk from air pollutants such as tobacco smoke, carbon monoxide, smog, suspended particles (dust, ash, and asbestos), and cleaning solvents; noise pollution; pesticides; chemical additives; and poor preparation of food. Workers also face safety and health risks caused by ergonomically poor work stations and stress. It is important that risk assessments continue to be in effect to identify and understand environmental problems in public health. The March of Dimes (2011) has published a helpful resource that summarizes the various risks posed in the environment to pregnant women and their fetuses.

Risky Sexual Practices

Potential risks related to sexual activity include undesired pregnancy and STIs. The risks are particularly high for adolescents and young adults who engage in sexual intercourse at earlier and earlier ages. Adolescents report many reasons for wanting to be sexually active: peer pressure, desire to love and be loved, experimentation, to enhance self-esteem, and to have fun. However, many teens do not have the decision-making or values-clarification skills needed to take this important step. They may also lack knowledge about contraception and STIs. Many do not believe that becoming pregnant or getting an STI will happen to them.

Although some STIs can be cured with antibiotics, many cause significant problems. Possible sequelae include infertility, ectopic pregnancy, neonatal morbidity and mortality, genital cancers, AIDS, and even death. The incidence of STIs is increasing rapidly and reaching epidemic proportion. Choice of contraception has an impact on the risk for contracting an STI. No method of contraception offers complete protection. (See Chapter 4 for a discussion of STIs and Chapter 5 for a discussion of contraception.)

Prevention of STIs is predicated on the reduction of high risk behaviors by educating toward a behavioral change. Behaviors of concern include multiple and casual sexual partners and unsafe sexual practices. Specific self-management measures to prevent STIs are listed in Box 3-9. The abuse of alcohol and drugs is a high risk behavior, resulting in impaired judgment and thoughtless acts. Behavioral changes must come from within; therefore the nurse must provide sufficient information for the individual or group to "buy into" the need for change. Education is a powerful tool in health promotion and prevention of STIs and pregnancy. However, it works best when delivered in a way that considers the language, culture, and lifestyle of the intended listener.

Risk for Certain Medical Conditions

Most women of reproductive age are relatively healthy. Heart disease; lung, breast, colon, and other nongynecologic cancers; chronic lung disease; and diabetes are all concerns for adult women because they are among the leading causes of death in women. Certain medical conditions present during pregnancy can have deleterious effects on both the woman and the fetus. Of particular concern are risks from all forms of diabetes, urinary tract disorders, thyroid disease, hypertensive disorders of pregnancy, cardiac disease, and seizure disorders. Effects on the fetus vary and include intrauterine growth restriction, macrosomia, anemia, prematurity, immaturity, and stillbirth. Effects on the woman also can be severe. These conditions are discussed in later chapters.

BOX 3-9 STI AND HIV PREVENTION

- Prevention of STIs and HIV is possible only if there is no oral, genital, or rectal exchange of body fluids or if a person is in a long-term, mutually monogamous relationship with an uninfected partner.
- Correct use of latex condoms, although greatly reducing risk, is not exclusively protective.
- Sexual partners should be selected with great care.
- Partners should be asked about history of STIs.
- Preexposure vaccination is one of the most effective methods for preventing transmission of some STIs (hepatitis A and hepatitis B, human papillomavirus).
- A new condom should be used for each act of sexual intercourse.
- Abstinence from sexual intercourse is encouraged for persons who are being treated for an STI or whose partners are being treated.

Adapted from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2010, *MMWR* 59(RR-12):11094, 2010.
STI, Sexually transmitted infection; *HIV,* human immunodeficiency virus.

Risk for Certain Gynecologic Conditions

Women are at risk throughout their reproductive years for pelvic inflammatory disease, endometriosis, STIs and other vaginal infections (see Chapter 4), uterine fibroids, uterine deformities such as bicornuate uterus, ovarian cysts, interstitial cystitis, and urinary incontinence related to pelvic relaxation. These gynecologic conditions may contribute negatively to pregnancy by causing infertility, miscarriage, preterm labor, and fetal and neonatal problems. Gynecologic cancers also affect women's health, although the risk for most cancers is low in pregnancy. Risk factors depend on the type of cancer. The impact of developing a gynecologic problem or cancer on women and their families is shaped by a number of factors, including the specific type of problem or cancer, the implications of the diagnosis for the woman and her family, and the timing of the occurrence in the woman's and the family's lives.

Female Genital Mutilation

Female genital mutilation is practiced in more than 45 countries, with the majority of these countries being in Africa. As emigrants from these countries arrive in North America, nurses in the United States and Canada will see patients who have had such procedures performed (see Cultural Competence box).

Violence Against Women

Intimate partner violence (IPV) is the most common form of violence experienced by women worldwide, with a reported incidence of one of every six women having been a victim of domestic violence. In the United States, IPV is a significant social problem and a major health care problem that affects millions of women and men each year and costs millions of dollars in annual medical costs. Statistics from the U.S. Department of Justice, Office of Violence Against Women (2012) reported that one in four women in the United States have experienced severe physical violence by a current or former intimate partner. In addition, 5.2 million women were victimized by stalkers. It is estimated that 1.3 million women are raped in the United States annually.

Although *IPV* is the preferred term, *wife battering, spouse abuse,* and *domestic* or *family violence* are also terms that may be applied to a pattern of assaultive and coercive behaviors inflicted by a male partner in a marriage or other heterosexual, significant, intimate

CULTURAL COMPETENCE

Female Genital Mutilation

Defined by the World Health Organization (WHO), female genital mutilation (FGM) is "all procedures that involve partial or total removal of the external female genitalia, or other injury to the female genital organs for non-medical reasons" (WHO, 2012). This includes female circumcision and is an attempt to control women through controlling their sexuality. FGM is supposed to remove sexual desire so that the girl will not become sexually active until married (McGargill, 2009).

Female circumcision occurs in women of many different ethnic, cultural, and religious backgrounds. Although circumcision is usually performed during childhood, some communities circumcise infants or older females. The procedure involves the removal of a portion of the clitoris but may extend to the removal of the entire clitoris and labia minora. In addition, the labia majora, which are often stitched together over the urethral and vaginal openings, may be affected.

The extent of the circumcision site affects the seriousness of complications. Common complications include bleeding, pain, local scarring, keloid or cyst formation, and infection. Impaired drainage of urine and menstrual blood may lead to chronic pelvic infections, pelvic and back pain, and chronic urinary tract infections. Some women may require surgery before vaginal examination, intercourse, or childbirth if the vaginal opening is obstructed.

FGM is illegal in the United States and punishable by fines, prison, and deportation. An obstetrician may incise the closed labia to deliver a baby or remove cysts but may not sew the labia back to its previous state of reinfibulation. If performed on a minor, FGM is considered child abuse in the United States. "The practice also violates the rights to health, security and physical integrity of the person, the right to be free from torture and cruel, inhuman or degrading treatment, and the right to life when the procedure results in death" (WHO, 2012).

Nurses are providing care to a growing number of women who have emigrated from the Middle East, Asia, and Africa, where female circumcision is more common. Nurses must be sensitive to the unique needs of these patients, especially if these women have concerns about maintaining or restoring the intactness of the circumcision after childbirth.

Data from McGargill P: Female genital mutilation, *On the Edge* 15(2 Summer), 2009, www.cinahl,com/cgi-bin/refsvc?jid=29638accno-2010331425; World Health Organization (2012 February). Female genital mutilation, www.who.int/mediacentre/factsheet/fs241/en/print.html.

relationship (and sometimes the man is the victim of violence). It is also important to note that not all violence against women is caused by an intimate partner; non-IPV also occurs. Montero, Escriba, Ruiz-Perez, et al. (2011) studied both IPV and non-IPV, noting that violence in general has negative effects on women's health and recommending that routine assessment of violence against women be included in primary care histories. Common elements of IPV are physical abuse; psychologic or emotional abuse; sexual assault; isolation; and controlling all aspects of the victim's life, including money, shelter, time, and food.

Battering is neither random nor constant; rather, it occurs in repeated cycles. Health care providers often refer to the "cycle of violence" (Fig. 3-9). A three-phase includes a period of increasing tension leading to the battery. The battery consists of slaps, punches to the face and head, kicking, stomping, punching, choking, pushing, breaking of bones, burns from irons, and mutilations from knives and guns. The **honeymoon phase** is characterized by a period of calm and remorse in which the male partner displays kind, loving

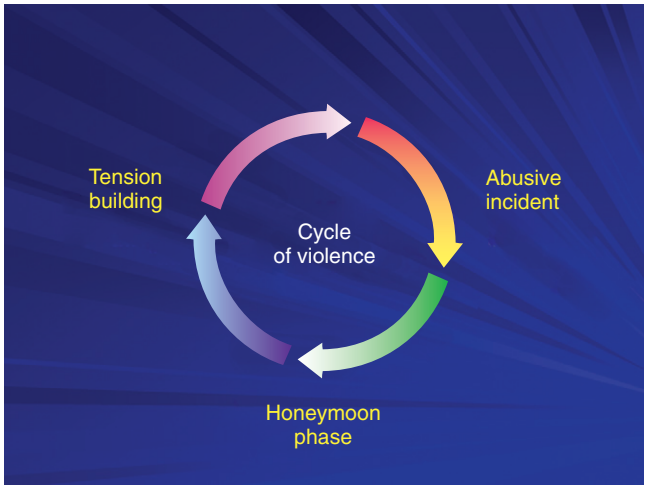

FIG 3-9 Cycle of violence.

behavior and pleas for forgiveness. This honeymoon phase lasts until stress or other factors cause conflict and tension to mount again toward another episode of battering. Over time, the tension and battering phases last longer and the calm phase becomes shorter until there is no honeymoon phase.

Because violence against women crosses all ethnic, educational, religious, and socioeconomic backgrounds and there are often misconceptions regarding who is at risk for being abused, it is important to differentiate myths from facts about this serious and often devastating condition. Table 3-2 presents myths and facts about IPV.

All women entering the health care system should be assessed for potential abuse. An abuse assessment screening tool can be used as part of the interview or written history. If a male partner is present, he should be asked to leave the room because the woman may not disclose experiences of abuse in his presence or he may try to answer questions for her to protect himself. The same procedure applies to partners of lesbians or the adult children of older women. At present there is no universally accepted screening tool for all populations (Rabin, Jennings, Campbell, et al., 2009). However, the American College of Obstetricians and Gynecologists [ACOG] and the Nursing Research Consortium on Violence and Abuse have each suggested questions that give a woman permission to disclose sensitive information. Fig. 3-10 presents a modification and combination of questions suggested by these two organizations.

It also is important that the nurse be alert to any indication from the woman that she is being abused, despite the fact that she may not have specifically stated that she is in an abusive relationship. Box 3-10 provides a list of signs of IPV.

Futures Without Violence (which was previously called the *Family Violence Prevention Fund*) collaborated with the Avon Foundation to explore ways to prevent violence on college campuses. They published a document referred to as *Beyond Title IX: Guidelines for Preventing and Responding to Gender-Based Violence in Higher Education* (Fleck-Henderson, Costello, Raghu, et al., 2012), which provides guidelines for college campuses in being vigilant to the possibility of gender-based violence.

A therapeutic relationship and skillful interviewing help women disclose and describe their abuse. Language is important when talking with women. For example, using the term *victim* connotes powerlessness and hopelessness; a more empowering term is *survivor*. Women who have identified their abuse may appear passive, hostile, anxious, depressed, or hysterical because they may think

TABLE 3-2 MYTHS AND FACTS ABOUT INTIMATE PARTNER VIOLENCE

MYTHS	FACTS
Battering occurs in a small percentage of the population.	One fourth of all women experience battering by an intimate partner.
Being pregnant protects the woman from battering.	From 4% to 8% of all women who are battered are battered during pregnancy. Battering frequently begins or escalates in frequency and intensity during pregnancy. Pregnancy may be the result of forced sex or of the man's control of contraception.
Battering occurs only in "problem" or lower-class families.	Intimate partner violence can occur in any family. Although lower-income families have a higher reported incidence of battering, it also occurs in middle- and upper-income families. Incidence is not accurately known because of the tendency of middle- and upper-income families to hide their battering.
Battered women like to be beaten and deliberately provoke the attack. They are masochistic.	Women are terrified of their assailants and go to great lengths to avoid a confrontation. In some cases, the woman may provoke her partner to release tension that, if left unchecked, might lead to a more severe beating and possible death.
Only men with psychologic problems abuse women.	Many batterers are successful professionals, including politicians, ministers, physicians, and lawyers. Research indicates that only a small number of abusers have psychologic problems.
Only people who come from abusive families end up in abusive relationships.	Most battered women report that their partners were the first person to beat them.
Alcohol and drug abuse cause battering.	Although alcohol may be involved in abusive incidents, it is not the cause. Many batterers use alcohol as an excuse to batter and shift the blame to the alcohol.
Women would leave the relationship if the abuse were really that bad.	Women who stay in the relationship do so out of fear and financial dependence. Shelters have long waiting lists.
Batterers and battered women cannot change.	Counseling may effectively help both batterers and battered women.

Data from Gelles R: *Intimate violence in families,* ed 3, Thousand Oaks, CA: 1997, Sage; National Institute on Alcohol Abuse and Alcoholism: Alcohol, violence, and aggression, *Alcohol Alert,* 38:1–6, 1997; National Women's Health Information Center: Violence against women, 2013, www.4woman.gov/violence/index.cfm.

they are at the mercy of the man's temper or that he is "out of control." In addition, they may be embarrassed, afraid, angry, sad, and shocked. Box 3-11 summarizes guidelines for communicating with abused women.

It is imperative that the woman has knowledge of resources available to her and a plan of action if she stays with the battering partner. First, the nurse should provide services and telephone numbers of a hotline and the battered women's shelter or other safe haven. The woman can be offered use of a telephone to call the shelter if this is an option she chooses. If she chooses to go back to the abuser, a safety plan includes necessities for a quick escape: a bag packed with personal items for an overnight stay (can be hidden or left with a neighbor), money or a checkbook, an extra set of car keys, and any legal documents for identification. Legal options such as those for restraining orders or arrest of the perpetrator also are important aspects of the safety plan. A restraining order can be obtained from the county court or police department 24 hours a day. Shelters also can be helpful with assistance in obtaining orders of protection. If the woman chooses not to act in the middle of a violent episode, she may use the hotline or shelter for some counseling when the threat of harm is no longer present.

Nurses should screen all women entering the health care system for abuse. Abuse is a life-threatening public health problem that affects millions of women and their children. The risk for intimate partner violence increases during pregnancy and after separation or divorce. Help for the woman may depend on the sensitivity with which the nurse screens for abuse, the discovery of abuse, and subsequent intervention. The nurse must be familiar with the laws governing abuse in the state in which she or he practices.

Pocket cards listing emergency numbers (abuse counseling, legal protection, and emergency shelter) can be obtained from local police departments, women's shelters, or emergency departments. It is helpful to have these on hand in the setting where screening is done.

Battering During Pregnancy

Estimates of prevalence of battering in pregnancy vary, ranging from 4% to 8% to as high as 20%. Most women abused before pregnancy will be abused during pregnancy, and the incidence may escalate. Abuse also may happen for the first time during pregnancy. Pregnant adolescents are abused at higher rates than are adult women; thus they should be considered at high risk. Battering during pregnancy in teenagers constitutes a particularly difficult situation. Adolescents may be more trapped in the abusive relationship than adult women because of their inexperience. They may ignore the violence because the jealous and controlling behavior is interpreted as love and devotion. Because pregnancy in young adolescent girls is frequently the result of sexual abuse, feelings about the pregnancy should be assessed.

During pregnancy the nurse should assess for abuse at each prenatal visit and on admission to labor. Battering episodes initiate or increase in pregnancy for a variety of reasons: (1) the biopsychosocial stresses of pregnancy may strain the relationship beyond the couple's ability to cope, and frustration is followed by violence; (2) the man may be jealous of the fetus, resenting the intrusion into the couple's relationship and the woman's displacement of attention; (3) the man may be angry at the unborn child or the woman; and (4) the beating may be the man's conscious or subconscious attempt to end the pregnancy. After birth, the mother may be so physically and emotionally drained that she may have difficulty **bonding** with her infant. She may be at risk for becoming an abusive mother whether or not she remains in the abusive relationship.

A pregnant woman is often accompanied by her husband to the prenatal appointment, especially if the woman does not speak English and the husband does. Unless an interpreter is available, it is difficult to interview the woman alone; in addition, asking questions about abuse through an interpreter is more difficult unless the interpreter is a woman and can communicate the nurse's sensitivity and concern accurately.

ABUSE ASSESSMENT SCREEN

- Are you with a spouse or partner who threatens or physically hurts you?
  - Yes _____ No _____
- Are you with a spouse or partner who emotionally hurts you?
  - Yes _____ No _____
- Within the past year or in this pregnancy (if the woman is pregnant) has anyone hit, slapped, kicked, or otherwise hurt you?
  - Yes _____ No _____
  - If yes, by whom _____
  - Number of times _____
  - Mark the area of injury on the body map.
- Has anyone forced you to have sexual activities that made you uncomfortable?
  - Yes _____ No _____
  - If yes, by whom _____
  - Number of times _____
- Are you afraid of your partner or anyone you listed above?
  - Yes _____ No _____

Screening tool for domestic violence. www.acog.org/About_ACOG/ACOG_Departments/Violence_Against_Women/Are_you_being_abused; Nursing Research Consortium on Violence and Abuse [1991].)

BOX 3-10 SIGNS OF INTIMATE PARTNER VIOLENCE

- Overuse of health services
- Vague, nonspecific complaints
- Missed appointments
- Unexplainable injuries
- Untreated serious injuries
- Injuries not matching the description
- Intimate partner never leaving the patient's side
- Intimate partner insisting on telling the story of the injury

Data from Krieger CL: Intimate partner violence: a review for nurses, *Nurs Women's Health* 12(3):224–234, 2008.

LEGAL TIP: Reporting Requirements for Domestic Violence

Domestic violence is considered a crime in all states, but it varies between misdemeanor and felony offenses, the majority being misdemeanors. Forty states and the District of Columbia have laws that mandate reporting by health care providers in situations in which the woman has an injury that may be caused by a deadly weapon. Some states also require reports when there is a reason to believe that the woman's injury may have resulted from an illegal act or act of violence. Because of the wide variation from state to state in mandatory reporting, nurses must be knowledgeable about the reporting requirements of the state in which they practice.

BOX 3-11 GUIDELINES FOR COMMUNICATING WITH ABUSED WOMEN

What *Not* to Say

1. Do not ask "why." This question "revictimizes" and blames the victim.
2. Do not talk negatively about the abuser to the victim. She may become defensive and stop talking.
3. Do not talk directly to the abuser about your suspicions of abuse. The abuser will assume the victim told you, and the victim risks retaliation.

What to Say

1. "I'm afraid for your safety (and the safety of your children)."
2. "I believe you."
3. "It is progressive and will only get worse."
4. "You deserve better than this. You deserve to be treated with respect."
5. "You are not alone."
6. "It is a crime."
7. "I'm here for you."

What to Do

1. Empower the victim.
2. Sit down with her.
3. Assure her of total privacy and confidentiality (but only if you can).
4. Use your best listening skills.
5. Call 911 and report any incident of imminent danger.
6. Give the woman the telephone number of the nearest battered women's shelter.

BOX 3-12 SPIRITUAL WELLNESS SELF-ASSESSMENT

The more questions for which you have an answer other than "I don't know," the higher the level of spiritual wellness.

1. What is your purpose in life?
2. What activities do you do regularly that bring you joy?
3. Do you believe in a higher power?
4. Who can you count on for encouragement and/or support?
5. To whom do you give encouragement and/or support?
6. Who loves you?
7. Whom do you love or care about?
8. In what areas are you growing?
9. What activities nurture you?
10. Is there something that you do just for yourself every day?
11. How do you go about forgiving yourself?
12. How do you go about forgiving others?
13. To whom do you confide your hopes, dreams, and pain?
14. What do you hope for in the future?
15. What do you do regularly just for fun?
16. When do you reach out to people?
17. What goals do you have for 6 months from now?
18. What goals do you have for 2 years from now?
19. Do you look forward to getting up in the morning?
20. Would you like to live to be 100?

Data from Condon M: Women's health: Body, mind, spirit: an integrated approach to wellness and illness, Upper Saddle River, NJ, 2004, Prentice-Hall.

SPIRITUAL APPROACHES TO WOMEN'S HEALTH PROMOTION

Many women find that spirituality is helpful in maintaining wellness as well as coping with illness. Spirituality refers to the essence of our being and humanity, reflected in a connection to a Sacred Source (Burkhardt and Nagai-Jacobson, 2013). The concept of Sacred Source is experienced in different ways, with some experiencing it as a person, some as a presence, and some as a non-describable mystery (Burkhardt and Nagai-Jacobson, 2013). The idea of connection is important, and experiencing this connection in a sacred space is central to spirituality. Spirituality may be experienced within a context of organized religion. Nurses, taking a holistic approach to women's wellness, must be sensitive and nonjudgmental to the spiritual aspect of their patients. In an optimal healing approach to care, nurses can facilitate and encourage the patient to express her spirituality in a way that is comfortable for the patient. Box 3-12 presents a spiritual wellness self-assessment guide.

ASSESSMENT OF THE WOMAN: HISTORY AND PHYSICAL EXAMINATION

Trends in women's health have expanded beyond a reproductive focus to include a holistic approach to health care across the life span and place women's health within the scope of primary care. Women's health assessment and screening focus on a systems evaluation that begins with a careful history and physical examination. During assessment and evaluation, the responsibility for self-management, health promotion, and enhancement of wellness is emphasized.

FIG 3-11 Nurse interviews a woman as part of routine history and physical examination. (Courtesy Ed Lowdermilk, Chapel Hill, NC.)

In a market-driven system such as managed care, specific guidelines may be provided for health screening by the insurer or the managed care organization. A nurse often takes the history, orders diagnostic tests, interprets test results, makes referrals, coordinates care, and directs attention to problems requiring medical intervention. Advanced practice nurses who have specialized in women's health such as nurse practitioners, clinical nurse specialists, and nurse-midwives perform complete physical examinations, including gynecologic examinations.

History

Contact with the woman usually begins with an interview, which is an integral part of the history. This interview should be conducted in a private, comfortable, and relaxed setting (Fig. 3-11). The nurse is seated and makes sure that the woman is comfortable. The woman is addressed by her title and name (e.g., Mrs. Martinez), and the nurse introduces herself or himself using name and title. It is important to phrase questions in a sensitive and nonjudgmental manner. Body language should match oral communication. The nurse is aware of a woman's vulnerability and assures her of strict confidentiality. For many women, fear, anxiety, and modesty make the examination a dreaded and stressful experience. Many women are uninformed, misguided by myths, or afraid they will appear ignorant by asking questions about sexual or reproductive functioning. The woman is assured that no question is irrelevant.

The history begins with an open-ended question such as "What brings you into the office/clinic/hospital today?" and is furthered by other questions such as "Anything else?" and "Tell me about it." Additional ways to encourage women to share information include:

- **Facilitation**: Using a word or posture that communicates interest such as leaning forward, making eye contact, or saying "Mm-hmmm" or "Go on"
- **Reflection:** Repeating a word or phrase that a woman has used
- **Clarification**: Asking the woman what is meant by a stated word or phrase
- **Empathic Responses**: Acknowledging the feelings of a woman by statements such as "That must have been frightening"

- **Confrontation**: Identifying something about the woman's behavior or feelings not expressed verbally or apparently inconsistent with her history
- **Interpretation**: Putting into words what you infer about the woman's feelings or about the meaning of her symptoms, events, or other matters

Nurses need to develop rapport and **trust** with their patients as they take a history; because communication within a caring context is core to nursing practice, nurses are well suited to taking a comprehensive patient history. Nurses should ask questions incrementally to build a comprehensive understanding. They should also share insights with the woman by eliciting her concerns or thoughts as well as offering clarification to her (Fawcett and Rhynas, 2012).

At a woman's first visit, she is often expected to fill out a form with biographic and historical data before meeting with the examiner. This form aids the health care provider in completing the history during the interview. Most forms include information about these categories:

- Biographic data
- Reason for seeking care
- Present health or history of present illness
- Past health
- Family history
- Screening for abuse
- Review of systems
- Functional assessment (activities of daily living)

Box 3-13 describes a complete health history based on the categories just mentioned.

Physical Examination

In preparation for the physical examination, the woman is instructed to undress and she is given a gown to wear during the examination. She is usually given the opportunity to undress privately. Objective data are recorded by system or location. A general statement of overall health status is a good way to start. Findings are described in detail.

- **General appearance**: age, race, sex, state of health, posture, height, weight, development, dress, hygiene, affect, alertness, orientation, cooperativeness, and communication skills
- **Vital signs**: temperature, pulse, respiration, blood pressure
- **Skin**: color; integrity; texture; hydration; temperature; edema; excessive perspiration; unusual odor; presence and description of lesions; hair texture and distribution; nail configuration, color, texture, and condition; presence of nail clubbing
- **Head**: size, shape, trauma, masses, scars, rashes, or scaling; facial symmetry; presence of edema or puffiness
- **Eyes**: pupil size, shape, reactivity, conjunctival injection, scleral icterus, fundal papilledema, hemorrhage, lids, extraocular movements, visual fields and acuity
- **Ears**: shape and symmetry, tenderness, discharge, external canal, and tympanic membranes; hearing—Weber should be midline (loudness of sound equal in both ears) and Rinne negative (no conductive or sensorineural hearing loss); should be able to hear whisper at 3 feet
- **Nose**: symmetry, tenderness, discharge, mucosa, turbinate inflammation, frontal or maxillary sinus tenderness; discrimination of odors
- **Mouth and throat**: hygiene; condition of teeth; dentures; appearance of lips, tongue, buccal and oral mucosa; erythema; edema; exudate; tonsillar enlargement; palate; uvula; gag reflex; ulcers
- **Neck**: mobility, masses, range of motion, tracheal deviation, thyroid size, carotid bruits
- **Lymphatic**: cervical, intraclavicular, axillary, trochlear, or inguinal adenopathy; size, shape, tenderness, and consistency
- **Breasts**: skin changes, dimpling, symmetry, scars, tenderness, discharge, masses; characteristics of nipples and areolae
- **Heart**: rate, rhythm, murmurs, rubs, gallops, clicks, heaves, or precordial movements
- **Peripheral vascular**: jugular vein distention, bruits, edema, swelling, vein distention, Homans' sign, or tenderness of extremities
- **Lungs**: chest symmetry with respirations, wheezes, crackles, rhonchi, vocal fremitus, whispered pectoriloquy, percussion, and diaphragmatic excursion; breath sounds equal and clear bilaterally
- **Abdomen**: shape, scars, bowel sounds, consistency, tenderness, rebound, masses, guarding, organomegaly, liver span, percussion (tympany, shifting, dullness), or costovertebral angel tenderness
- **Extremities**: edema, ulceration, tenderness, varicosities, erythema, tremor, or deformity
- **Genitourinary**: external genitalia, perineum, vaginal mucosa, cervix; inflammation, tenderness, discharge, bleeding, ulcers, nodules, or masses; internal vaginal support, bimanual and rectovaginal palpation of cervix, uterus, and adnexa
- **Rectal**: sphincter tone, masses, hemorrhoids, rectal wall contour, tenderness, and stool for occult blood
- **Musculoskeletal**: posture, symmetry of muscle mass, muscle atrophy, weakness, appearance of joints, tenderness or crepitus, joint range of motion, instability, redness, swelling, or spinal deviation
- **Neurologic**: mental status, orientation, memory, mood, speech clarity and comprehension, cranial nerves II to XII, sensation, strength, deep tendon and superficial reflexes, gait, balance, and coordination with rapid alternating motions

Cultural Considerations and Communication Variations in the History and Physical

Recognizing signs and symptoms of disease and deciding to seek treatment are influenced by cultural perceptions. Culture evolves over time and is a system of symbols that are learned, shared, and passed on through generations of a social group. In recognizing the value of these differences, the nurse can modify the plan of care to meet the needs of each woman. Modifications may be necessary for the physical examination. In many cultures a woman examiner is preferred. In some cultures it may be considered inappropriate for the woman to disrobe completely for the physical examination.

Communication may be hindered by different beliefs, even when the nurse and woman speak the same language. Examples of communication variations are listed in the Cultural Competence box.

History and Physical Examination in Women with Disabilities

Women with emotional or physical disorders have special needs. Women who have vision, hearing, emotional, or physical disabilities should be respected and involved in the assessment and physical examination to the full extent of their capabilities. The nurse should communicate openly, directly, and with sensitivity. It is often helpful to learn about the disability directly from the woman

BOX 3-13 HEALTH HISTORY AND REVIEW OF SYSTEMS

Identifying data: Name, age, race, sex, marital status, occupation, religion, and ethnicity

Reason for seeking care: A response to the question, "What problem or symptom brought you here today?" More than one reason? Focus on the one she thinks is most important.

Present health: Current health status is described with attention to the following:

- *Use of safety measures:* seat belts, bicycle helmets, designated driver
- Exercise and leisure activities: regularity
- *Sleep patterns:* length and quality
- *Sexuality:* Is she sexually active? With men, women, or both? Risk-reducing sex practices?
- Diet, *including beverages:* 24-hour dietary recall
- *Nicotine, alcohol, illicit or recreational drug use:* type, amount, frequency, duration, and reactions
- *Environmental and chemical hazards:* home, school, work, and leisure setting; exposure to extreme heat or cold, noise, industrial toxins such as asbestos or lead, pesticides, radiation, cat feces, or cigarette smoke

History of present illness: A chronologic narrative of the problem that includes a description of the following—Location, quality or character, quantity or severity, timing (onset, duration, frequency), setting, factors that aggravate or relieve, associated factors, and woman's perception of the meaning of the symptom

Past health:

- *Infectious diseases:* e.g., measles, mumps, rubella, tuberculosis (TB), hepatitis, sexually transmitted infections (STIs)
- *Chronic disease and system disorders:* e.g., arthritis, cancer, diabetes, heart, lung, kidney
- *Adult injuries, accidents*
- *Hospitalizations, operations, blood transfusions*
- *Obstetric history*
- *Allergies:* medications, previous transfusion reactions, environmental allergies
- *Immunizations:* e.g., diphtheria, pertussis, tetanus, mumps, rubella, influenza
- *Last date of screening tests:* e.g., Pap test, mammogram, cholesterol test
- *Current medications:* name, dose, frequency, duration, reason for taking, and compliance with prescription medications; home remedies, over-the-counter drugs, vitamin and mineral or herbal supplements used

Family history: Information about the ages and health of family members. Check for history of diabetes, heart disease, or other chronic disorders.

Screen for abuse: Has she ever been hit, kicked, slapped, or forced to have sex against her wishes? Verbally or emotionally abused? History of childhood sexual abuse? If yes, has she received counseling or does she need referral?

Review of systems: It is probable that all questions in each system will not be included every time a history is taken. The essential areas to be explored are listed in the following head-to-toe sequence. If a woman gives a positive response to a question about an essential area, more detailed questions should be asked.

- *General:* weight change, fatigue, weakness, fever, chills, or night sweats
- *Skin:* skin, hair, and nail changes; itching, bruising, bleeding, rashes, sores, lumps, or moles
- *Lymph nodes:* enlargement, inflammation, pain, or drainage
- *Head:* trauma, vertigo (dizziness), convulsive disorder, syncope (fainting); headache: location, frequency, pain type, nausea and vomiting, or visual symptoms present
- *Eyes:* glasses, contact lenses, blurriness, tearing, itching, photophobia, diplopia, inflammation, trauma, cataracts, glaucoma, or acute visual loss
- *Ears:* hearing loss, tinnitus (ringing), vertigo, discharge, pain, fullness, recurrent infections, or mastoiditis
- *Nose and sinuses:* trauma, rhinitis, nasal discharge, epistaxis, obstruction, sneezing, itching, allergy, or smelling impairment
- *Mouth, throat, and neck:* hoarseness, voice changes, soreness, ulcers, bleeding gums, goiter, swelling, or enlarged nodes
- *Breasts:* masses, pain, lumps, dimpling, nipple discharge, fibrocystic changes, or implants; breast self-examination practice
- *Respiratory:* shortness of breath, wheezing, cough, sputum, hemoptysis
- *Cardiovascular:* hypertension, rheumatic fever, murmurs, angina, palpitations, dyspnea, tachycardia, orthopnea, edema, chest pain, cough, cyanosis, cold extremities, ascites, phlebitis, or skin color changes
- *Gastrointestinal:* appetite, nausea, vomiting, indigestion, dysphagia, abdominal pain, ulcers, bleeding with stools or black, tarry stools, diarrhea, constipation, bowel movement frequency, food intolerance, hemorrhoids, jaundice, or hepatitis
- *Genitourinary:* frequency, hesitancy, urgency, polyuria, dysuria, hematuria, nocturia, incontinence, stones, infection, or urethral discharge; menstrual history, dyspareunia, discharge, sores, itching
- *Sexual health and sexual activity:* with men, women, or both; contraceptive use; sexually transmitted infections
- *Peripheral vascular:* coldness, numbness and tingling, leg edema, varicose veins, thromboses, or emboli
- *Endocrine:* heat and cold intolerance, dry skin, excessive sweating, polyuria, polydipsia, polyphagia, thyroid problems, diabetes, or secondary sex characteristic changes
- *Hematologic:* anemia, easy bruising, bleeding, petechiae, purpura, or transfusions
- *Musculoskeletal:* muscle weakness, pain, joint stiffness, scoliosis, lordosis, kyphosis, range-of-motion, instability, redness, swelling, arthritis, or gout
- *Neurologic:* loss of sensation, numbness, tingling, tremors, weakness, vertigo, paralysis, fainting, twitching, blackouts, seizures, convulsions, loss of consciousness or memory
- *Mental status:* moodiness, depression, anxiety, obsessions, delusions, illusions, or hallucinations
- *Functional assessment:* ability to care for self

while maintaining eye contact. Family and significant others should be relied on only when necessary. The assessment and physical examination can be adapted to each woman's individual needs.

Communication with a woman who is hearing-impaired can be accomplished without difficulty. Many of these women can read lips, write, or both. The interviewer who speaks and enunciates each word slowly and in full view may be easily understood. If a woman is not comfortable with lip reading, she may use an interpreter. In this case it is important to continue to address the woman directly, avoiding the temptation to speak directly with the interpreter.

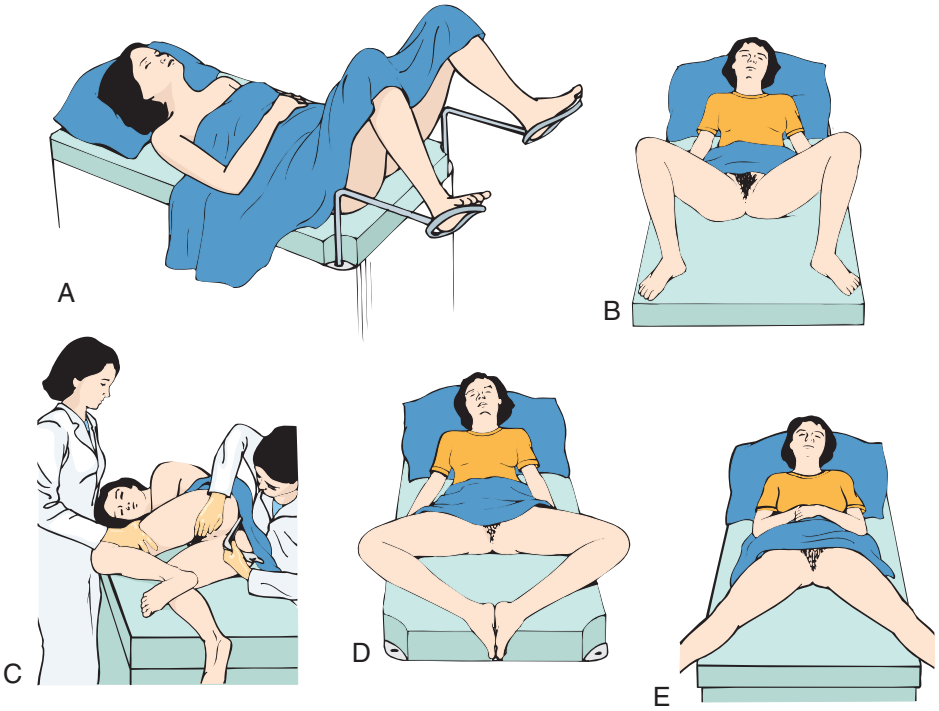

FIG 3-12 Lithotomy and variable positions for women who have a disability. **A,** Lithotomy position. **B,** M-shaped position. **C,** Side-lying position. **D,** Diamond-shaped position. **E,** V-shaped position.

CULTURAL COMPETENCE

Communication Variations

- Conversational style and pacing: Silence may show respect or acknowledgment that the listener has heard. In cultures in which a direct "no" is considered rude, silence may mean no. Repetition or loudness may mean emphasis or anger.
- Personal space: Cultural conceptions of personal space differ. Based on one's culture, for example, someone may be perceived as distant for backing off when approached or aggressive for standing too close.
- Eye contact: Eye contact varies among cultures from intense to fleeting. Consistent with the effort to refrain from invading personal space, avoiding direct eye contact may be a sign of respect.
- Touch: The norms about how people should touch each other vary among cultures. In some cultures, physical contact with the same sex (embracing, walking hand in hand) is more appropriate than that with an unrelated person of the opposite sex.
- Time orientation: In some cultures, involvement with people is more valued than being "on time." In other cultures, life is scheduled and paced according to clock time, which is valued over personal time.

Data from Galanti G: *Caring for patients from different cultures*, ed 4. Philadelphia, 2008, University of Pennsylvania Press; Mattson S: Striving for cultural competence: providing care for the changing face of the US, *AWHONN Lifelines* 4(3):48–52, 2000.

The visually impaired woman needs to be oriented to the examination room and may have her guide dog with her. As with all patients, the visually impaired woman needs a full explanation of what the examination entails before proceeding. Before touching her, the nurse explains, "Now I am going to take your blood pressure. I am going to place the cuff on your right arm." The woman can be asked if she would like to touch each of the items that will be used in the examination to reduce her anxiety.

Many women with physical disabilities cannot comfortably lie in the lithotomy position for the pelvic examination. Several alternative positions may be used, including a lateral (side-lying) position, a V-shaped position, a diamond-shaped position, and an M-shaped position (Fig. 3-12). The woman can be asked what has worked best for her previously. If she has never had a pelvic examination or has never had a comfortable pelvic examination, the nurse proceeds slowly by showing her a picture of various positions and asking her which one she prefers. The nurse's support and reassurance can help the woman relax, which will make the examination go more smoothly.

History and Physical Examination in Adolescent Girls (Ages 13 to 19)

As a young woman matures, she should be asked the same questions that are included in any history. Particular attention should be paid to hints about risky behaviors, eating disorders, and depression. Sexual activity is addressed after rapport has been established. It is best to talk to a teen with the parent (or partner or friend) out of the room. The nurse should engage with the patient in a sensitive manner, using active listening and conveying a nonjudgmental stance.

Injury prevention should be a part of the counseling at routine health examinations, with special attention to seat belts, helmets, firearms, recreational hazards, and sports involvement. The use of drugs and alcohol and the nonuse of seat belts contribute to motor vehicle injuries, accounting for the greatest proportion of accidental deaths in women. Contraceptives/STI prevention information may be needed for teens who are sexually active.

To provide developmentally appropriate care, it is important to review the major tasks for women in this stage of life. Major tasks

for teens include values assessment; education and work goal setting; formation of peer relationships that focus on love, commitment, and becoming comfortable with sexuality; and separation from parents. The teen is egocentric as she progresses rapidly through emotional and physical change. Her feelings of invulnerability may lead to misconceptions such as the belief that unprotected sexual intercourse will not lead to pregnancy.

Pelvic Examination

Many women fear the gynecologic portion of the physical examination. The nurse can be instrumental in allaying these fears by providing information and assisting the woman to express her feelings to the examiner.

The woman is assisted into the lithotomy position (see Fig. 3-12, *A*) for the pelvic examination. When she is in the lithotomy position, the woman's hips and knees are flexed, with buttocks at the edge of the table, and her feet are supported by heel or knee stirrups.

Some women prefer to keep their shoes or socks on, especially if the stirrups are not padded. Many women express feelings of vulnerability and strangeness when in the lithotomy position. During the procedure the nurse assists the woman with relaxation techniques (Box 3-14).

Many women find it distressing to attempt to converse in the lithotomy position. Most women appreciate an explanation of the procedure as it unfolds, as well as coaching for the type of sensations they may expect. Generally, however, women prefer not to have to respond to questions until they are again upright and at eye level with the examiner. Being asked questions during the procedure, especially if they cannot see their questioner's eyes, may make women tense.

A teen's first speculum examination is the most important because she will develop perceptions that will remain with her for future examinations. What the examination entails should be discussed with the teen while she is dressed. Models or illustrations can be used to show exactly what will happen. All of the necessary equipment should be assembled so there are no interruptions. Pediatric specula that are 1 to 1.5 cm wide can be inserted with minimal discomfort. If the teen is sexually active, a small adult speculum may be used.

External Inspection

The examiner wears gloves and sits at the foot of the table for the inspection of the external genitalia and the speculum examination. In good lighting, external genitalia are inspected for sexual maturity, clitoris, labia, perineum, and lesions indicative of STIs. After childbirth or other trauma, healed scars may be present.

External Palpation

Before touching the woman, the examiner explains what is going to be done and what the woman should expect to feel (e.g., pressure). The examiner may touch the woman in a less sensitive area such as the inner thigh to alert her that the genitalia examination is beginning. This gesture may put the woman more at ease. The labia are spread apart to expose the structures in the vestibule: urinary meatus, Skene glands, vaginal orifice, and Bartholin glands (Fig. 3-13). To assess Skene glands, the examiner inserts one finger into the vagina and "milks" the area of the urethra. Any exudate from the urethra or the Skene glands is cultured. Masses and erythema of either structure are assessed further. Ordinarily the openings to the Skene glands are not visible; prominent openings may be seen if the glands are infected (e.g., with gonorrhea). During the examination

BOX 3-14 NURSE'S ROLE IN ASSISTING WITH PELVIC EXAMINATIONS

1. Wash hands. Assemble equipment (see illustration below).
2. Ask woman to empty her bladder before the examination (obtain clean-catch urine specimen as needed).
3. Assist with relaxation techniques. Have the woman place her hands on her chest at about the level of the diaphragm and breathe deeply and slowly.
4. Encourage the woman to become involved with the examination if she shows interest. For example, a mirror can be placed so that she can see the area being examined.
5. Assess for and treat signs of problems such as supine hypotension.
6. Warm the speculum in warm water if a prewarmed one is not available.
7. Instruct the woman to bear down when the speculum is being inserted.
8. Apply gloves and assist the examiner with collection of specimens for cytologic examination, such as a Pap test. After handling specimens, remove gloves and wash hands.
9. Lubricate the examiner's fingers with water or water-soluble lubricant before bimanual examination.
10. Assist the woman at completion of the examination to a sitting position and then a standing position.
11. Provide tissues to wipe lubricant from perineum.
12. Provide privacy for the woman while she is dressing.

Equipment used for pelvic examination. (Courtesy Michael S. Clement, MD, Mesa, AZ.)

the examiner keeps in mind the data from the review of systems such as history of burning on urination.

The vaginal orifice is examined. Hymenal tags are normal findings. With one finger still in the vagina, the examiner repositions the index finger near the posterior part of the orifice. With the thumb outside the posterior part of the labia majora, the examiner compresses the area of Bartholin glands located at the 8 o'clock and 4 o'clock positions and looks for swelling, discharge, and pain.

The support of the anterior and posterior vaginal wall is assessed. The examiner spreads the labia with the index and middle finger and asks the woman to strain down. Any bulge from the anterior wall (urethrocele or **cystocele**) or posterior wall **(rectocele)** is noted and compared with the history, such as difficulty starting the stream of urine or constipation.

The perineum (area between the vagina and anus) is assessed for scars from old lacerations or episiotomies, thinning, fistulas, masses, lesions, and inflammation. The anus is assessed for hemorrhoids, hemorrhoidal tags, and integrity of the anal sphincter. The anal area is also assessed for lesions, masses, abscesses, and tumors. If there is

FIG 3-13 External examination: separation of the labia. (From Wilson SF, Giddens JF: *Health assessment for nursing practice*, ed 5, St Louis, 2013, Mosby.)

a history of STI, the examiner may want to obtain a culture specimen from the anal canal at this time. Throughout the genital examination the examiner notes any odor, which may indicate infection or poor hygiene.

Vulvar Self-Examination. The pelvic examination provides a good opportunity for the practitioner to emphasize the need for regular *vulvar self-examination (VSE)* and to teach this procedure. Because there has been a dramatic increase in cancerous and precancerous conditions of the vulva in recent years, VSE should be an integral part of preventive health care for all women who are sexually active or 18 years of age or older. VSE should be performed monthly between menses or more often if there are symptoms or a history of serious vulvar disease. Most lesions, including malignancy, condyloma acuminatum (wartlike growth), and Bartholin cysts, can be seen or palpated and are easily treated if diagnosed early.

The VSE can be performed by the practitioner and woman together by using a mirror. A simple diagram of the anatomy of the vulva can be given to the woman, with instructions to perform the examination herself that evening to reinforce what she has learned. She does the examination in a sitting position with adequate lighting, holding a mirror in one hand and using the other hand to expose the tissues surrounding the vaginal introitus. She then systematically examines the mons pubis, clitoris, urethra, labia majora, perineum, and perianal area and palpates the vulva, noting any changes in appearance or abnormalities such as ulcers, lumps, warts, and changes in pigmentation.

Internal Examination

A vaginal speculum consists of two blades and a handle. Specula come in a variety of types and styles. A vaginal speculum is used to view the vaginal vault and cervix. The speculum is gently placed into the vagina and inserted to the back of the vaginal vault. The blades are opened to reveal the cervix and are locked into the open position. The cervix is inspected for position and appearance of the os: color, lesions, bleeding, and discharge (Fig. 3-14, *A-D*). Cervical findings that are not within normal limits include ulcerations, masses, inflammation, and excessive protrusion into the vaginal vault. Anomalies such as a cockscomb (a protrusion over the cervix that looks like a rooster's comb), a hooded or collared cervix (seen in diethylstilbestrol [DES] daughters), or polyps are noted.

Collection of Specimens. The collection of specimens for cytologic examination is an important part of the gynecologic examination. Infection can be diagnosed by examination of specimens collected during the pelvic examination. These infections include candidiasis, trichomoniasis, bacterial vaginosis, group B streptococcus, gonorrhea, chlamydia, and herpes simplex virus. Once the diagnoses have been made, treatment can be instituted.

Papanicolaou Test. Carcinogenic conditions, whether potential or actual, can be determined by examination of cells from the cervix collected during the pelvic examination (i.e., a Pap test) (Box 3-15).

Vaginal Wall Examination. After the specimens are obtained, the vagina is viewed when the speculum is rotated. The speculum blades are unlocked and partially closed. As the speculum is withdrawn, it is rotated; the vaginal walls are inspected for color, lesions, rugae, fistulas, and bulging.

Bimanual Palpation

The examiner stands for this part of the examination. A small amount of lubricant is placed on the first and second fingers of the gloved hand for the internal examination. To avoid tissue trauma and contamination, the thumb is abducted, and the ring and little fingers are flexed into the palm (Fig. 3-15).

The vagina is palpated for distensibility, lesions, and tenderness. The cervix is examined for position, shape, consistency, motility, and lesions. The fornix around the cervix is palpated.

The other hand is placed on the abdomen halfway between the umbilicus and symphysis pubis and exerts pressure downward toward the pelvic hand. Upward pressure from the pelvic hand traps reproductive structures for assessment by palpation. The uterus is assessed for position, size, shape, consistency, regularity, motility, masses, and tenderness.

With the abdominal hand moving to the right lower quadrant and the fingers of the pelvic hand in the right lateral fornix, the adnexa is assessed for position, size, tenderness, and masses. The examination is repeated on the woman's left side.

Just before the intravaginal fingers are withdrawn, the woman is asked to tighten her vagina around the fingers as much as she can. If the muscle response is weak, the woman is assessed for her knowledge about **Kegel exercises.**

Rectovaginal Palpation

To prevent contamination of the rectum from organisms in the vagina (e.g., *Neisseria gonorrhoeae*), it is necessary to change gloves, add fresh lubricant, and then reinsert the index finger into the vagina and the middle finger into the rectum (Fig. 3-16). Insertion is facilitated if the woman strains down. The maneuvers of the abdominovaginal examination are repeated. The rectovaginal examination permits assessment of the rectovaginal septum, the posterior surface of the uterus, and the region behind the cervix and the adnexa. The vaginal finger is removed and folded into the palm, leaving the middle finger free to rotate 360 degrees. The rectum is palpated for rectal tenderness and masses.

After the rectal examination the woman is assisted into a sitting position, given tissues or wipes to cleanse herself, and afforded privacy to dress. The examiner returns after the woman is dressed to discuss findings and the plan of care.

Pelvic Examination During Pregnancy

The pelvic examination during pregnancy is done in the same way as it is during a routine examination on a nonpregnant woman. Pelvic measurements are completed, and uterine size is estimated. A Pap test may be done initially and cytologic specimens collected to test for gonorrhea, chlamydia, human papillomavirus, herpes simplex virus, and group B streptococcus. As the pregnancy

FIG 3-14 Insertion of speculum for vaginal examination. **A,** Opening of the introitus. **B,** Oblique insertion of the speculum. **C,** Final insertion of the speculum. **D,** Opening of the speculum blades. (From Wilson SF, Giddens JF: *Health assessment for nursing practice*, ed 5, St Louis, 2013, Mosby.)

progresses, the nurse inspects the woman's abdomen, palpates fetal size and position, auscultates fetal heart tones, and measures fundal height at each visit.

While the pregnant woman is in lithotomy position, the nurse must watch for supine hypotension (decrease in blood pressure) caused by the weight of the uterus pressing on the vena cava and aorta. Symptoms of supine hypotension include pallor, dizziness, faintness, breathlessness, tachycardia, nausea, clammy skin, and sweating. The woman should be positioned on her side until symptoms resolve and vital signs stabilize. The vaginal examination can be done with the woman in lateral position.

Pelvic Examination After Hysterectomy

The pelvic examination after hysterectomy is done much as it is done on a woman with a uterus. Vaginal screening using the Pap test is not recommended in women who have had a total hysterectomy with removal of the cervix for benign disease. Because of the epidemic of human papillomavirus, which causes vaginal intraepithelial neoplasia, sampling of the vaginal walls after hysterectomy may still be practiced, with schedules varying from every year to every 2 to 3 years.

Laboratory and Diagnostic Procedures

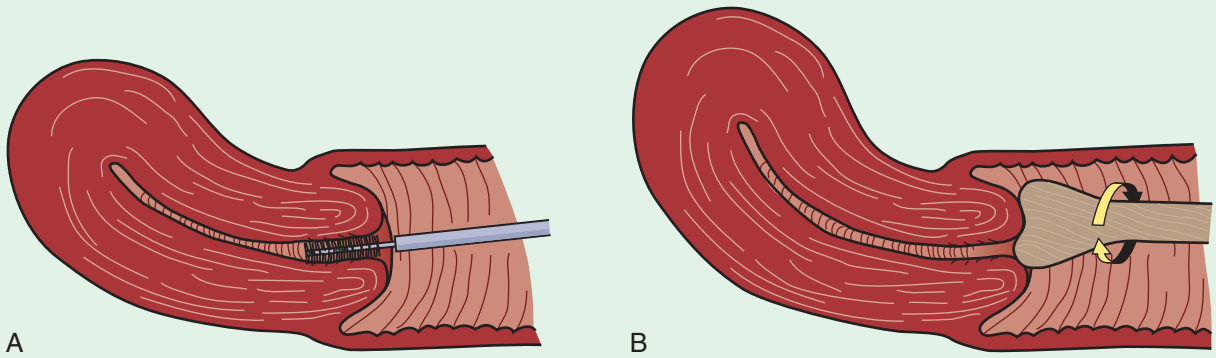
The following laboratory and diagnostic procedures are ordered at the discretion of the clinician, considering the patient and family history: hemoglobin, fasting blood glucose, total blood cholesterol, lipid profile, urinalysis, syphilis serology (Venereal Disease Research Laboratories [VDRL] or rapid plasma reagent [RPR]) and other screening tests for STIs, mammogram, tuberculosis skin testing, hearing, visual acuity, electrocardiogram, chest x-ray, pulmonary function, fecal occult blood, flexible sigmoidoscopy, and bone mineral density (dual energy x-ray absorptiometry [DEXA] scan). Results of these tests may be reported in person, by phone call, or by letter. Tests for HIV, hepatitis B, and drug screening may be offered with informed consent in high risk populations. These test results are usually reported in person.

Health Screening for Women Across the Life Span

To promote wellness and prevent illness, it is imperative that women adhere to specific screening guidelines to detect conditions that, if found early, are amenable to treatment and/or cure. Table 3-3 summarizes the screening procedures for women across the life span.

BOX 3-15 PAPANICOLAOU TEST

- In preparation, make sure the woman has not douched, used vaginal medications, or had sexual intercourse for 24 to 48 hours before the procedure. Reschedule the test if the woman is menstruating. Midcycle is the best time for the test.
- Explain to the woman the purpose of the test and what sensations she will feel as the specimen is obtained (e.g., pressure but not pain).
- The woman is assisted into a lithotomy position. A speculum is inserted into the vagina.
- The cytologic specimen is obtained before any digital examination of the vagina is made or endocervical bacteriologic specimens are taken. A cotton swab may be used to remove excess cervical discharge before the specimen is collected.
- The specimen is obtained by using an endocervical sampling device (Cytobrush, Cervex-brush, spatula, or broom) (see Figs. *A* and *B*). If the two-sample method of obtaining cells is used, the Cytobrush is inserted into the canal and rotated 90 to 180 degrees, followed by a gentle smear of the entire transformation zone by using a spatula. Broom devices are inserted and rotated 360 degrees five times. They obtain endocervical and ectocervical samples at the same time. If the patient has had a hysterectomy, the vaginal cuff is sampled. Areas that appear abnormal on visualization will require colposcopy and biopsy. If using a one-slide technique, the spatula sample is smeared first. This is followed by applying the Cytobrush sample (rolling the brush in the opposite direction from which it was obtained), which is less subject to drying artifact; then the slide is sprayed with preservative within 5 seconds.



A, Collecting cells from endocervix using a Cytobrush. **B,** Obtaining cells from the transformation zone using a wooden spatula. (From Lentz GM, Lobo RA, Gershenson DM, et al: *Comprehensive gynecology*, ed 6, St Louis, 2012, Mosby.)

- The ThinPrep or SurePath Pap Test is a liquid-based method of preserving cells that reduces blood, mucus, and inflammation. The Pap specimen is obtained in the manner described above except that the cervix is not swabbed before collection of the sample. The collection device (brush, spatula, or broom) is rinsed in a vial of preserving solution that is provided by the laboratory. The sealed vial with solution is sent off to the appropriate laboratory. A special processing device filters the contents, and a thin layer of cervical cells is deposited on a slide, which is then examined microscopically. The AutoPap and Papnet tests are similar to the ThinPrep test. If cytology is abnormal, liquid-based methods allow follow-up testing for human papillomavirus (HPV) DNA with the same sample.
- Label the slides or vial with the woman's name and site. Include on the form to accompany the specimens the woman's name, age, parity, and chief complaint or reason for taking the cytologic specimens.
- Send specimens to the pathology laboratory promptly for staining, evaluation, and a written report, with special reference to abnormal elements, including cancer cells.
- Advise the woman that repeated tests may be necessary if the specimen is not adequate.
- Instruct the woman concerning routine checkups for cervical and vaginal cancer. Women vaccinated against HPV should follow the same screening guidelines as unvaccinated women. Current recommendations of the U.S. Preventive Services Task Force (USPSTF) (2012) and the American Cancer Society (ACS) (2012) for Pap tests are that women ages 21 through 65 be screened every 3 years, or for women ages 30 through 65 every 5 years (if they had a pap test plus HPV test that were both negative). These guidelines recommend no screening in women younger than 21, although if a girl becomes sexually active, the guidelines recommend that she get a Pap test within 3 years of initiating sexual activity or at age 21—whichever comes first. Women with high risk factors such as exposure to diethylstilbestrol (DES) in utero, those treated for cervical intraepithelial neoplasia (CIN) 2, CIN 3, cervical cancer, or human immunodeficiency virus (HIV) may need more frequent screening.
- Young women who have been treated with excisional procedures for dysplasia have had an increase in premature births. A large majority of the cervical dysplasias in adolescents caused by HPV resolve on their own without treatment. It is important to avoid unnecessary instrumentation and procedures that negatively affect the cervix. Women who have had a complete hysterectomy for noncancerous reasons who have no history of high-grade CIN may have routine cervical cytology testing discontinued. Women who are older than 65 years who have not had serious cervical precancer or cancer in the past 20 years may discontinue cervical cancer screening (American Cancer Society, 2012).
- Record the examination date on the woman's record.
- Communicate findings to the woman per agency protocol.

TABLE 3-3 HEALTH SCREENING GUIDELINES AND IMMUNIZATION RECOMMENDATIONS FOR WOMEN AGES 18 YEARS AND OLDER

INTERVENTION	RECOMMENDATION*
Physical Examination	
Blood pressure	Every visit, but at least every 2 years
Height and weight	Every visit, but at least every 2 years
Pelvic examination	Annually until age 70; recommended for any woman who has ever been sexually active
Breast Examination	
Clinical examination	Every 3 years, ages 20 to 39; after age 40 with periodic examination, preferably annually
High risk	Annually after age 18 with history of premenopausal breast cancer in first-degree relative
Risk Groups	
Skin examination	Family history of skin cancer or increased exposure to sunlight every 3 years between ages 20 and 40; annually after age 40; monthly mole self-examinations also recommended
Oral cavity examination	History of mouth lesions or exposure to tobacco or excessive alcohol at least annually
Laboratory and Diagnostic Tests	
Blood cholesterol (fasting lipoprotein analysis)	Between ages 20 and 45 only if high risk; Beginning at age 45 if level is within normal limits, every 5 years; more often if abnormal levels or have risk factors for coronary artery disease
Papanicolaou (Pap) test	Between ages 21 and 65—every 3 years with Pap test done Between ages 30 and 65—every 5 years if Pap test plus human papillomavirus (HPV) test done After age 65 and 3 negative tests and no risks and after total hysterectomy for benign disease—women may choose to stop screening
Mammography†	Every 1 to 2 years between ages 40 and 49 or earlier if at high risk Annually after age 40 Annually after age 50 Biennially, ages 50 to 74 After age 75, discuss with your health care provider

Continued

TABLE 3-3 HEALTH SCREENING GUIDELINES AND IMMUNIZATION RECOMMENDATIONS FOR WOMEN AGES 18 YEARS AND OLDER—cont'd

INTERVENTION	RECOMMENDATION*
Colon cancer screening	Use 1 of these 3 methods: • Fecal occult blood test annually ages 50 to 74 • Flexible sigmoidoscopy every 5 years ages 50 to 74 • Colonoscopy every 10 years ages 50 to 74 Screen more often if family history of colon cancer or polyps After age 75, discuss with your health care provider
Hearing screen	Starting at age 18, then every 10 years until 49 Every 3 years after age 50 Annually with exposure to excessive noise or when loss is suspected
Vision screen	At least once between ages 20 and 29; at least twice between ages 30 and 39; Every 2 to 4 years between ages 40 and 64; every 1 to 2 years after age 65
Risk Groups	
Fasting blood sugar	Annually with family history of diabetes or gestational diabetes or if significantly obese; every 3 to 5 years for all women older than 45 years
Thyroid-stimulating hormone (TSH) test	As determined by the health care provider
Sexually transmitted infection test (e.g., gonorrhea, syphilis, herpes)	As needed if sexually active with multiple partners and engaging in risky sexual behaviors
Chlamydia test	If sexually active, yearly until age 25; after age 25, test as needed when sexually active with new or multiple partners
Human immunodeficiency virus (HIV) test	At least once between ages 18 and 64 to determine HIV status; test if there is a high risk for HIV infection
Tuberculin skin test	Annually with exposure to persons with tuberculosis or in risk categories for close contact with the disease
Endometrial biopsy	At menopause for women at risk for endometrial cancer; repeat as needed
Bone mineral density testing	All women age 65 and older at least once; repeat testing as needed; younger women with risk for osteoporosis may need periodic screenings
Immunizations	
Tetanus-diphtheria-pertussis (Td/Tdap)	Tdap vaccine once; then booster is given every 10 years
Measles, mumps, rubella	Once if born after 1956 and no evidence of immunity
Hepatitis A	Primary series of two injections for all who are in risk categories
Hepatitis B	Primary series of three injections for all who are in risk categories
Influenza	Annually
Pneumococcal	1-2 doses between ages 19 and 64; 1 dose after age 65
Herpes zoster (shingles)	One dose at age 65
Human papillomavirus (HPV) vaccine	Primary series of three injections for girls ages 9 to women 26 years old; intended for those not previously exposed to HPV

Data from American Cancer Society (ACS): *Cancer prevention and early detection facts and figures,* Atlanta, 2012, Author; Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices: *Recommended adult immunization schedule, United States,* 2012, www.cdc.gov/vaccines; Centers for Disease Control and Prevention (CDC): Sexually transmitted diseases treatment guidelines, *MMWR Recomm Rep* 59(RR12):1–109, 2010; National Women's Health Information Center: *Screenings tests for women,* 2012, www.4woman.gov; U.S. Preventive Services Task Force: *Screening for cervical cancer,* 2012, www.preventiveservicestaskforce.org/uspstf/uspscerv.htm.

*The information in this table is only a guide; health care providers will individualize the timing of tests and immunizations for each woman.
†Note: No consensus has been reached regarding mammograms for women between 40 and 49 years of age; therefore various recommendations are listed. Women are urged to discuss circumstances with their health care providers.

KEY POINTS

- Normal feedback regulation of the menstrual cycle depends on an intact hypothalamic-pituitary-gonadal mechanism.
- The female's reproductive tract structures and breasts respond predictably to changing levels of sex steroids across her life span.
- The myometrium of the uterus is uniquely designed to expel the fetus and promote hemostasis after birth.
- Periodic health screening, including history, physical examination, and diagnostic and laboratory tests, provides the basis for overall health promotion, prevention of illness, early diagnosis of problems, and referral for management.
- Culture, religion, socioeconomic status, personal circumstances, the uniqueness of the individual, and the stage of development influence a person's recognition of need for care and the response to the health care system and therapy.
- Preconception counseling allows identification and possible remediation of potentially harmful personal and social conditions, medical and psychologic conditions, environmental conditions, and barriers to care before pregnancy occurs.
- Conditions that increase a woman's health risks also increase risks for her offspring.
- Effective educational programs about sex and family life are imperative to control the rate of teen pregnancy and STIs.
- Health promotion and prevention of illness assist women to actualize health potential by increasing motivation, providing information, and suggesting how to access specific resources.
- IPV against women is a major social and health care problem in the United States and includes physical, sexual, emotional, psychologic, and economic abuse.
- Battering affects all races; all socioeconomic, educational, and religious groups; and many pregnant women.

CHAPTER

4

Reproductive System Concerns

Deitra Leonard Lowdermilk

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Differentiate among the signs and symptoms of common menstrual disorders.
- Develop a nursing care plan for the woman with primary dysmenorrhea.
- Outline patient teaching about premenstrual syndrome.
- Relate the pathophysiology of endometriosis to associated symptoms.
- Evaluate the use of alternative therapies for menstrual disorders.
- Describe prevention and treatment of sexually transmitted infections in women.
- Summarize the care of women with selected viral infections (i.e., human immunodeficiency virus and hepatitis B virus).
- Differentiate signs, symptoms, and management of selected vaginal infections.
- Review principles of infection control for human immunodeficiency virus and bloodborne pathogens.
- Discuss the pathophysiology and emotional effects of selected benign breast conditions and malignant neoplasms of the breasts found in women.

Problems may occur at any point in the menstrual cycle. Many factors, including anatomic abnormalities, physiologic imbalances, and lifestyle, can affect the menstrual cycle. The average woman is likely to have some concerns related to her menstrual and gynecologic health at some point in her life and will experience bleeding, pain, discharge, or infections associated with her reproductive organs or functions. This chapter provides information on common menstrual problems, sexually transmitted infections, and selected other infections that can affect reproductive functions. Benign breast conditions are also discussed. Breast cancer is included because it is the most common reproductive cancer occurring in women.

MENSTRUAL DISORDERS

Once a cyclic, predictable pattern of monthly bleeding is established, women may worry about any deviation from that pattern or from what they have been told is normal for all menstruating women. A woman may be concerned about her ability to conceive and bear children or believe that she is not really a woman without monthly evidence. A sign such as amenorrhea or excess menstrual bleeding can be a source of severe distress and concern for a woman.

Amenorrhea

Amenorrhea, the absence of menstrual flow, is a clinical sign of a variety of disorders. Generally the following circumstances should be evaluated: (1) the absence of both menarche and secondary sexual characteristics by age 13 years; (2) the absence of menses by age 16.5 years, regardless of normal growth and development (primary amenorrhea); or (3) a 6-month or more cessation of menses after a period of menstruation (secondary amenorrhea) (Lobo, 2012d).

A moderately obese girl (20% to 30% above ideal weight) may have early-onset menstruation, whereas delay of onset is known to be related to malnutrition (starvation such as that with anorexia). Girls who exercise strenuously before menarche can have delayed onset of menstruation until about age 18 (Lobo, 2012d).

Although amenorrhea is not a disease, it is often a sign of disease. It may occur from any defect or interruption in the hypothalamic-pituitary-ovarian-uterine axis. It may also result from anatomic abnormalities, other endocrine disorders such as hypothyroidism or hyperthyroidism, chronic diseases such as type 1 diabetes, medications such as phenytoin (Dilantin), illicit drug abuse (opiates, marijuana, cocaine), eating disorders, strenuous exercise, emotional

stress, and oral contraceptive use. Secondary amenorrhea is commonly the result of pregnancy.

Hypogonadotropic Amenorrhea

Hypogonadotropic amenorrhea reflects a problem in the central hypothalamic-pituitary axis. In rare instances a pituitary lesion or genetic inability to produce follicle-stimulating hormone (FSH) and luteinizing hormone (LH) is at fault.

Hypogonadotropic amenorrhea often results from hypothalamic suppression as a result of stress (in the home, school, or workplace) or a sudden and severe weight loss, eating disorders, strenuous exercise, or mental illness (Wambach and Alexander, 2012). Research on the interaction between nervous system or neurotransmitter functions and hormone regulation throughout the body has demonstrated a biologic basis for the relation of stress to physiologic processes. Women who are more than 20% underweight for height or who have had rapid weight loss and women with eating disorders such as anorexia nervosa may report amenorrhea. Amenorrhea is one of the classic signs of anorexia nervosa; and the interrelation of disordered eating, amenorrhea, and premature osteoporosis has been described as the female athlete triad (George, Leonard, and Hutchinson, 2011) (www.femaleathletetriad.org). A loss of calcium from the bone, comparable to that seen in postmenopausal women, may occur with this type of amenorrhea.

Exercise-associated amenorrhea can occur in women undergoing vigorous physical and athletic training and is thought to be associated with many factors, including body composition (height, weight, and percentage of body fat); type, intensity, and frequency of exercise; nutritional status; and presence of emotional or physical stressors. Women who participate in sports emphasizing low body weight are at greatest risk, including the following:

- Sports in which performance is subjectively scored (e.g., dance, gymnastics)
- Endurance sports favoring participants with low body weight (e.g., distance running, cycling)
- Sports in which body contour–revealing clothing is worn (e.g., swimming, diving, volleyball)
- Sports with weight categories for participation (e.g., rowing, martial arts)
- Sports in which prepubertal body shape favors success (e.g., gymnastics, figure skating).

Assessment of amenorrhea begins with a thorough history and physical examination. Specific components of the assessment process depend on a patient's age—adolescent, young adult, or perimenopausal—and whether she has menstruated previously.

An important initial step, often overlooked, is to be sure that the woman is not pregnant. Once pregnancy has been ruled out by a β-human chorionic gonadotropin (hCG) pregnancy test, diagnostic tests may include FSH level, thyroid-stimulating hormone (TSH) and prolactin levels, radiographic or computed tomography (CT) scan of the sella turcica, and a progestational challenge (Lobo, 2012d).

Management. When amenorrhea is caused by hypothalamic disturbances, the nurse is an ideal health professional to assist women because many of the causes are potentially reversible (e.g., stress, weight loss for nonorganic reasons). Counseling and education are primary interventions and appropriate nursing roles. When a stressor known to predispose a woman to hypothalamic amenorrhea is identified, initial management involves addressing the stressor. Together the woman and nurse plan how the woman can decrease or discontinue medications known to affect menstruation, correct weight loss, deal more effectively with psychologic stress, address emotional distress, and alter exercise routine.

The nurse works with the woman to help her identify, cope with, and eliminate sources of stress in her life. Deep-breathing exercises and relaxation techniques are simple yet effective stress-reduction measures. Referral for biofeedback or massage therapy also may be useful. In some instances referrals for psychotherapy may be indicated.

If a woman's exercise program is thought to contribute to her amenorrhea, several options exist for management. She may decide to decrease the intensity or duration of her training or modify her diet to include the appropriate nutrition for her age. Accepting the former alternative may be difficult for one who is committed to a strenuous exercise regimen. The woman and nurse may have several sessions before the woman elects to try exercise reduction. Many young female athletes may not understand the consequences of low bone density or osteoporosis; nurses can point out the connection between low bone density and stress fractures. The nurse and woman should also investigate other factors that may be contributing to the amenorrhea and develop plans for altering lifestyle and decreasing stress.

Although research on effectiveness is inconclusive, a daily calcium intake of 1200 to 1500 mg plus 400 to 800 International Units of vitamin D and 60 to 90 mg of potassium are recommended for women experiencing amenorrhea associated with the female athlete triad. Oral contraceptives have a positive effect on bone density in amenorrheic women but are usually not used in young women with amenorrhea associated with female athlete triad unless the woman is not willing to comply with dietary and exercise recommendations or she continues to be amenorrheic even with compliance (Joy, 2012).

Dysmenorrhea

Dysmenorrhea, pain during or shortly before menstruation, is one of the most common gynecologic problems in women of all ages. Many adolescents have dysmenorrhea in the first 3 years after menarche. Young adult women ages 17 to 24 years are most likely to report painful menses. Approximately 75% of women report some level of discomfort associated with menses, and approximately 15% report severe dysmenorrhea (Lentz, 2012); however, the amount of disruption in women's lives is difficult to determine. Researchers have estimated that as many as 10% of women with dysmenorrhea have severe enough pain to interfere with their functioning for 1 to 3 days a month. Menstrual problems, including dysmenorrhea, are relatively more common in women who smoke and are obese. Severe dysmenorrhea is also associated with early menarche, nulliparity, and stress (Lentz, 2012). Traditionally dysmenorrhea is differentiated as primary or secondary. Symptoms usually begin with menstruation, although some women have discomfort several hours before onset of flow. The range and severity of symptoms are different from woman to woman and from cycle to cycle in the same woman. Symptoms of dysmenorrhea may last several hours or several days.

Pain is usually located in the suprapubic area or lower abdomen. Women describe the pain as sharp, cramping, or gripping or as a steady dull ache. For some women pain radiates to the lower back or upper thighs.

Primary Dysmenorrhea

Primary dysmenorrhea is a condition associated with ovulatory cycles. Research has shown that primary dysmenorrhea has a

CRITICAL THINKING CASE STUDY

Management of Dysmenorrhea

Cheri, 16, has come to the adolescent health clinic for a checkup. She reports that she has "really bad cramps" for the first 2 days of her period. She has been taking Midol Menstrual Complete but says that it does not help "a lot." She wants to know if anything else can be done to relieve her pain. How should the nurse respond?

1. Evidence—Is evidence sufficient to draw conclusions about what advice the nurse should give?
2. Assumptions—Describe underlying assumptions about the following issues:
   a. Causes and symptoms of primary dysmenorrhea
   b. Cyclic perimenstrual pain and discomfort
   c. Self-help strategies (e.g., comfort measures, medications)
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

FIG 4-1 Yoga asana: triangle pose. Helpful for assisting digestion and stretching and strengthening the spine; also used for dysmenorrheal and pelvic congestion. (Courtesy Julie Perry Nelson, Loveland, CO.)

biochemical basis and arises from the release of prostaglandins with menses. During the luteal phase and subsequent menstrual flow, prostaglandin F_2-alpha ($PGF_{2\alpha}$) is secreted. Excessive release of $PGF_{2\alpha}$ increases the amplitude and frequency of uterine contractions and causes vasospasm of the uterine arterioles, resulting in ischemia and cyclic lower abdominal cramps. Systemic responses to $PGF_{2\alpha}$ include backache, weakness, sweats, gastrointestinal symptoms (anorexia, nausea, vomiting, and diarrhea), and central nervous system symptoms (dizziness, syncope, headache, and poor concentration). Pain usually begins at the onset of menstruation and lasts 8 to 48 hours (Lentz, 2012).

Primary dysmenorrhea usually appears 6 to 12 months after menarche when ovulation is established. Anovulatory bleeding, common in the few months or years after menarche, is painless. Because both estrogen and progesterone are necessary for primary dysmenorrhea to occur, it is experienced only with ovulatory cycles. This problem is more common among women in their late teens and early twenties than in women in older age-groups; the incidence declines with age. Psychogenic factors may influence symptoms, but symptoms are definitely related to ovulation and do not occur when ovulation is suppressed.

Management. Management of primary dysmenorrhea depends on the severity of the problem and the individual woman's response to various treatments. Important components of nursing care are information and support. Because menstruation is so closely linked to reproduction and sexuality, menstrual problems such as dysmenorrhea can have a negative influence on sexuality and self-worth. Nurses can correct myths and misinformation about menstruation and dysmenorrhea by providing facts about what is normal. Women need support to foster their feelings of positive sexuality and self-worth.

Often you can offer more than one alternative for alleviating menstrual discomfort and dysmenorrhea, which gives women options to try to decide which works best for them (see Critical Thinking Case Study).

Heat (heating pad or hot bath) minimizes cramping by increasing vasodilation and muscle relaxation and minimizing uterine ischemia. Massaging the lower back can reduce pain by relaxing paravertebral muscles and increasing the pelvic blood supply. Soft, rhythmic rubbing of the abdomen **(effleurage)** is useful because it provides a distraction and an alternative focal point. Biofeedback, transcutaneous electrical nerve stimulation (TENS), progressive relaxation, Hatha yoga, acupuncture, and meditation are also used to decrease menstrual discomfort, although evidence is insufficient to determine their effectiveness (Lentz, 2012) (Fig. 4-1).

Exercise helps relieve menstrual discomfort through increased vasodilation and subsequent decreased ischemia. It also releases endogenous opiates (specifically beta-endorphins), suppresses prostaglandins, and shunts blood flow away from the viscera, resulting in reduced pelvic congestion. One specific exercise that nurses can suggest is pelvic rocking.

In addition to maintaining good nutrition at all times, specific dietary changes are helpful in decreasing some of the systemic symptoms associated with dysmenorrhea. Decreased salt and refined sugar intake 7 to 10 days before expected menses may reduce fluid retention. Natural diuretics such as asparagus, cranberry juice, peaches, parsley, or watermelon may help reduce edema and related discomforts. A low-fat vegetarian diet may also help minimize dysmenorrheal symptoms (Lentz, 2012).

Medications used to treat primary dysmenorrhea include prostaglandin synthesis inhibitors, primarily nonsteroidal antiinflammatory drugs (NSAIDs) (Lentz, 2012) (Table 4-1). NSAIDs are most effective if started several days before menses or at least by the onset of bleeding. All NSAIDs have potential gastrointestinal side effects, including nausea, vomiting, and indigestion. Warn all women taking them to report dark-colored stool because this may be an indication of gastrointestinal bleeding.

! NURSING ALERT

If one NSAID is ineffective, often a different one may be effective. If the second drug is unsuccessful after a 6-month trial, combined oral contraceptive pills (OCPs) may be used. Women with a history of aspirin sensitivity or allergy should avoid all NSAIDs.

TABLE 4-1 NONSTEROIDAL ANTIINFLAMMATORY AGENTS USED TO TREAT DYSMENORRHEA

DRUG	BRAND NAME AND STATUS	RECOMMENDED DOSAGE (ORAL)*	COMMON SIDE EFFECTS†	COMMENTS	CONTRAINDICATIONS
Diclofenac	Cataflam Rx	50 mg tid or 100 mg initially, then 50 mg tid up to 150 mg/day	Nausea, diarrhea, constipation, abdominal distress, dyspepsia, heartburn, flatulence, dizziness, tinnitus, itching, rash	Enteric coated; immediate release	For all NSAIDs: Do not give if woman has hemophilia or bleeding ulcers; do not give if woman has had an allergic or anaphylactic reaction to aspirin or another NSAID; do not give if woman is taking anticoagulant medication
Ibuprofen	Motrin Rx, Advil OTC, Nuprin OTC, Motrin IB OTC	400 mg q 6-8 hr, 200 mg q 4-6 hr up to 1200 mg/day	See diclofenac	If GI upset occurs, take with food, milk, or antacids; avoid alcoholic beverages; do not take with aspirin; stop taking and call care provider if rash occurs	
Ketoprofen	Orudis Rx	25-50 mg q 6-8 hr up to 300 mg/day	See diclofenac	See ibuprofen	
	Orudis KT OTC, Actron OTC	12.5 mg q 6-8 hr up to 75 mg/day			
Meclofenamate	Meclomen Rx	100 mg tid up to 300 mg	See diclofenac	See ibuprofen	
Mefenamic acid	Ponstel Rx	500 mg initially, then 250 mg q 6 hr/day	See diclofenac	Very potent and effective prostaglandin-synthesis inhibitor; antagonizes already formed prostaglandins; increased incidence of adverse GI side effects	
Naproxen	Naprosyn Rx	500 mg initially, then 250 mg q 6-8 hr up to 1250 mg/day	See diclofenac	See ibuprofen	
Naproxen sodium	Anaprox Rx	550 mg initially, then 275 mg q 6-8 hr or 550 mg q 12 hr up to 1375 mg/day	See diclofenac	See ibuprofen	
	Aleve OTC	440 mg initially, then 220 mg q 6-8 hr up to 660 mg/day			
Celecoxib	Celebrex	400 mg initially, then 200 mg bid	See diclofenac	See ibuprofen

GI, Gastrointestinal; *NSAID,* nonsteroidal antiinflammatory drug; *OTC,* over the counter.

OCPs are a reasonable choice for women who want to use a contraceptive agent. The benefits of their use are attributed to decreased prostaglandin synthesis associated with an atrophic decidualized endometrium (Lentz, 2012). OCPs are effective in relieving symptoms of primary dysmenorrhea for approximately 90% of women. No single OCP has been shown to be superior to another for the relief of primary dysmenorrheal, including low-dose and extended-cycle OCPS (Lentz, 2012). OCPs are a particularly good choice for therapy because they combine contraception with a positive effect on dysmenorrhea, menstrual flow, and menstrual

TABLE 4-2 HERBAL MEDICINALS TAKEN ORALLY FOR MENSTRUAL DISORDERS

SYMPTOMS OR INDICATIONS	HERBAL THERAPY*	ACTION
Menstrual cramping, dysmenorrhea	Black haw	Uterine antispasmodic
	Fennel	Uterotonic
	Catnip	Uterine antispasmodic
	Dong quai	Uterotonic; antiinflammatory
	Ginger	Antiinflammatory
	Motherwort	Uterotonic
	Wild yam	Uterine antispasmodic
	Valerian	Uterine antispasmodic
Premenstrual discomfort, tension	Black cohosh root	Estrogen-like luteinizing hormone suppressant; binds to estrogen receptors
	Chamomile	Antispasmodic
Breast pain	Chaste tree fruit	Decreases prolactin levels
	Bugleweed	Antigonadotropic; decreases prolactin levels

*Many women's herbs do not have rigorous scientific studies backing their use; most uses and properties of herbs have not been validated by the US Food and Drug Administration,.

irregularities. Adolescents may benefit from use of the long-acting injectable contraceptive (depot medroxyprogesterone), but more research is needed. Since OCPs have side effects, women may not wish to use them for dysmenorrhea. They may be contraindicated for some women. (See Chapter 5 for a complete discussion of OCPs.)

Over-the-counter (OTC) preparations that are indicated for primary dysmenorrhea contain the same active ingredients (e.g., ibuprofen or naproxen sodium) as prescription preparations. However, the labeled recommended dose may be subtherapeutic. Preparations containing acetaminophen are even less effective because acetaminophen does not have the antiprostaglandin properties of NSAIDs.

Alternative and complementary therapies are increasingly popular and used in developed countries. Therapies such as acupuncture, acupressure, biofeedback, desensitization, hypnosis, massage, reiki, relaxation exercises, and therapeutic touch have been used to treat pelvic pain. Herbal preparations have long been used for managing menstrual problems, including dysmenorrhea (Table 4-2). Herbal medicines may be valuable in treating dysmenorrhea. However, it is essential that women understand that these therapies are not without potential toxicity and may cause drug interactions.

! NURSING ALERT

Nurses must routinely ask women about use of herbal and other alternative therapies and document their use.

Secondary Dysmenorrhea

Secondary dysmenorrhea is menstrual pain that develops later in life than primary dysmenorrhea, typically after age 25. It is associated with pelvic pathology such as adenomyosis, endometriosis, pelvic inflammatory disease, endometrial polyps, or submucous or interstitial myomas (fibroids). Women with secondary dysmenorrhea often have other symptoms that may suggest the underlying cause. For example, heavy menstrual flow with dysmenorrhea suggests a diagnosis of leiomyomata, adenomyosis, or endometrial polyps. Pain associated with endometriosis often begins a few days before menses but can be present at ovulation and continue through the first days of menses or start after menstrual flow has begun. In contrast to primary dysmenorrhea, the pain of secondary dysmenorrhea is often characterized by dull, lower abdominal aching that radiates to the back or thighs. Often women experience feelings of bloating or pelvic fullness. In addition to a physical examination with a careful pelvic examination, diagnosis may be assisted by ultrasound examination, dilation and curettage (D&C), endometrial biopsy, or laparoscopy. Treatment is directed toward removal of the underlying pathology. Many of the measures described for pain relief of primary dysmenorrhea are also helpful for women with secondary dysmenorrhea.

Premenstrual Syndrome

Approximately 30% to 80% of women experience mood or somatic symptoms (or both) that occur with their menstrual cycles (Lentz, 2012). Establishing a universal definition of **premenstrual syndrome (PMS)** is difficult, given that so many symptoms have been associated with the condition and at least two different syndromes have been recognized: PMS and **premenstrual dysphoric disorder (PMDD).**

PMS is a complex, poorly understood condition that includes one or more of a large number (more than 150) of physical and psychologic symptoms beginning in the luteal phase of the menstrual cycle, occurring to such a degree that lifestyle or work is affected, and followed by a symptom-free period. Symptoms include fluid retention (abdominal bloating, pelvic fullness, edema of the lower extremities, breast tenderness, and weight gain), behavioral or emotional changes (depression, crying spells, irritability, panic attacks, and impaired ability to concentrate), premenstrual cravings (sweets, salt, increased appetite, and food binges), and headache, fatigue, and backache.

All age-groups are affected, with women in their 20s and 30s most frequently reporting symptoms. Ovarian function is necessary for the condition to occur because it does not occur before puberty, after menopause, or during pregnancy. The condition is not dependent on the presence of monthly menses: women who have had a hysterectomy without bilateral salpingo-oophorectomy (BSO) still can have cyclic symptoms.

PMDD is a more severe variant of PMS in which 3% to 8% of women have marked irritability, dysphoria, mood lability, anxiety, fatigue, appetite changes, and a sense of feeling overwhelmed (Lentz, 2012). The most common symptoms are those associated with mood disturbances.

A diagnosis of PMS is made when the following criteria are met (American College of Obstetricians and Gynecologists [ACOG], 2000):

- Symptoms consistent with PMS occur in the luteal phase and resolve within a few days of menses onset.
- Symptom-free period occurs in the follicular phase.
- Symptoms are recurrent.
- Symptoms have a negative effect on some aspect of a woman's life.
- Other diagnoses that better explain the symptoms have been excluded.

For a diagnosis of PMDD, the following criteria must be met (American Psychiatric Association [APA], 2000):

- Five or more affective and physical symptoms are present in the week before menses and absent in the follicular phase of the menstrual cycle.
- At least one of the symptoms is irritability, depressed mood, anxiety, or emotional lability.
- Symptoms interfere markedly with work or interpersonal relationships.
- Symptoms are not caused by an exacerbation of another condition or disorder.

These criteria must be confirmed by prospective daily ratings for at least two menstrual cycles.

The causes of PMS and PMDD continue to be investigated, but there is general agreement that they are distinct psychiatric and medical syndromes rather than an exacerbation of an underlying psychiatric disorder. They do not occur if there is no ovarian function. A number of biologic and neuroendocrine etiologies have been suggested; however, none have been conclusively substantiated as the causative factor. It is likely that biologic, psychosocial, and sociocultural factors contribute to PMS and PMDD (Lentz, 2012).

Management

There is little agreement on management. A careful, detailed history and daily log of symptoms and mood fluctuations spanning several cycles may give direction to a plan of management. Any changes that help a woman with PMS exert control over her life have a positive effect. For this reason, lifestyle changes are often effective in its treatment.

Education is an important component of the management of PMS. Nurses can advise women that self-help modalities often result in significant symptom improvement. Women have found a number of complementary and alternative therapies to be useful in managing the symptoms of PMS. Diet and exercise changes can provide symptom relief for some women. Nurses can suggest that women not smoke and limit their consumption of refined sugar, salt, red meat, alcohol, and caffeinated beverages. Women can be encouraged to include whole grains, legumes, seeds, nuts, vegetables, fruits, and vegetable oils in their diet. Three small to moderate-size meals and three small snacks a day that are rich in complex carbohydrates and fiber have been reported to relieve symptoms (American College of Obstetricians and Gynecologists [ACOG] 2011; Lentz, 2012). Use of natural diuretics (see section on dysmenorrhea management on pp. 76-78) may also help reduce fluid retention. Nutritional supplements may assist in symptom relief. Calcium (1200 mg daily) and vitamin B_6 have been shown to be moderately effective in relieving symptoms, to have few side effects, and to be safe. Daily supplements of evening primrose oil are reportedly useful in relieving breast symptoms with minimal side effects, but research reports are conflicting (Biggs and Demuth, 2011; Lentz, 2012). Other herbal therapies have long been used to treat PMS; however, research on effectiveness is lacking, or studies are flawed (Dante and Facchinetti, 2011).

Regular exercise (aerobic exercise three or four times a week), especially in the luteal phase, is widely recommended for relief of PMS symptoms (Lentz, 2012). A monthly program that varies in intensity and type of exercise according to PMS symptoms is best. Women who exercise regularly seem to have less premenstrual anxiety than do nonathletic women. Researchers believe aerobic exercise increases beta-endorphin levels to offset symptoms of depression and elevate mood.

Yoga, acupuncture, hypnosis, light therapy, chiropractic therapy, and massage therapy have all been reported to have a beneficial effect on PMS. Further research is needed for all of these therapies.

Nurses can explain the relation between cyclic estrogen fluctuation and changes in serotonin levels, that serotonin is one of the brain chemicals that assist in coping with normal life stresses, and the ways in which the different management strategies recommended help maintain serotonin levels. Support groups or individual or couples counseling may be helpful. Stress-reduction techniques also may help with symptom management (Lentz, 2012).

If these strategies do not provide significant symptom relief in 1 to 2 months, medication is often added. Many medications have been used in treatment of PMS, but no single medication alleviates all PMS symptoms. Medications often used in the treatment of PMS include diuretics, prostaglandin inhibitors (NSAIDs), progesterone, and OCPs. These have been used mainly for the physical symptoms. Studies of progesterone have not shown that it is an effective treatment (Ford, Lethaby, Roberts, et al., 2012). Serotonergic-activating agents, including the selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine (Prozac or Sarafem), sertraline (Zoloft), citalopram (Celexa), escitalopram (Lexapro), and paroxetine (Paxil CR) are approved by the U.S. Food and Drug Administration (FDA) as agents for PMS and are first-line pharmacologic therapy. Use of these medications during the luteal phase of the menstrual cycle results in a decrease in emotional premenstrual symptoms, especially depression (Biggs and Demuth, 2011; Lentz, 2012). Common side effects are headaches, sleep disturbances, dizziness, weight gain, dry mouth, and decreased libido.

Endometriosis

Endometriosis is characterized by the presence and growth of endometrial tissue outside of the uterus. The tissue may be implanted on the ovaries; anterior and posterior cul-de-sac; broad, uterosacral, and round ligaments; rectovaginal septum; sigmoid colon; appendix; pelvic peritoneum; cervix; and inguinal area (Fig. 4-2). Endometrial lesions have been found in the vagina and surgical scars and on the vulva, perineum, and bladder. They have also been found on sites far from the pelvic area such as the thoracic cavity, gallbladder, and heart. A cystic lesion of endometriosis found in the ovary is sometimes described as a chocolate cyst because of the dark coloring of the contents of the cyst caused by the presence of old blood.

Endometrial tissue contains glands and stoma and responds to cyclic hormone stimulation in the same way that the uterine endometrium does but often out of phase with it. The tissue grows during the proliferative and secretory phases of the cycle. During or immediately after menstruation the tissue bleeds, resulting in an inflammatory response with subsequent fibrosis and adhesions to adjacent organs.

The overall incidence of endometriosis is 5% to 15% in reproductive-age women, 30% to 45% in infertile women, and 33% in women with chronic pelvic pain (Lobo, 2012b). Although the

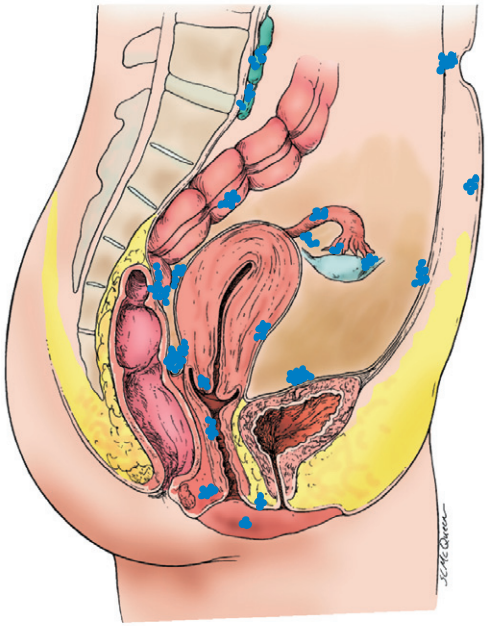

FIG 4-2 Common sites of endometriosis. (From Lentz GM, Lobo RA, Gershenson DM, et al, editors: *Comprehensive gynecology*, ed 6, Philadelphia, 2012, Mosby.)

condition usually develops in the third or fourth decade of life, endometriosis has been found in adolescents with disabling pelvic pain or abnormal vaginal bleeding. Endometriosis may worsen with repeated cycles, or it may remain asymptomatic and undiagnosed, eventually disappearing after menopause. However, it has been reported to occur in about 5% of postmenopausal women receiving menopausal hormone therapy. There appears to be a familial tendency to develop endometriosis; the condition is 7 times more prevalent in women who have a first-degree relative with endometriosis as compared to the general population (Lobo, 2012b).

Several theories concerning the cause of endometriosis have been suggested. However, the etiology and pathology of this condition continue to be poorly understood. One of the most widely accepted theories is transplantation or retrograde menstruation. According to this theory, endometrial tissue is refluxed through the uterine tubes during menstruation into the peritoneal cavity, where it implants on the ovaries and other organs. Retrograde menstruation has been documented in a number of surgical studies and is estimated to occur in 90% of menstruating women. For most women endometrial tissue outside the uterus is destroyed before it can implant or seed in the peritoneal cavity or elsewhere. Other theories include genetic disposition, immunologic changes, and hormonal influences (Lobo, 2012b).

Symptoms from nonexistent to incapacitating vary among women. Severity of symptoms can change over time and may not reflect the extent of the disease. The major symptoms of endometriosis are pelvic pain, dysmenorrhea, and **dyspareunia** (painful intercourse). Women may also have chronic noncyclic pelvic pain, pelvic heaviness, or pain radiating into the thighs. Many women report bowel symptoms such as diarrhea, pain with defecation, and constipation caused by avoiding defecation because of the pain. Less common symptoms include abnormal bleeding (hypermenorrhea, menorrhagia, or premenstrual staining) and pain during exercise as a result of adhesions (Lobo, 2012b).

Impaired fertility may result from adhesions around the uterus that pull the uterus into a fixed, retroverted position. Adhesions around the uterine tubes may block the fimbriated ends or prevent the spontaneous movement that carries the ovum to the uterus.

Management

Treatment is based on the severity of symptoms and the goals of the woman or couple. Women without pain who do not want to become pregnant need no treatment. In women with mild pain who may desire a future pregnancy, treatment may be limited to use of NSAIDs during menstruation (see earlier discussion of these medications).

Suppression of endogenous estrogen production and subsequent endometrial lesion growth is the cornerstone of management of the disease. Two main classes of medications are used to suppress endogenous estrogen levels: gonadotropin-releasing hormone (GnRH) agonists and androgen derivatives. GnRH agonist therapy (leuprolide [Lupron], nafarelin acetate [Synarel], goserelin acetate [Zoladex]) acts by suppressing pituitary gonadotropin secretion. FSH and LH stimulation of the ovary declines markedly, and ovarian function decreases significantly. A medically induced menopause develops, resulting in anovulation and amenorrhea. Shrinkage of already established endometrial tissue, significant pain relief, and interruption in further lesion development follow. The hypoestrogenism results in hot flashes in almost all women. Trabecular bone loss is common, although most loss is reversible within 12 to 24 months after the medication is stopped (Lobo, 2012b).

Leuprolide (3.75 mg intramuscular injection given once a month), nafarelin (200 mg administered twice daily by nasal spray), and goserelin 3.6 mg every 28 days by subcutaneous implant are effective and well tolerated. These medications reduce endometrial lesions and pelvic pain associated with endometriosis and have posttreatment pregnancy rates similar to that of danazol (Danocrine) therapy (Lobo, 2012b). Common side effects of these drugs are those of natural menopause—hot flashes and vaginal dryness. Occasionally women report headaches and muscle aches. Treatment is usually limited to 6 months to minimize bone loss. Although unlikely, it is possible for a woman to become pregnant while taking a GnRH agonist. Because the potential teratogenicity of this drug is unclear, women should use a barrier contraceptive during treatment.

Danazol, a mildly androgenic synthetic steroid, suppresses FSH and LH secretion, thus producing anovulation and hypogonadotropism. This results in decreased secretion of estrogen and progesterone and regression of endometrial tissue. Danazol can produce side effects severe enough to cause a woman to discontinue the drug, including masculinizing traits (weight gain, edema, decreased breast size, oily skin, hirsutism, and deepening of the voice), all of which often disappear when treatment is discontinued. Other side effects are amenorrhea, hot flashes, vaginal dryness, insomnia, and decreased libido. Migraine headaches, dizziness, fatigue, and depression are also reported. Danazol treatment has been reported to adversely affect lipids, with a decrease in high-density lipoprotein levels and an increase in low-density lipoprotein levels. Danazol should never be prescribed when pregnancy is suspected, and barrier contraception should be used with it because ovulation may not be suppressed. Danazol can produce pseudohermaphroditism in female fetuses. The medication is contraindicated in women with liver disease and should be used with caution in women with cardiac and renal disease. Danazol is less frequently used to treat endometriosis than other medical therapies (Lobo, 2012b).

Women who have early symptomatic disease and who can postpone pregnancy may be treated with continuous OCPs that have a

NURSING CARE PLAN

Woman with Endometriosis

NURSING DIAGNOSIS	EXPECTED PATIENT OUTCOMES	NURSING INTERVENTIONS	RATIONALE
Acute Pain related to menstruation secondary to endometriosis	Woman will verbalize a decrease in intensity and frequency of pain during each menstrual cycle.	Assess location, type, and duration of pain and history of discomfort. Administer analgesics. Administer hormone-altering medications if ordered. Provide nonpharmacologic methods such as heat.	To determine severity of dysmenorrhea To assist with pain relief To suppress ovulation To increase blood flow to the pelvic region
Deficient Knowledge related to unfamiliarity with treatment, as evidenced by woman's statements	Woman will verbalize correct understanding of the use of self-care methods and prescribed therapies.	Assess woman's current understanding of the disorder and related therapies. Give information to woman regarding the disorder and treatment regimen.	To validate the accuracy of knowledge base To empower the woman to become a partner in her own care
Situational Low Self-Esteem related to infertility as evidenced by woman's statements of decreased self-worth	Woman will verbalize positive feelings of self-worth.	Provide therapeutic communication. Refer to support group.	To validate feelings and provide support To enhance feelings of self-worth through group communication
Anxiety related to possible invasive surgical procedure as evidenced by woman's verbal report	Woman will report a decreased number of anxious feelings. Reinforce information provided to keep expectations realistic and dispel myths or inaccuracies	Provide opportunity to discuss feelings. Provide emotional support.	To identify source of anxiety To encourage verbalization of feelings
Risk for Injury related to disease progression	Woman will report any changes in health status to health care provider	Teach woman to report any changes in health status. Review side effects of medications. Encourage ongoing communication with health care provider.	To initiate prompt treatment To recognize possible causes for changes in health status To promote trust and comfort

low estrogen-to-progestin ratio to shrink endometrial tissue. Any low-dose OCPs can be used if taken for 15 weeks, followed by 1 week of withdrawal. This therapy is associated with minimal side effects and can be taken for extended periods (Lobo, 2012b). Limited data exist on the effectiveness of progestogen-only medications for treating pain related to endometriosis (Brown, Kives, and Akhtar, 2012).

Continuous combined hormone therapy (OCPs, estrogen/progestin patch, estrogen/progestin vaginal ring) for menstrual suppression and administration of NSAIDs are the usual treatment for adolescents under the age of 16 who have endometriosis. GnRH agonist therapy for severe symptoms may have possible adverse effects on bone mineralization in adolescents, and bone mineral density should be carefully monitored (Laufer, 2008).

Surgical intervention is often needed for severe, acute, or incapacitating symptoms. Decisions regarding the extent and type of surgery are influenced by a woman's age, desire for children, and location of the disease. For women who do not want to preserve their ability to have children, the only definite cure is total abdominal hysterectomy with BSO (TAH with BSO). In women who want children and in whom the disease does not prevent bearing children, reproductive capacity should be retained through careful removal by laparoscopic surgery or laser therapy (coagulation, vaporization, or resection) of all endometrial tissue possible with retention of ovarian function (Lobo, 2012b).

Regardless of the type of treatment (short of TAH with BSO), endometriosis recurs in approximately 40% of women. Thus for many women endometriosis is a chronic disease with conditions such as chronic pain or infertility. Counseling and education are critical components of nursing care for women with endometriosis. Women need an honest discussion of treatment options, with review of the potential risks and benefits of each option. Because pelvic pain is a subjective, personal experience that can be frightening, support is important. Sexual dysfunction resulting from dyspareunia is common and may necessitate referral for counseling. Support groups for women with endometriosis may be found in some locations. Resolve (www.resolve.org), an organization for infertile couples, or the Endometriosis Association (www.ivf.com/endohtml.html) may also be helpful. The nursing care discussed in the previous section on dysmenorrhea is appropriate for managing chronic pelvic pain and dysmenorrhea experienced by women with endometriosis (see Nursing Care Plan).

Alterations in Cyclic Bleeding

Women often experience changes in amount, duration, interval, or regularity of menstrual cycle bleeding. Commonly women worry about menstruation that is infrequent **(oligomenorrhea),** is scanty

at normal intervals **(hypomenorrhea),** is excessive **(menorrhagia),** or occurs between periods **(metrorrhagia).**

Treatment depends on the cause and may include education and reassurance. For example, tell women that OCPs can cause scanty menstrual flow and midcycle spotting. Progestin intramuscular injections and implants can also cause midcycle bleeding. A single episode of heavy bleeding may signal an early pregnancy loss such as a miscarriage or ectopic pregnancy. This type of bleeding is often thought to be a period that is heavier than usual, perhaps delayed, and is associated with abdominal pain or pelvic discomfort. When early pregnancy loss is suspected, hematocrit and pregnancy tests are indicated.

Uterine **leiomyomas** (fibroids or myomas) are a common cause of menorrhagia. Fibroids are benign tumors of the smooth muscle of the uterus with an unknown cause. Fibroids occur in approximately one fourth of women of reproductive age; their incidence is higher in African-American women than in Caucasian, Asian, or in Hispanic women (Katz, 2012). Other uterine growths ranging from endometrial polyps to adenocarcinoma and endometrial cancer are common causes of heavy menstrual bleeding and intermenstrual bleeding.

! NURSING ALERT

If the woman herself considers the amount or duration of bleeding to be excessive, the problem should be investigated.

Treatment for menorrhagia depends on the cause of the bleeding. If the bleeding is related to contraceptive method (e.g., an intrauterine device [IUD]), provide factual information and reassurance and discuss other contraceptive options.

If there is no known cause for the bleeding and anatomic causes have been rules out, therapy is aimed at reducing the amount of heavy bleeding. Current options for treatment include OCPs and NSAIDs (non–Food and Drug Administration [FDA] approved for this use) and FDA-approved therapies: the levonorgestrel-releasing IUD and antifibrinolytic agents (e.g., tranexamic acid) (Lobo, 2012a, Wilton, 2012).

If bleeding is related to the presence of fibroids, the degree of disability and discomfort associated with the fibroids and the woman's plans for childbearing influence treatment decisions. Treatment options include medical and surgical management. Most fibroids can be monitored by frequent examinations to judge growth, if any, and correction of anemia if present. Warn women with metrorrhagia to avoid using aspirin because of its tendency to increase bleeding. Medical treatment is directed toward temporarily reducing symptoms, shrinking the myoma, and reducing its blood supply (Katz, 2012). This reduction is often accomplished with the use of a GnRH agonist. However, usually after cessation of this treatment, the myomas return to their pretreatment size (Katz, 2012). If the woman wishes to retain childbearing potential, a myomectomy may be performed. Myomectomy, or removal of the tumors only by laparoscopic or hysteroscopic resection or laser surgery, is particularly difficult if multiple myomas must be removed. One in four women will have a hysterectomy performed within 20 years of having a myomectomy. If the woman does not want to preserve her childbearing function or if she has severe symptoms (severe anemia, severe pain, considerable disruption of lifestyle), uterine artery embolization (UAE) (procedure that blocks blood supply to fibroid), or hysterectomy (removal of uterus) may be performed. After UAE 20% to 30% of women will undergo a hysterectomy within 5 years (Katz, 2012).

Important nursing roles include reassurance, counseling, education, and support.

Dysfunctional Uterine Bleeding

Abnormal uterine bleeding (AUB) is any form of uterine bleeding that is irregular in amount, duration, or timing and is not related to regular menstrual bleeding. Box 4-1 lists possible causes of AUB. Although often used interchangeably, the terms AUB and dysfunctional uterine bleeding (DUB) are not synonymous. AUB can have

BOX 4-1 POSSIBLE CAUSES OF ABNORMAL UTERINE BLEEDING

Pregnancy-Related Conditions
- Threatened or spontaneous miscarriage
- Retained products of conception after elective abortion
- Ectopic pregnancy
- Placenta previa/placenta abruptio
- Trophoblastic disease

Lower Reproductive Tract Infections
- Cervicitis
- Endometritis
- Myometritis
- Salpingitis

Benign Anatomic Abnormalities
- Adenomyosis
- Leiomyomata
- Polyps of the cervix or endometrium

Neoplasms
- Endometrial hyperplasia
- Cancer of cervix and endometrium
- Hormonally active tumors (rare)
- Vaginal tumors (rare)

Malignant Lesions
- Cervical squamous cell carcinoma
- Endometrial adenocarcinoma
- Estrogen-producing ovarian tumors
- Testosterone-producing ovarian tumors
- Leiomyosarcoma

Trauma
- Genital injury (accidental, coital trauma, sexual abuse)
- Foreign body
- Lacerations

Systemic Conditions
- Adrenal hyperplasia and Cushing's disease
- Blood dyscrasias
- Coagulopathies
- Hypothalamic suppression (from stress, weight loss, excessive exercise)
- Polycystic ovary disease
- Thyroid disease
- Pituitary adenoma or hyperprolactinemia
- Severe organ disease (renal or liver failure)

Iatrogenic Causes
- Medications with estrogenic activity
- Anticoagulants
- Exogenous hormone use (oral contraceptives, menopausal hormone therapy)
- Selective serotonin reuptake inhibitors
- Tamoxifen
- Intrauterine devices
- Herbal preparation (ginseng)

Modified from Albers JR, Hull SK, Wesley RM: Abnormal uterine bleeding, *Am Fam Physician* 69:1915–1926; 1931–1932, 2004.

organic causes such as systemic diseases, reproductive tract disease, or DUB that is usually hormonally related.

DUB can be anovulatory or ovulatory but is most commonly caused by anovulation. When no surge of LH occurs or if insufficient progesterone is produced by the corpus luteum to support the endometrium, it will begin to involute and shed. This process most often occurs at the extremes of a woman's reproductive years, when the menstrual cycle is just becoming established at menarche or when it draws to a close at menopause. DUB also occurs with any condition that gives rise to chronic anovulation associated with continuous estrogen production. Such conditions include obesity, hyperthyroidism and hypothyroidism, polycystic ovarian syndrome, and any of the endocrine conditions discussed in the sections on amenorrhea oligomenorrhea. A diagnosis of DUB is made only after ruling out all other causes of abnormal menstrual bleeding (Lobo, 2012a).

Management. The most effective medical treatment of acute bleeding episodes of DUB is administration of oral or intravenous estrogen. D&C may be done if the bleeding has not stopped in 12 to 24 hours. An oral conjugated estrogen and progestin regimen is usually given for at least 3 months after the acute phase has passed. Such long-term treatment will help prevent recurrence of the pattern of DUB and hemorrhage. If the woman wants contraception, she should continue to take OCPs. If she has no need for contraception, the treatment may be stopped to assess the woman's bleeding pattern. If her menses does not resume, a progestin regimen (e.g., medroxyprogesterone, 10 mg each day for 10 days before the expected date of her menstrual period) may be prescribed after ruling out pregnancy. This is done to prevent persistent anovulation with chronic unopposed endogenous estrogen hyperstimulation of the endometrium, which can result in eventual atypical tissue changes (Lobo, 2012a).

If the recurrent, heavy bleeding is not controlled by hormone therapy or D&C, ablation of the endometrium through laser treatment may be performed. Nursing roles include informing patients of their options, counseling and education as indicated, and referring to the appropriate specialists and health care services.

CARE MANAGEMENT

Nursing assessments for women who have a menstrual disorder include:

- Taking a thorough menstrual, obstetric, sexual, and contraceptive history.
- Exploring the woman's perceptions of her condition, cultural or ethnic influences, lifestyle, and patterns of coping.
- Evaluating the amount of pain or bleeding experienced and its effect on daily activities.
- Noting any home remedies and prescriptions to relieve discomfort. A symptom diary, in which the woman records emotions, behaviors, physical symptoms, diet, and exercise and rest patterns, is a useful diagnostic tool.

Possible nursing diagnoses include:

- Risk for Ineffective Individual Coping related to:
  - Insufficient knowledge of the cause of the disorder
  - Emotional and physiologic effects of the disorder
- Deficient Knowledge related to:
  - Self-management
  - Available therapy for the disorder
- Risk for Disturbed Body Image related to:
  - Menstrual disorder
  - Sexual dysfunction
- Risk for Situational Low Self-Esteem related to:
  - Others' perception of her discomfort
  - Inability to conceive
- Acute or Chronic Pain related to:
  - Menstrual disorder

Expected outcomes for the woman are that she will do the following:

- Verbalize her understanding of reproductive anatomy, cause of her disorder, medication regimen, and diary use.
- Verbalize her understanding and accept her emotional and physical responses to her menstrual cycle.
- Develop personal goals that benefit her emotionally and physically.
- Choose appropriate therapeutic measures for her menstrual problems.
- Adapt successfully to the condition if cure is not possible.

In addition to the medical, surgical, and nursing interventions discussed with each problem, additional nursing interventions may include:

- Accepting the woman's symptoms as valid.
- Correlating data from the daily diary of emotional status, subjective feelings, and physical state with physiologic changes.
- Encouraging the woman to express her feelings about her symptoms.
- Providing information about therapeutic options (pharmacologic and nonpharmacologic) so the woman (couple) makes (make) choices considered best for her (them).
- Providing information about local support groups.

Care has been effective when the woman reports improvement in the quality of her life, skill in self-management, and a positive self-concept and body image.

INFECTIONS

Infections of the reproductive tract can occur throughout a woman's life and are often the cause of significant reproductive morbidity, including ectopic pregnancy and tubal factor infertility. The direct economic costs of these infections can be substantial, and the indirect cost is equally overwhelming. Some consequences of maternal infection such as infertility last a lifetime. The emotional costs may include damaged relationships and lowered self-esteem.

Sexually Transmitted Infections

Sexually transmitted infections (STIs) are infections or infectious disease syndromes transmitted primarily by sexual contact. The term **sexually transmitted infection** includes more than 25 infectious organisms that are transmitted through sexual activity and the dozens of clinical syndromes that they cause (Box 4-2). STIs are among the most common health problems in the United States today, with an estimated 19 million people in the United States being infected with STIs every year (CDC, 2010a). The following discussion focuses on the most common STIs in women. Chapter 25 discusses neonatal effects.

Prevention

Preventing infection (primary prevention) is the most effective way of reducing the adverse consequences of STIs for women. Prompt diagnosis and treatment of current infections (secondary prevention) also can prevent personal complications and

BOX 4-2 SEXUALLY TRANSMITTED INFECTIONS

Bacteria
- Chlamydia
- Gonorrhea
- Syphilis
- Chancroid
- Lymphogranuloma venereum
- Genital mycoplasmas
- Group B streptococci

Viruses
- Human immunodeficiency virus
- Herpes simplex virus, types 1 and 2
- Cytomegalovirus
- Viral hepatitis A and B
- Human papillomavirus

Protozoa
- Trichomoniasis

Parasites
- Pediculosis (may or may not be sexually transmitted)
- Scabies (may or may not be sexually transmitted)

transmission to others. Preventing the spread of STIs requires that women at risk for transmitting or acquiring infections change their behavior. A critical first step is to include questions about a woman's sexual history, sexual risk behaviors, and drug-related risky behaviors as a part of her assessment (Box 4-3). When you identify risk factors or risky behaviors, you have an opportunity to provide prevention counseling. Techniques that are effective in providing prevention counseling include using open-ended questions, using understandable language, and reassuring the woman that treatment will be provided regardless of consideration such as ability to pay, language spoken, or lifestyle (CDC, 2010a; Fantasia, Fontenot, Sutherland, et al., 2011). Prevention messages should include descriptions of specific actions to prevent contracting or transmitting STIs (e.g., refraining from sexual activity when STI-related symptoms are present) and should be individualized for each woman, giving attention to her specific risk factors.

To be motivated to take preventive actions, a woman must believe that acquiring a disease will be serious for her and that she is at risk for infection. Most individuals tend to underestimate their personal risk of infection in a given situation. Thus many women may not perceive themselves as being at risk for contracting an STI, and telling them that they should carry condoms may not be well received. Although levels of awareness of STIs are generally high, widespread misconceptions or specific gaps in knowledge also exist. Therefore nurses have a responsibility to ensure that their patients have accurate, complete knowledge about transmission and symptoms of STIs and the behaviors that place them at risk for contracting an infection.

Primary preventive measures are individual activities aimed at avoiding infection. Risk-free options include complete abstinence from sexual activities that transmit semen, blood, or other body fluids or that allow for skin-to-skin contact (CDC, 2010a). Involvement in a mutually monogamous relationship with an uninfected partner also eliminates risk of contracting STIs.

Sexually Transmitted Infections/Human Immunodeficiency Virus Prevention Strategies. An essential component of primary prevention is counseling the woman regarding sexual practices so she can avoid acquiring or transmitting STIs, including attaining knowledge of her partner, reducing her number of partners, practicing low risk sex, avoiding the exchange of body fluids, and vaccination.

BOX 4-3 ASSESSING SEXUALLY TRANSMITTED INFECTION AND HUMAN IMMUNODEFICIENCY VIRUS RISK BEHAVIORS

Sexual Risk
- Are you sexually active now?
- If no, have you had sex in the past?
- Ever had an oral, vaginal, or anal sexual experience with another person?
- With how many different people? 1? 2 or 3? 4 to 10? More than 10?
- Have your partners been men, women, both?
- Ever thought that a sex partner put you at risk for AIDS or an STI (IV drug user, bisexual)?
- Ever had an STI (herpes, gonorrhea, genital warts, chlamydia)?
- Ever had sex against your will?
- What do you do to protect yourself from HIV and STIs?
- Do you use male condoms? Female condoms? Other barriers?

Drug Use–Related Risk
- Ever injected drugs using shared equipment, including street drugs, steroids?
- Ever had sex with a person who uses and shares?
- Ever had sex while so stoned, high, or drunk that you can't remember the details?
- Ever exchanged sex for drugs, money, shelter?

Blood-Related Risks
- Ever had a blood transfusion?
- Ever had sex with a person who had a blood transfusion?
- Ever had sex with a person with hemophilia?
- Ever received donor semen, egg, transplanted organ or tissue?
- Ever shared equipment for tattoo, body piercing?

Other
- Ever had a test for HIV?
- Ever worried about AIDS and would like to talk with someone about it?

Data from Marrazzo JM, Cates W: Reproductive tract infections, including HIV and other sexually transmitted infections. In Hatcher RA, Trussell J, Nelson AL, et al., editors, *Contraceptive technology,* ed 21, Atlanta, 2011, Ardent Media.
AIDS, Acquired immunodeficiency syndrome; *HIV,* human immunodeficiency virus; *IV,* intravenous; *STI,* sexually transmitted infection.

Reducing the number of partners and avoiding partners who have had many previous sexual partners decrease a woman's chances of contracting an STI. Discussing each new partner's previous sexual history and exposure to STIs augments other efforts to reduce risk; however, sexual partners are not always truthful about their sexual history.

Women should be taught low risk sexual practices and which sexual practices to avoid. Sexual fantasizing is safe, as are caressing, hugging, body rubbing, and massage. Mutual masturbation is low risk as long as there is no contact with a partner's semen or vaginal secretions. All sexual activities are safe when both partners are monogamous, trustworthy, and known (by testing) to be free of disease. Anal-genital intercourse, anal-oral contact, and anal-digital activity are high risk sexual behaviors and should be avoided.

COMMUNITY FOCUS

Sexually Transmitted Infections

Interview a nurse working in a clinic about sexually transmitted infections commonly seen there.

- What are the most common infections seen in the clinic?
- Has the incidence of infections changed over the last 5 years? Which infections have increased, and which have decreased in incidence during that time?
- Are adolescents seen in the clinic? Is there a special clinic for adolescents?
- How much independence does the nurse have in diagnosing and treating sexually transmitted infections?
- What patient teaching guidelines are available in the clinic? Are the guidelines available in languages other than English?

The physical barrier promoted for the prevention of sexual transmission of human immunodeficiency virus (HIV) and other STIs is the latex male condom. The nurse should remind women to use a condom with every sexual encounter; to use latex or plastic male condoms rather than natural skin condoms for STI protection; to use a condom with a current expiration date; to use each one only once; and to handle it carefully to avoid damaging it with fingernails, teeth, or other sharp objects. Condoms should be stored away from high heat. Although it is not ideal, women may choose to safely carry condoms in wallets, shoes, or inside a bra. They can be taught the differences among condoms: price ranges, sizes, and where they can be purchased. Explicit instructions for how to apply a male condom are included in Chapter 5.

The female condom (i.e., a lubricated polyurethane sheath with a ring on each end that is inserted into the vagina) has been shown in laboratory studies to be an effective mechanical barrier to viruses, including HIV. Studies suggest that the female condom is at least as effective as male condoms in preventing transmission of STIs (CDC, 2010a). What is important and should be stressed by nurses is the consistent use of condoms for every act of sexual intimacy when there is the possibility of transmission of disease.

Evidence has shown that vaginal spermicides do not protect against certain STIs (e.g., chlamydia, cervical gonorrhea) and that frequent use of spermicides containing nonoxynol-9 has been associated with genital lesions and may increase HIV transmission. Condoms lubricated with nonoxynol-9 are not recommended (CDC, 2010a).

Vaccination is an effective method for the prevention of some STIs such as hepatitis B and human papillomavirus (HPV). Hepatitis B vaccine is recommended for women at high risk for STIs. A vaccine is available for HPV types 6, 11, 16, and 18 for girls and women 9 to 26 years of age (CDC, 2010a) (see later discussion).

Counsel women to watch out for situations that make it hard to talk about and practice risk reduction. These situations include romantic times when condoms are not available and when alcohol or drugs make it difficult to make wise decisions (see Community Focus box).

Sexually Transmitted Bacterial Infections

Chlamydia

Chlamydia trachomatis is the most frequently reported infectious disease in the United States, yet most cases are still undiagnosed (CDC, 2010a). These infections are often silent and highly destructive; their sequelae and complications are very serious. In women chlamydial infections are difficult to diagnose; the symptoms, if present, are nonspecific, and the organism is expensive to culture.

Acute salpingitis, or pelvic inflammatory disease, is the most serious complication of chlamydial infections. Past chlamydial infections are associated with an increased risk of ectopic pregnancy and tubal factor infertility. Furthermore, chlamydial infection of the cervix causes inflammation, resulting in microscopic cervical ulcerations that may increase risk of acquiring HIV infection. More than half of infants born to mothers with chlamydia will develop conjunctivitis or pneumonia after perinatal exposure to the mother's infected cervix. *C. trachomatis* is the most common infectious cause of ophthalmia neonatorum.

Sexually active women younger than 20 years are the ones most likely to become infected with chlamydia, with the highest rates in African-American women ages 15 to 19 years (CDC, 2010a). Women older than age 30 have the lowest rate of infection. Risky behaviors, including multiple partners and not using barrier methods of birth control, increase a woman's risk of chlamydial infection.

Screening and Diagnosis. In addition to obtaining information regarding the presence of risk factors (e.g., women younger than 25 years old, older women who do not use barrier contraceptives, women with new or multiple partners), inquire about the presence of any symptoms (CDC, 2010a). Although infection is usually asymptomatic, some women may experience spotting or postcoital bleeding, mucoid or purulent cervical discharge, or dysuria. Bleeding results from inflammation and erosion of the cervical columnar epithelium.

Laboratory diagnosis of chlamydia is by culture (expensive and labor intensive), DNA probe (relatively less expensive but less sensitive), enzyme immunoassay (also relatively less expensive but less sensitive), and nucleic acid amplification tests (NAATs) (expensive but have relatively higher sensitivity) of urine specimens or specimens from the endocervix/vagina (CDC, 2010a; Fantasia, Fontenot, Sutherland et al., 2011). All pregnant women should have cervical cultures for chlamydia at the first prenatal visit. Screening late in the third trimester (36 weeks) may be carried out if the woman was positive previously or if she is younger than 25 years, has a new sex partner, or has multiple sex partners.

Management. The CDC (2010a) recommendations for the treatment of chlamydial infections include doxycycline or azithromycin (Table 4-3). Azithromycin is often prescribed when compliance is a problem because only one dose is needed. Because chlamydia is often asymptomatic, caution the woman to take all medication prescribed. All exposed sexual partners should be treated. Woman treated with doxycycline or azithromycin do not need to be retested unless symptoms continue (CDC, 2010a).

Gonorrhea

Gonorrhea is probably the oldest communicable disease in the United States. An estimated 300,000 American men and women contract gonorrhea each year (CDC, 2010a). The incidence of drug-resistant cases of gonorrhea, in particular penicillinase-producing *Neisseria gonorrhoeae*, is increasing dramatically in the United States.

Gonorrhea is caused by the aerobic, gram-negative diplococci *N. gonorrhoeae*. It is almost exclusively transmitted by sexual contact. The principal means of transmission is genital-to-genital contact during sexual activity; however, it is also spread by oral-genital and anal-genital contact. There is also evidence that infection may spread in females from vagina to rectum. Although the organism has been recovered from inanimate objects artificially inoculated with the bacteria, there is no evidence that natural transmission occurs this way.

TABLE 4-3 SEXUALLY TRANSMITTED INFECTIONS AND DRUG THERAPIES FOR WOMEN*

DISEASE	NONPREGNANT WOMEN (13-17 YR)	NONPREGNANT WOMEN (>18 YR)	PREGNANT WOMEN	LACTATING WOMEN†
Chlamydia	*Recommended:* Azithromycin, 1 g orally once *or* Doxycycline, 100 mg orally bid for 7 days	*Recommended:* Azithromycin, 1 g orally once *or* Doxycycline, 100 mg orally bid for 7 days	*Recommended:* Azithromycin, 1 g orally once *or* Amoxicillin, 500 mg orally tid for 7 days	*Recommended:* Azithromycin, 1 g orally once *or* Amoxicillin, 500 mg orally tid for 7 days
Gonorrhea	*Recommended:* Ceftriaxone, 125 mg IM once (adolescents who weigh >45 kg can be treated with any regimen recommended for adults) Plus treatment for chlamydia as above	*Recommended:* Ceftriaxone, 250 mg IM once Plus treatment for chlamydia as above	*Recommended:* Ceftriaxone, 250 mg IM once Plus treatment for chlamydia as above	*Recommended:* Ceftriaxone, 250 mg IM once Plus treatment for chlamydia as above
Syphilis	**Primary, secondary, early-latent disease:** *Recommended:* Benzathine penicillin G, 2.4 million units IM once **Late-latent or unknown-duration disease:** *Recommended:* Benzathine penicillin G, 7.2 million units total, administered as three doses, 2.4 million units each, at 1-wk intervals **Penicillin allergy:** Doxycycline, 100 mg orally qid for 14 days *or* Tetracycline, 500 mg orally qid for 14 days	**Primary, secondary, early-latent disease:** *Recommended:* Benzathine penicillin G, 2.4 million units IM once **Late-latent or unknown-duration disease:** *Recommended:* Benzathine penicillin G, 7.2 million units total, administered as three doses, 2.4 million units each, at 1-wk intervals **Penicillin allergy:** Doxycycline, 100 mg orally qid for 14 days *or* Tetracycline, 500 mg orally qid for 14 days	**Primary, secondary, early-latent disease:** *Recommended:* Benzathine penicillin G, 2.4 million units IM once (some experts recommend a second dose of benzathine penicillin, 2.4 million units, 1 wk later) **Late-latent or unknown-duration disease:** *Recommended:* Benzathine penicillin G, 7.2 million units total, administered as three doses, 2.4 million units each, at 1-wk intervals No proven alternatives to penicillin in pregnancy Pregnant women who have a history of allergy to penicillin should be desensitized and treated with penicillin	**Primary, secondary, early-latent disease:** *Recommended:* Benzathine penicillin G, 2.4 million units IM once
Human papillomavirus	*Recommended for external genital warts:* **Patient-applied:** Podofilox, 0.5% solution, or gel to wart bid for 3 days followed by 4-day rest for ≤4 cycles *or* Imiquimod, 5% cream, at hs 3 times a week for ≤16 wk *or* Sinecatechins 15% oint tid for ≤16 wk **Provider-applied:** Cryotherapy with liquid nitrogen or cryoprobe *or* Podophyllin resin, 10%-25% in tincture of benzoin compound weekly (wash off in 1-4 hr). Repeat weekly as necessary *or* Trichloracetic acid (TCA) or bichloracetic acid (BCA) 80%-90% weekly	*Recommended for external genital warts:* **Patient-applied:** Podofilox, 0.5% solution, or gel to wart bid for 3 days followed by 4-day rest for ≤4 cycles *or* Imiquimod, 5% cream, at hs 3 times a week for ≤16 wk *or* Sinecatechins 15% oint tid for ≤16 wk **Provider-applied:** Cryotherapy with liquid nitrogen or cryoprobe *or* Podophyllin resin, 10%-25% in tincture of benzoin compound weekly (wash off in 1-4 hr). Repeat weekly as necessary *or* TCA or BCA 80%-90% weekly	*Recommended for external genital warts:* **Provider applied:** Cryotherapy with liquid nitrogen or cryoprobe *or* TCA or BCA 80%-90% weekly Imiquimod, podophyllin (Podocon-25), sinecatechins, and podofilox should not be used in pregnancy	*Recommended for external genital warts:* **Provider applied:** Cryotherapy with liquid nitrogen or cryoprobe *or* TCA or BCA 80%-90% weekly Imiquimod, podophyllin, sinecatechins, and podofilox should not be used during lactation

TABLE 4-3 SEXUALLY TRANSMITTED INFECTIONS AND DRUG THERAPIES FOR WOMEN*—cont'd

DISEASE	NONPREGNANT WOMEN (13-17 YR)	NONPREGNANT WOMEN (>18 YR)	PREGNANT WOMEN	LACTATING WOMEN†
Genital herpes simplex virus (HSV-1 or HSV-2)	**Primary infection:** Acyclovir, 400 mg orally tid for 7-10 days *or* Acyclovir, 200 mg orally 5 times a day for 7-10 days *or* Famciclovir, 250 mg orally tid for 7-10 days *or* Valacyclovir, 1 g orally bid for 7-10 days **Recurrent infection:** Acyclovir, 400 mg orally tid for 5 days *or* Acyclovir, 800 mg orally bid for 5 days *or* Acyclovir, 800 mg orally tid for 2 days *or* Famciclovir, 125 mg orally bid for 5 days *or* Famciclovir 1000 mg orally bid for 1 day *or* Famciclovir, 500 mg once, then 250 mg bid for 2 days *or* Valacyclovir, 500 mg orally bid for 3 days *or* Valacyclovir, 1 g orally once a day for 5 days **Suppression therapy:** *Take daily for 1 year or more:* Acyclovir, 400 mg orally bid *or* Famciclovir, 250 mg orally bid *or* Valacyclovir, 500 mg orally once a day *or* Valacyclovir, 1 g orally once a day	**Primary infection:** Acyclovir, 400 mg orally tid for 7-10 days *or* Acyclovir, 200 mg orally 5 times a day for 7-10 days *or* Famciclovir, 250 mg orally tid for 7-10 days *or* Valacyclovir, 1 g orally bid for 7-10 days **Recurrent infection:** Acyclovir, 400 mg orally tid for 5 days *or* Acyclovir, 800 mg orally bid for 5 days *or* Acyclovir, 800 mg orally tid for 2 days *or* Famciclovir, 125 mg orally bid for 5 days *or* Famciclovir, 1000 mg orally bid for 1 day *or* Famciclovir 500 mg once, then 250 mg bid for 2 days *or* Valacyclovir, 500 mg orally bid for 3 days *or* Valacyclovir, 1 g orally once a day for 5 days **Suppression therapy:** *Take daily for 1 year or more:* Acyclovir, 400 mg orally bid *or* Famciclovir, 250 mg orally bid *or* Valacyclovir, 500 mg orally once a day *or* Valacyclovir, 1 g orally once a day	No increase in birth defects beyond the general population has been found with acyclovir use in pregnancy Acyclovir, 400 mg orally tid for 7 days for first episode or severe recurrent infection; may be given IV if infection is severe Suppression therapy 4 weeks before the birth for women with recurrent infections can reduce the need for a cesarean birth	Acyclovir usually is considered compatible with breastfeeding Acyclovir, 400 mg tid for 7 days

Data from American Academy of Pediatrics Committee on Drugs: The transfer of drugs and other chemicals into human milk, *Pediatrics* 108(3):776–789, 2002; Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines 2010, *MMWR Morbidity and Mortality Weekly Report,* 59(RR-12):1–109, 2010; Centers for Disease Control and Prevention (CDC): Update to CDC's sexually transmitted diseases treatment guidelines, 2010: oral cephalosporins no longer recommended for gonococcal infections, *MMWR Morbidity and Mortality Report* 61(31):590–594, 2012.

*List is not inclusive of all drugs that may be used as alternatives.

†These medications are usually compatible with breastfeeding.

bid, Twice daily; *hs,* bedtime; *HSV,* herpes simplex virus; *IM*, intramuscularly; *IV*, intravenously; *qid*, four times daily; *tid*, three times daily.

Age is probably the most important risk factor associated with gonorrhea. In the United States the highest reported rates of infection are among sexually active teenagers, young adults, and African-Americans. The majority of those contracting gonorrhea are younger than 20 years of age and engage in sexual activities with multiple partners (CDC, 2010a).

Women are often asymptomatic; but, when they are symptomatic, they may have a greenish-yellow purulent endocervical discharge or may experience menstrual irregularities. Women may complain of pain (i.e., chronic or acute severe pelvic or lower abdominal pain) or menses that last longer or are more painful than normal. Gonococcal rectal infection may occur in women after anal intercourse. Individuals with rectal gonorrhea may be completely asymptomatic or conversely may experience severe symptoms with profuse purulent anal discharge, rectal pain, and blood in the stool. Rectal itching, fullness, pressure, and pain are also common symptoms, as is diarrhea. A diffuse vaginitis with vulvitis is the most common form of gonococcal infection in prepubertal girls. There may be few signs of infection; or vaginal discharge, dysuria, or swollen, reddened labia are sometimes present.

Gonococcal infections in pregnancy potentially affect both mother and infant. Women with cervical gonorrhea may develop salpingitis in the first trimester. Perinatal complications of gonococcal infection include premature rupture of the membranes, preterm birth, chorioamnionitis, neonatal sepsis, intrauterine growth restriction, and maternal postpartum sepsis. Amniotic infection syndrome—manifested by placental, fetal, and umbilical cord inflammation following premature rupture of the membranes—may result from gonorrheal infection during pregnancy.

Screening and Diagnosis. Because gonococcal infections in women are often asymptomatic, the CDC recommends screening all women at risk for gonorrhea (CDC, 2010a). All pregnant women should be screened at the first prenatal visit, and infected women and those identified with risky behaviors rescreened at 36 weeks of gestation. Gonococcal infection cannot be diagnosed reliably by clinical signs and symptoms alone. Individuals may have "classic" symptoms, vague symptoms that may be attributed to a number of conditions, or no symptoms at all. Cultures should be obtained from the endocervix, the rectum, and when indicated the pharynx. Thayer-Martin cultures are recommended to diagnose gonorrhea in women. Because coinfection is common, any woman suspected of having gonorrhea should have a chlamydial culture and serologic test for syphilis unless one has been done within the past 2 months.

Management. Management of gonorrhea is becoming more challenging as drug-resistant strains are increasing. The treatment of choice for uncomplicated urethral, endocervical, and rectal infections in pregnant and nonpregnant women is ceftriaxone given intramuscularly once. The CDC also recommends concomitant treatment for chlamydia because coinfection is common (CDC, 2010a) (see Table 4-3). All women with both gonorrhea and syphilis should also be treated for syphilis according to CDC guidelines (see discussion of syphilis later in this chapter).

Gonorrhea is highly communicable. Recent (past 30 days) sexual partners should be examined, cultured, and treated with appropriate regimens. Most treatment failures result from reinfection. The woman needs to be informed of this and of the consequences of reinfection in terms of chronicity, complications, and potential infertility. Women are counseled to use condoms. All women with gonorrhea should be offered confidential counseling and testing for HIV infection.

LEGAL TIP: Reporting a Communicable Disease

Gonorrhea is a reportable communicable disease. Health care providers are legally responsible for reporting all cases of gonorrhea to health authorities, usually the local health department in the patient's county of residence. Women should be informed that the case will be reported, told why, and informed of the possibility of being contacted by a health department epidemiologist.

Syphilis

Syphilis, one of the earliest described STIs, is caused by *Treponema pallidum*, a motile spirochete. Transmission is thought to be by entry through microscopic abrasions in the subcutaneous tissue, which can occur during sexual intercourse. The disease can also be transmitted through kissing, biting, or oral-genital sex. Transplacental transmission may occur at any time during pregnancy; the degree of risk is related to the quantity of spirochetes in the maternal bloodstream.

Syphilis rates decreased in women in 2010. The rates for African-American women account for almost one-half of the cases (CDC, 2011b).

Syphilis is a complex disease that can lead to serious systemic disease and even death when untreated. Infection manifests itself in distinct stages with different symptoms and clinical manifestations. Primary syphilis is characterized by a primary lesion, the chancre, which appears 5 to 90 days after infection (Fig. 4-3, *A*). This lesion

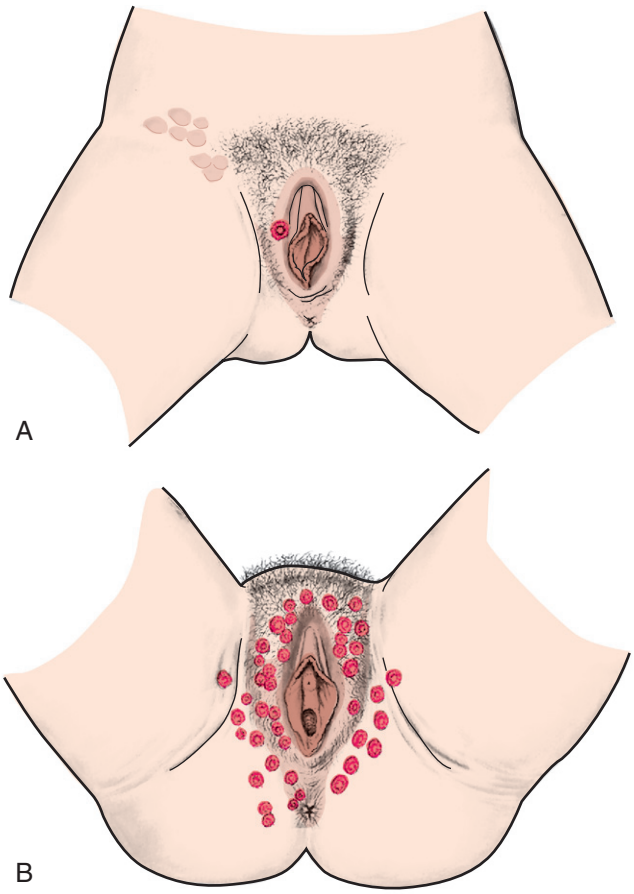

FIG 4-3 Syphilis. **A,** Primary stage: chancre with inguinal adenopathy. **B,** Secondary stage: condylomata lata.

often begins as a painless papule at the site of inoculation and erodes to form a nontender, shallow, indurated, clean ulcer several millimeters to centimeters in size. Secondary syphilis occurs 6 weeks to 6 months after the appearance of the chancre. It is characterized by a widespread, symmetric, maculopapular rash on the palms and soles and generalized lymphadenopathy. The infected individual also may experience fever, headache, and malaise. Condylomata lata (broad, painless, pink-gray, wartlike infectious lesions) may develop on the vulva, perineum, or anus (see Fig. 4-3, *B*). If the woman is untreated, she enters a latent phase that is asymptomatic for the majority of individuals. Left untreated, about one third of these women will develop tertiary syphilis. Neurologic, cardiovascular, musculoskeletal, or multiorgan system complications can develop in the third stage.

Screening and Diagnosis. All women who are diagnosed with another STI or with HIV should be screened for syphilis. All pregnant women should be screened for syphilis at the first prenatal visit, again in the late third trimester, and at the time of giving birth if high risk (CDC, 2010a). Diagnosis depends on microscopic examination of primary and secondary lesion tissue and serology during latency and late infection. A test for antibodies may not be reactive in the presence of active infection because it takes time for the immune system of the body to develop antibodies to any antigens. Up to one third of people in early primary syphilis may have nonreactive serologic tests. Two types of serologic tests are used: nontreponemal and treponemal. Nontreponemal antibody tests such as Venereal Disease Research Laboratories (VDRL) and rapid plasma reagin (RPR) are used as screening tests. False-positive results are not unusual, particularly when conditions such as acute infection, autoimmune disorders, malignancy, pregnancy, and drug addiction exist and after immunization or vaccination. The treponemal tests, fluorescent treponemal antibody absorbed, and microhemagglutination assays for antibody to *T. pallidum* are used to confirm positive results. Test results in patients with early primary or incubating syphilis may be negative. Seroconversion usually takes place 6 to 8 weeks after exposure; thus testing should be repeated in 1 to 2 months when a suggestive genital lesion exists.

Tests (e.g., wet preparations and cultures) for concomitant STIs (e.g., chlamydia and gonorrhea) should be done, and HIV testing offered if indicated.

Management. Penicillin G is the preferred drug for treating patients with all stages of syphilis, including pregnant women (see Table 4-3). Although doxycycline, tetracycline, and erythromycin are alternative treatments for penicillin-allergic patients, both tetracycline and doxycycline are contraindicated in pregnancy, and erythromycin is unlikely to cure a fetal infection. Therefore if necessary pregnant women should receive skin testing and be treated with penicillin or be desensitized (CDC, 2010a). Specific protocols are recommended by the CDC.

! NURSING ALERT

Patients treated for syphilis may experience a Jarisch-Herxheimer reaction. This is an acute febrile reaction often accompanied by headache, myalgias, and arthralgias that develop within the first 24 hours of treatment. The reaction may be treated symptomatically with analgesics and antipyretics. If treatment precipitates this reaction in the second half of pregnancy, women are at risk for preterm labor and birth. They should be advised to contact their health care provider if they notice any change in fetal movement or have any contractions.

Monthly follow-up is mandatory so repeated treatment may be given if needed. The nurse should emphasize the necessity of long-term serologic testing even in the absence of symptoms. The woman should be advised to practice sexual abstinence until treatment is completed, all evidence of primary and secondary syphilis is gone, and serologic evidence of a cure is demonstrated. Women should be told to notify all partners who may have been exposed. They should be informed that the disease is reportable. Preventive measures should be discussed.

Pelvic Inflammatory Disease

Pelvic inflammatory disease (PID) is an infectious process that most commonly involves the uterine tubes, causing salpingitis; the uterus, causing endometritis; and, more rarely, the ovaries and peritoneal surfaces. Multiple organisms have been found to cause PID; most cases are associated with more than one organism. In the past the most common causative agent was thought to be *N. gonorrhoeae;* however, *C. trachomatis* is now estimated to cause one half of all cases. In addition to gonorrhea and chlamydia, a wide variety of anaerobic and aerobic bacteria cause PID. It encompasses a wide variety of pathologic processes; the infection can be acute, subacute, or chronic and can have a wide range of symptoms.

Most PID results from the ascending spread of microorganisms from the vagina and endocervix to the upper genital tract. This spread most commonly happens at the end of or just after menses following reception of an infectious agent. During the menstrual period several factors facilitate the development of an infection: the cervical os is slightly open, the cervical mucus barrier is absent, and menstrual blood is an excellent medium for growth. PID also may develop after a miscarriage or an induced abortion, pelvic surgery, or childbirth.

Risk factors for acquiring PID are those associated with the risk of contracting an STI, including young age, multiple partners, high rate of new partners, and a history of STIs. Women who use IUDs may be at increased risk for PID if they have more than one sexual partner or if the partner has other sexual partners because they are at higher risk for acquiring an STI. Most of this risk occurs in the 3 weeks after IUD insertion (Eckert and Lentz, 2012). PID tends to recur.

Women who have had PID are at increased risk for ectopic pregnancy, infertility, and chronic pelvic pain. After a single episode of PID, a woman's risk for ectopic pregnancy increases sevenfold compared with the risk for women who have never had it. Other problems associated with PID include dyspareunia, pyosalpinx (pus in the uterine tubes), tubo-ovarian abscess, and pelvic adhesions.

The symptoms of PID vary, depending on whether the infection is acute, subacute, or chronic; however, pain is common to all types of infection. It may be dull, cramping, intermittent (subacute) or severe, persistent, and incapacitating (acute). Women may also report one or more of the following: fever, chills, nausea and vomiting, increased vaginal discharge, symptoms of a urinary tract infection, and irregular bleeding. Abdominal pain is usually present (Eckert and Lentz, 2012).

Screening and Diagnosis. PID is difficult to diagnose because of the accompanying wide variety of symptoms. The CDC recommends treatment for PID in all sexually active young women and others at risk for STIs if the following criteria are present and no other cause or causes of the illness are found: lower abdominal tenderness, bilateral adnexal tenderness, and cervical motion tenderness. Other criteria for diagnosing PID include an oral temperature of 38.3° C or above, abnormal cervical or vaginal discharge, elevated erythrocyte sedimentation rate, elevated C-reactive protein,

and laboratory documentation of cervical infection with *N. gonorrhoeae* or *C. trachomatis* (CDC, 2010a).

Management. Perhaps the most important nursing intervention is prevention counseling. Primary prevention includes education in avoiding contracting STIs; secondary prevention involves preventing a lower genital tract infection from ascending to the upper genital tract. Instructing women in self-protective behaviors such as practices to avoid contracting STIs and using barrier methods is critical. Women using hormonal contraception or an IUD and those who have chosen tubal ligation must be reminded to use a condom with intercourse when indicated. Also important is the detection of asymptomatic gonorrheal and chlamydial infections through routine screening of women who practice risky behaviors or have specific risk factors such as age.

Although treatment regimens vary with the infecting organism, generally a broad-spectrum antibiotic is used (CDC, 2010a). Treatment for mild-to–moderately severe PID may be oral (e.g., ceftriaxone plus doxycycline with or without metronidazole) or parenteral (e.g., cefotetan or cefoxitin plus doxycycline [oral]), and regimens can be administered in inpatient or outpatient settings. Pregnant women should be hospitalized and given parenteral antibiotics (CDC, 2010a).

The woman with acute PID should be on bed rest in a semi-Fowler's position. Comfort measures include analgesics for pain and all other nursing measures applicable to a patient confined to bed. Few pelvic examinations should be done during the acute phase of the disease. During the recovery phase the woman should restrict her activity and make every effort to get adequate rest and a nutritionally sound diet. Follow-up laboratory work after treatment should include endocervical cultures for a test of cure.

Health education is central to effective management of PID. Nurses should explain the nature of the disease to women and encourage them to comply with all therapy and prevention recommendations, emphasizing the need to take all medication, even if symptoms disappear. Any potential problems (such as a lack of money for prescriptions or a lack of transportation to return for follow-up appointments) that would prevent a woman from completing a course of treatment should be identified, referrals made for assistance as needed, and the importance of follow-up visits stressed. Women should be counseled to refrain from sexual intercourse until their treatment is completed. Contraceptive counseling, including information on barrier methods such as condoms, the contraceptive sponge, and the diaphragm, should be provided.

The potential or actual loss of reproductive capabilities can be devastating and can adversely affect the woman's self-concept. Part of the nurse's role is to help the woman adjust her self-concept to fit reality and accept alterations in a way that promotes health. Because PID is so closely tied to sexuality, body image, and self-concept, the woman diagnosed with it needs supportive care. Her feelings should be discussed, and her partner(s) included when appropriate.

Sexually Transmitted Viral Infections

Human Papillomavirus

Human papillomavirus (HPV) infection, also known as *condylomata acuminata,* or *genital warts,* is the most common viral STI seen in ambulatory health care settings. An estimated 20 million Americans are infected with HPV, and about 6.2 million new infections occur every year (CDC, 2012a). HPV, a double-stranded DNA virus, has more than 30 serotypes that can be sexually transmitted, 5 of which are known to cause genital wart formation, and 8 of which are currently thought to have oncogenic potential (CDC, 2010a). HPV is the primary cause of cervical neoplasia (ACS, 2012).

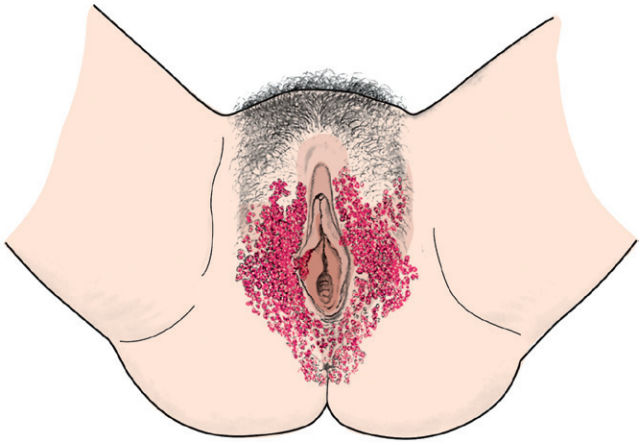

FIG 4-4 Human papillomavirus infection. Genital warts or condylomata acuminata.

In women HPV lesions are most commonly seen in the posterior part of the introitus. Lesions also are found on the buttocks, vulva, vagina, anus, and cervix (Fig. 4-4). Typically the lesions are small (2 to 3 mm in diameter and 10 to 15 mm in height), soft, papillary swellings occurring singly or in clusters on the genital and anal-rectal region. Infections of long duration may appear as a cauliflower-like mass. In moist areas such as the vaginal introitus, the lesions may appear to have multiple fine, fingerlike projections. Vaginal lesions are often multiple. Flat-topped papules, 1 to 4 mm in diameter, are seen most often on the cervix. Often these lesions are visualized only under magnification. Warts are usually flesh colored or slightly darker on Caucasian women, black on African-American women, and brownish on Asian women. The lesions are usually painless; but they may be uncomfortable, particularly when very large, inflamed, or ulcerated. Chronic vaginal discharge, pruritus, or dyspareunia can occur.

HPV infections are thought to be more common in pregnant than in nonpregnant women, with an increase in incidence from the first trimester to the third. Furthermore, a significant proportion of preexisting HPV lesions enlarge greatly during pregnancy, a proliferation presumably resulting from the relative state of immunosuppression present during this period. Lesions may become so large during pregnancy that they affect urination, defecation, mobility, and fetal descent, although birth by cesarean is rarely necessary. Cesarean birth may be performed when extensive growths are present. Initial observation of large growths can be misleading, suggesting that the entire vagina is involved. However, all of the growth may derive from one stalk; and in such cases it may be possible to push the large mass to the side, allowing the baby to pass through.

Screening and Diagnosis. A woman with HPV lesions may complain of symptoms such as a profuse, irritating vaginal discharge; itching; dyspareunia; or postcoital bleeding. She also may report "bumps" on her vulva or labia. History of a known exposure is important; however, because of the potentially long latency period and the possibility of subclinical infections in men, the lack of a history of known exposure cannot be used to exclude a diagnosis of HPV infection.

Physical inspection of the vulva, the perineum, the anus, the vagina, and the cervix is essential whenever HPV lesions are suspected or seen in one area. Because speculum examination of the

vagina may block some lesions, it is important to rotate the speculum blades until all areas are visualized. When lesions are visible, the characteristic appearance previously described is considered diagnostic. However, in many instances cervical lesions are not visible, and some vaginal or vulvar lesions also may be unobservable to the naked eye. Because of the potential spread of vulvar or vaginal lesions to the anus, gloves should be changed between vaginal and rectal examinations.

Viral screening and typing for HPV are available but not standard practice. History, evaluation of signs and symptoms, Papanicolaou (Pap) test, and physical examination are used in making a diagnosis. The HPV-DNA test can be used in women older than the age of 30 in combination with the Pap test to screen for types of HPV that are likely to cause cancer or in women with abnormal Pap test results (ACS, 2012). The only definitive diagnostic test for presence of HPV is histologic evaluation of a biopsy specimen.

Management. Untreated warts may resolve on their own in young women since their immune systems may be strong enough to fight the HPV infection. Treatment of genital warts, if needed, is often difficult. No therapy has been shown to eradicate HPV. Therefore the goal of treatment is removal of warts and relief of signs and symptoms. The patient often must make multiple office visits; frequently many different treatment modalities will be used.

Treatment of genital warts should be guided by preference of the woman, available resources, and experience of the health care provider. No one of the treatments is superior to all other treatments, and no one treatment is ideal for all warts (CDC, 2010a). Imiquimod, podophyllin, and podofilox are common treatments but should not be used during pregnancy (see Table 4-3). Because the lesions can proliferate and become friable during pregnancy, many experts recommend their removal using cryotherapy or various surgical techniques (CDC, 2010a).

Women who have discomfort associated with genital warts may find that bathing with an oatmeal solution and drying the area with cool air from a hair dryer provides some relief. Keeping the area clean and dry also decreases the growth of the warts. Cotton underwear and loose-fitting clothes that decrease friction and irritation may lessen discomfort. Women should be advised to maintain a healthy lifestyle to aid the immune system and be counseled regarding diet, rest, stress reduction, and exercise.

Patient counseling is essential. Women must understand the virus, how it is transmitted, that no immunity is conferred with infection, and that reinfection is likely with repeated contact (Royer and Falk, 2012). Encourage all sexually active women with multiple partners or a history of HPV to use latex condoms for intercourse to decrease acquisition or transmission of the infection. Semiannual or annual health examinations are recommended to assess disease recurrence and screening for cervical cancer. Women who have been treated for HPV infections should have at least annual Pap tests (CDC, 2010a).

Prevention. Preventive strategies that have been suggested include abstinence from all sexual activity, staying in a long-term monogamous relationship, and prophylactic vaccination (CDC, 2010a). Two vaccines, Cervarix and Gardasil, are available; and other vaccines continue to be investigated. Cervarix prevents infection from HPV viruses 16 and 18, whereas Gardasil prevents infection from viruses 6, 11, 16, and 18. Both can be administered to girls and women ages 9 to 26. The three-dose vaccines are most effective if given before the woman has her first sexual contact (CDC, 2012a). Practitioners should stay current with results of these clinical trials and make recommendations about vaccination based on the outcomes of the research.

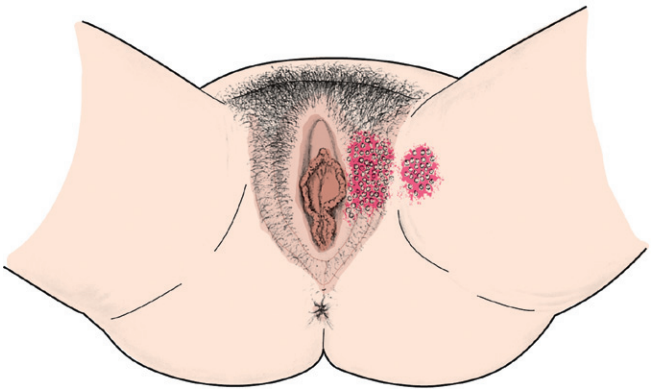

FIG 4-5 Herpes genitalis.

Herpes Simplex Virus

Unknown until the middle of the twentieth century, herpes simplex virus (HSV) infection is now widespread in the United States, especially in women. It results in painful, recurrent ulcers. It is caused by two different antigen subtypes of HSV: HSV type 1 (HSV-1) and HSV type 2 (HSV-2). HSV-2 is usually transmitted sexually, and HSV-1 nonsexually. Although HSV-1 is more commonly associated with gingivostomatitis and oral labial ulcers (fever blisters) and HSV-2 with genital lesions, neither type is exclusively associated with the respective sites.

Although HSV infection is not a reportable disease, it is estimated that about 50 million people in the United States are infected with genital herpes (CDC, 2010a). Women between the ages of 15 and 34 are most likely to become infected, especially if they have multiple partners. Recurrent HSV infections are much more common. Most persons infected with HSV-2 have not been diagnosed, and most infections are transmitted by persons unaware that they are infected.

An initial HSV genital infection is characterized by multiple painful lesions, fever, chills, malaise, and severe dysuria and may last 2 to 3 weeks. Women generally have a more severe clinical course than do men. Women with primary genital herpes have many lesions that progress from macules to papules; they then progress to form vesicles, pustules, and ulcers that crust and heal without scarring (Fig. 4-5). These ulcers are extremely tender, and primary infections may be bilateral. Women also may have itching, inguinal tenderness, and lymphadenopathy. Severe vulvar edema may develop, and women may have difficulty sitting. HSV cervicitis is common with initial HSV-2 infections. The cervix may appear normal or be friable, reddened, ulcerated, or necrotic. A heavy, watery-to-purulent vaginal discharge is common. Extragenital lesions may be present because of autoinoculation. Urinary retention and dysuria may occur secondary to autonomic involvement of the sacral nerve root.

Women with recurrent episodes of HSV infections commonly have only local symptoms that are usually less severe than those associated with the initial infection. Systemic symptoms are usually absent, although the characteristic prodromal genital tingling is common. Recurrent lesions are unilateral, are less severe, and usually last 5 to 7 days. Lesions begin as vesicles and progress rapidly to ulcers. Few women with recurrent disease have cervicitis.

During pregnancy maternal infection with HSV-2 can have adverse effects on both the mother and fetus. Viremia occurs during the primary infection, and congenital infection is possible although rare. Primary infections during the first trimester have been associated with increased miscarriage rates (CDC, 2010a).

Screening and Diagnosis. Although a diagnosis of herpes infection may be suspected from the history and physical examination, it is confirmed by laboratory studies. A viral culture is obtained by swabbing exudate during the vesicular stage of the disease.

Management. Genital herpes is a chronic and recurring disease for which there is no known cure. Management is directed toward specific treatment during primary and recurrent infections, prevention, self-help measures, and psychologic support.

Oral medications used for treating the first clinical HSV infection include acyclovir, famciclovir, and valacyclovir. These medications are considered for episodic or suppressive therapy for recurrent HSV. Intravenous acyclovir may be used for women with severe disease (CDC, 2010a). The safety of acyclovir, valacyclovir, and famciclovir therapy during pregnancy has not been established; however, acyclovir may be used to reduce the symptoms of HSV if the benefits to the woman outweigh the potential harm to the fetus (CDC, 2010a). Continued investigation of HSV therapy with these medications during pregnancy is needed.

Cleaning lesions twice a day with saline helps prevent secondary infection. Bacterial infection must be treated with appropriate antibiotics. Measures that may increase comfort for women when lesions are active include warm sitz baths with baking soda; keeping lesions dry by using cool air from a hair dryer or patting dry with a soft towel; wearing cotton underwear and loose clothing; using drying aids such as hydrogen peroxide, Burow's solution, or oatmeal baths; and applying cool, wet, black tea bags to lesions. Women can also apply compresses with an infusion of cloves or peppermint oil and clove oil to lesions.

Oral analgesics such as aspirin or ibuprofen may be used to relieve pain and systemic symptoms associated with initial infections. Because the mucous membranes affected by herpes are extremely sensitive, any topical agents should be used with caution. Nonantiviral ointments, especially those containing cortisone, should be avoided. A thin layer of lidocaine ointment or an antiseptic spray may be applied to decrease discomfort, especially if walking is difficult.

Counseling and education are critical components of the nursing care of women with herpes infections. Information regarding the etiology, signs and symptoms, transmission, and treatment should be provided. The nurse should explain that each woman is unique in her response to herpes and emphasize the variability of symptoms. Women should be helped to understand when viral shedding and thus transmission to a partner are most likely. They should be counseled to refrain from sexual contact from the onset of prodrome until complete healing of lesions.

Some authorities recommend consistent use of condoms for all persons with genital herpes. Condoms may not prevent transmission, particularly male-to-female transmission; however, this does not mean that the partners should avoid all intimacy. Women can be encouraged to maintain close contact with their partners while avoiding contact with lesions. They should be taught how to look for herpetic lesions using a mirror and good light source and a wet cloth or finger covered with a finger cot to rub lightly over the labia. The nurse should ensure that women understand that, when lesions are active, sharing intimate articles (e.g., washcloths or wet towels) that come into contact with the lesions should be avoided. Only plain soap and water are needed to clean hands that have come in contact with herpetic lesions; isolation is neither necessary nor appropriate.

Stress, menstruation, trauma, febrile illnesses, chronic illness, and ultraviolet light have all been found to trigger genital herpes. Women may wish to keep a diary to identify stressors that seem to be associated with recurrent herpes attacks so they can avoid these stressors when possible. The role of exercise in reducing stress can be discussed. Referral for stress-reduction therapy, yoga, or meditation classes may be indicated. Avoiding excessive heat, sun, and hot baths and using a lubricant during sexual intercourse to reduce friction also may be helpful. Women in their childbearing years should be counseled regarding the risk of herpes infection during pregnancy. They should be instructed to use condoms if there is any risk of contracting an STI from a sexual partner. If they become pregnant while taking acyclovir, the risk of birth defects does not appear to be higher than for the general population; however, continued use should be based on whether the benefits for the woman outweigh the possible risks to the fetus. Acyclovir does enter breast milk, but the amount of medication ingested during breastfeeding is very low and usually not a health concern (Weiner and Buhimschi, 2009).

Because neonatal HSV infection is such a devastating disease, prevention is critical. Current recommendations include carefully examining and questioning all women about symptoms at onset of labor (CDC, 2010a). If visible lesions are not present at onset of labor, vaginal birth is acceptable. Cesarean birth within 4 hours after labor begins or membranes rupture is recommended if visible lesions are present. Infants who are born through an infected vagina should be observed carefully and cultured. Some experts recommend presumptive treatment of infants who were exposed to HSV during birth. Because HSV infection may be associated with cervical dysplasia, women must be encouraged to have annual Pap tests and gynecologic examinations.

The emotional effect of contracting an incurable STI such as herpes is considerable. At diagnosis many emotions may surface—helplessness, anger, denial, guilt, anxiety, shame, or inadequacy. Women need the opportunity to discuss their feelings and help in learning to live with the disease. Herpes can affect a woman's sexuality, her sexual practices, and her current and future relationships. She may need help in raising the issue with her partner or future partners.

Hepatitis

Five different viruses (hepatitis viruses A, B, C, D, and E) account for almost all cases of viral hepatitis in humans. Hepatitis viruses A, B, and C are discussed here. Hepatitis D and E viruses, common among users of intravenous drugs and recipients of multiple blood transfusions, are not included in this discussion.

Hepatitis A. Hepatitis A virus (HAV) infection is acquired primarily through a fecal-oral route by ingestion of contaminated food, particularly milk, shellfish, or polluted water, or via person-to-person contact. Influenza-like symptoms with malaise, fatigue, anorexia, nausea, pruritus, fever, and upper–right quadrant pain characterize HAV infection. Serologic testing to detect the immunoglobulin M (IgM) antibody confirms acute infections. Because HAV infection is self-limited and does not result in chronic infection or chronic liver disease, treatment is usually supportive. Women who become dehydrated from nausea and vomiting or who have fulminating hepatitis A may need to be hospitalized. Medications that might cause liver damage or that are metabolized in the liver should be used with caution. No specific diet or activity restrictions are necessary. Hepatitis A vaccine and immunoglobulin (IG) for intramuscular administration are effective in preventing most hepatitis A infections (CDC, 2010a).

Hepatitis B. Hepatitis B virus (HBV) infection is an STI and is the virus most threatening to the fetus and neonate. It is caused by a large DNA virus and is associated with three antigens and their

antibodies: hepatitis B surface antigen (HBsAg), HBV antigen (HBeAg), HBV core antigen (HBcAg), antibody to HBsAg (anti-HBs), antibody to HBeAg (anti-HBe), and antibody to HBcAg (anti-HBc). Screening for active or chronic disease or disease immunity is based on testing for these antigens and their antibodies.

Populations at risk include women of Asian, Pacific Island (Polynesian, Micronesian, Melanesian), or Alaskan-Eskimo descent and those born in Haiti or sub-Saharan Africa. Women who have a history of acute or chronic liver disease, who work or receive treatment in a dialysis unit, or who have household or sexual contact with a hemodialysis patient are at greater risk. Women who work or live in institutions for the mentally handicapped are considered to be at risk, as are those with a history of multiple blood transfusions. Health care workers and public safety workers exposed to blood in the workplace are at risk. Behaviors such as multiple sexual partners and a history of intravenous drug use increase the risk of contracting HBV infections.

HBsAg has been found in blood, saliva, sweat, tears, vaginal secretions, and semen. Drug abusers who share needles are at risk, as are health care workers who are exposed to blood and needlesticks. Perinatal transmission most often occurs in infants of mothers who have acute hepatitis infection late in the third trimester or during the intrapartum or postpartum periods from exposure to HBsAg-positive vaginal secretions, blood, amniotic fluid, saliva, and breast milk. HBV has also been transmitted by artificial insemination. Although it can be transmitted by blood transfusion, the incidence of such infections has decreased significantly since testing of blood for HBsAg became routine.

HBV infection is a disease of the liver and is often a silent infection. In the adult its course can be fulminating, and the outcome fatal. Symptoms of HBV infection are similar to those of hepatitis A: arthralgias, arthritis, lassitude, anorexia, nausea, vomiting, headache, fever, and mild abdominal pain. Later the woman may have clay-colored stools, dark urine, increased abdominal pain, and jaundice. Between 5% and 10% of individuals with HBV have persistent HBsAg and become chronic hepatitis B carriers.

Screening and Diagnosis. All women at high risk for contracting HBV should be screened on a regular basis. However, screening only individuals at high risk may not identify up to 50% of HBsAg-positive women. Screening for the presence of HBsAg is recommended on all pregnant women at the first prenatal visit, regardless of whether they have been tested previously; screening should be done on admission for labor and birth for women at high risk for infection during pregnancy or if prenatal test results are not available (CDC, 2012b, USPSTF, 2009).

The HBsAg screening test is usually performed, given that a rise in HBsAg occurs at the onset of clinical symptoms and usually indicates an active infection. If HBsAg persists in the blood, the woman is identified as a carrier. If the HBsAg test result is positive, further laboratory studies may be ordered: anti-HBe, anti-HBc, serum glutamic-oxaloacetic transaminase (SGOT), alkaline phosphatase, and liver panel.

Management. There is no specific treatment for hepatitis B. Recovery is usually spontaneous in 3 to 16 weeks. Pregnancies complicated by acute viral hepatitis are managed on an outpatient basis. Women should be advised to increase bed rest; eat a high-protein, low-fat diet; and increase their fluid intake. They should avoid medications metabolized in the liver and alcohol. Pregnant women with a definite exposure to HBV should be given HBIG and begin the hepatitis B vaccine series within 14 days of the most recent contact to prevent infection (CDC, 2010a). Vaccination during pregnancy is not thought to pose risks to the fetus.

All nonimmune women at high or moderate risk of hepatitis should be informed of the availability of hepatitis B vaccine. Vaccination is recommended for all individuals who have had multiple sex partners within the past 6 months (CDC, 2010a). In addition, intravenous drug users, residents of correctional or long-term care facilities, persons seeking care for an STI, prostitutes, women whose partners are intravenous drug users or bisexual, and women whose occupation exposes them to high risk should be vaccinated. The vaccine is given in a series of three (four if rapid protection is needed) doses over a 6-month period, with the first two doses given at least 1 month apart. The vaccine is given in the deltoid muscle (CDC, 2010a).

Patient education includes explaining the meaning of hepatitis B infection, including transmission, state of infectivity, and sequelae. The nurse also should explain the need for immunoprophylaxis for household members and sexual contacts. To decrease transmission of the virus, women with hepatitis B or those who test positive for HBV should be advised to maintain a high level of personal hygiene (e.g., wash hands after using the toilet; carefully dispose of tampons, pads, and bandages in plastic bags; not to share razor blades, toothbrushes, needles, or manicure implements; have male partner use a condom if unvaccinated and without hepatitis; avoid sharing saliva through kissing or sharing silverware or dishes; and wipe up blood spills immediately with soap and water). They should inform all health care providers of their carrier state. Postpartum women should be reassured that breastfeeding is not contraindicated if their infants received prophylaxis at birth and are currently on the immunization schedule.

Hepatitis C. Hepatitis C virus (HCV) infection is approximately the most common chronic bloodborne infection in the United States and is responsible for nearly 50% of the cases of chronic viral hepatitis (CDC, 2010a). The most common risk factor for pregnant women is a history of intravenous drug use. Other risk factors include STIs such as HBV and HIV, multiple sexual partners, and a history of blood transfusions. HCV is readily transmitted through exposure to blood.

Most patients with HCV are asymptomatic or have general flu-like symptoms similar to those of HAV. HCV infection is confirmed by the presence of anti-C antibody during laboratory testing. Interferon alfa alone or with ribavirin for 6 to 12 months is the main treatment for HCV infection, although effectiveness of this treatment varies (CDC, 2010a). Currently there is no vaccine to prevent HCV. Its transmission through breastfeeding has not been reported.

Human Immunodeficiency Virus

An estimated 34,247 new HIV infections occur in the United States each year (CDC, 2011a). An estimated 23% of these new infections occur in women. African-American women are estimated to have 57% of these infections, Caucasian women 17%, Hispanic women 14%, and Native American women less than 1% (CDC, 2011a).

Severe depression of the cellular immune system associated with HIV infection characterizes acquired immunodeficiency syndrome (AIDS). Although behaviors that place women at risk have been well documented, all women should be assessed for the possibility of HIV exposure. The most commonly reported opportunistic diseases are *Pneumocystis (jirovecii)* pneumonia (PCP), *Candida* esophagitis, and wasting syndrome. Other viral infections such as HSV and cytomegalovirus infections seem to be more prevalent in women than men (CDC, 2010a). PID is often more severe in HIV-infected women than in the general population, and rates of HPV and cervical dysplasia are sometimes higher in non–HIV-infected women (Eckert and Lentz, 2012). The clinical course of HPV infection in

women with HIV infection is accelerated, and recurrence is more frequent in non–HIV-infected women.

Once HIV enters the body, seroconversion to HIV positivity usually occurs within 6 to 12 weeks. Although HIV seroconversion may be totally asymptomatic, it usually is accompanied by a viremic, influenza-like response. Symptoms include fever, headache, night sweats, malaise, generalized lymphadenopathy, myalgias, nausea, diarrhea, weight loss, sore throat, and rash.

Laboratory studies may reveal leukopenia, thrombocytopenia, anemia, and an elevated erythrocyte sedimentation rate. HIV has a strong affinity for surface-marker proteins on T lymphocytes. This affinity leads to significant T-cell destruction. Both clinical and epidemiologic studies have shown that declining CD4 levels are strongly associated with increased incidence of AIDS-related diseases and death in many different groups of HIV-infected persons.

Transmission of the virus from mother to infant can occur throughout the perinatal period. Exposure may occur to the fetus through the maternal circulation as early as the first trimester of pregnancy, to the infant during labor and birth by inoculation or ingestion of maternal blood and other infected fluids, or to the infant through breast milk.

Screening and Diagnosis. Screening, teaching, and counseling regarding HIV risk factors; indications for being tested; and testing are major roles for nurses caring for women today. A number of behaviors place women at risk for HIV infection, including intravenous drug use, high risk sex partners, multiple sex partners, and a previous history of multiple STIs. HIV infection is usually diagnosed by using HIV-1 and HIV-2 antibody tests. Antibody testing is done first with a sensitive screening test such as the enzyme immunoassay. Reactive screening tests must be confirmed by an additional test such as the Western blot or an immunofluorescence assay. If a positive antibody test is confirmed by a supplemental test, it means that a woman is infected with HIV and is capable of infecting others. HIV antibodies are detectable in at least 95% of patients within 3 months after infection. Although a negative antibody test usually indicates that a person is not infected, antibody tests cannot exclude recent infection. Because HIV antibody crosses the placenta, definite diagnosis of HIV in children younger than 18 months is based on laboratory evidence of HIV in blood or tissues by culture, nucleic acid, or antigen detection (CDC, 2010a).

The FDA has approved six methods of rapid testing for HIV, variously using a blood sample obtained by fingerstick or venipuncture, serum, or plasma or an oral fluid sample. The tests have accuracy rates of 98% to 99%. If the results are reactive, further testing is done (CDC, Division of HIV/AIDS prevention, 2008a; USFDA, 2008). Quick results mean that patients don't have to make extra visits for follow-up standard tests, and the oral test provides an option for patients who do not want to have a blood test.

The CDC (2010a) recommends offering HIV testing to all women whose behavior places them at risk for HIV infection. It may be useful to allow women to self-select for HIV testing. On entry to the health care system, a woman can be handed written information about the risk factors for the AIDS virus and asked to inform the nurse if she believes she is at risk. She should be told that she does not have to say why she may be at risk, only that she thinks she might be.

Counseling for HIV Testing. Counseling before and after HIV testing is standard nursing practice today. It is a nursing responsibility to assess a woman's understanding of the information such a test would provide and to be sure the woman thoroughly understands the emotional, legal, and medical implications of a positive or negative test before she is ready to take it.

! NURSING ALERT

Counseling associated with HIV testing has two components: pretest and posttest. During pretest counseling, a personalized risk assessment is conducted, the meaning of positive and negative test results is explained, informed consent for HIV testing is obtained, and women are helped to develop a realistic plan for reducing risk and preventing infection. Posttest counseling includes informing the patient of the test results, reviewing the meaning of the results, and reinforcing prevention messages. All pretest and posttest counseling should be documented.

Given the strong social stigma attached to HIV infection, nurses must consider the issue of confidentiality and documentation before providing counseling and offering HIV testing to patients.

LEGAL TIP: HIV Testing

If HIV test results are placed in the patient's chart—the appropriate place for all health information—they are available to all who have access to the chart. Inform the woman of this availability before testing. Informed consent must be obtained before an HIV test is performed. In some states written consent is mandated. In many sites HIV testing is performed unless patients decline (i.e., opt-out testing). Nurses must know which procedures are being used for informed consent in their facility.

Unless rapid testing is done, there is generally a 1- to 3-week waiting period after testing for HIV; this can be a very anxious time for the woman. It is helpful if the nurse informs her that this time period between blood drawing and test results is routine. Test results must always be communicated in person, and women should be informed in advance that this is the procedure. Whenever possible, the person who provided the pretest counseling should also tell the woman her test results.

When some women are informed of negative results, they may escalate risk behaviors because they equate negativity with immunity. Others may believe that negative means "bad" and positive means "good." The woman's reaction to a negative test should be explored by asking, "How do you feel?" Counseling sessions for women with an HIV-negative result are another opportunity to provide education. Emphasis can be placed on ways in which a woman can remain HIV free. She should be reminded that, if she has been exposed to HIV in the past 6 months, she should be retested, and that she should have ongoing testing if she continues high risk behaviors.

In posttest counseling of an HIV-positive woman, privacy with no interruptions is essential. Adequate time for the counseling sessions also should be provided. The nurse should make sure that the woman understands what a positive test means and review the reliability of the test results. Risk reduction practices should be reemphasized. Referral for appropriate medical evaluation and follow-up should be made, and the need or desire for psychosocial or psychiatric referrals should be assessed.

The importance of early medical evaluation so a baseline assessment can be made and prophylactic medication begun should be stressed. If possible, the nurse should make a referral or appointment for the woman at the posttest counseling session.

Management. During the initial contact with an HIV-infected woman, the nurse should establish what the woman knows about HIV infection and that she is being cared for by a medical practitioner or facility with expertise in caring for persons with HIV

infections, including AIDS. Psychologic referral also may be indicated. Resources such as counseling for financial assistance, legal advocacy, suicide prevention, and death and dying may be appropriate. All women who are drug users should be referred to a substance-abuse program. A major focus of counseling is prevention of transmission of HIV to partners.

Nurses counseling seropositive women wishing contraceptive information can recommend oral contraceptives and latex condoms or tubal sterilization or vasectomy and latex condoms. Suggest female condoms or abstinence to women whose male partners refuse to use condoms.

No cure is available for HIV infections at this time. Rare and unusual diseases are characteristic of HIV infections. Opportunistic infections and concurrent diseases are managed vigorously with treatment specific to the infection or disease. Routine gynecologic care for HIV-positive women should include a pelvic examination every 6 months. Thorough Pap screening is essential because of the greatly increased incidence of abnormal findings on examination (CDC, 2010a). In addition, HIV-positive women should be screened for syphilis, gonorrhea, chlamydia, and other vaginal infections and treated if infections are present. General prevention strategies are an important part of care (e.g., smoking cessation, sound nutrition) as is antiretroviral therapy. Discussion of the medical care of HIV-positive women or women with AIDS is beyond the scope of this chapter because of the rapidly changing recommendations. The reader is referred to the CDC (www.cdc.gov), AIDS hotlines (800-342-2437), and Internet websites such as HIV/AIDS Treatment Information Service (www.hivatis.org) for the current information and recommendations.

Pregnancy and Human Immunodeficiency Virus. HIV counseling and testing should be offered to all women at their initial entry into prenatal care as part of routine prenatal testing unless the woman opts out of the screening (CDC, 2010a). Universal testing versus selective testing for maternal HIV is recommended because it results in a greater number of women being screened and treated and can reduce the likelihood of perinatal transmission and maintain the health of the woman (CDC, 2010a). The CDC also recommends retesting in the third trimester for women known to be at high risk for HIV and rapid HIV testing in labor for women with unknown HIV status.

Perinatal transmission of HIV has decreased significantly in the past decade because of the administration of antiretroviral prophylaxis (e.g., zidovudine) to pregnant women in the prenatal and the perinatal periods. Treatment of HIV-infected women with the triple-drug antiviral therapy or highly active antiretroviral therapy (HAART) during pregnancy has been reported to decrease the mother-to-child transmission to 1% to 2% (CDC, 2010a). All HIV-infected women should be treated with a combination of antiretroviral drugs (e.g., HAART) during pregnancy, regardless of their CD4 cell counts (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010). Data are insufficient to support or refute the teratogenic risk of antiretroviral medications given for prophylaxis in the first 10 weeks or pregnancy. Current research does not support major teratogenic effects for most of the antiretroviral agents (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010). Women who are infected with HIV and need treatment for their own health should start the therapy as soon as possible, even in the first trimester. Women who are taking the therapy as prophylaxis usually start therapy after the first trimester (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010).

Antiviral therapy is administered orally and continued throughout pregnancy. The major side effect of this therapy is bone marrow suppression. Periodic hematocrit, white blood cell count, and platelet count assessments should be performed (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010). Women who are HIV positive should also be vaccinated against hepatitis B, pneumococcal infection, *Haemophilus influenzae* type B, and viral influenza. To support any pregnant woman's immune system, appropriate counseling is provided about optimal nutrition, sleep, rest, exercise, and stress reduction. Use of condoms is encouraged to minimize further exposure to HIV if her partner is the source.

In the intrapartum period antiretroviral therapy and cesarean birth are recommended to prevent vertical transmission of HIV (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010). The Panel recommends a scheduled cesarean birth at 38 weeks of gestation for women with a viral load of more than 1000 copies/mL. A vaginal birth may be an option for HIV-infected women who have a viral load of less than 1000 copies/mL at 36 weeks, if a woman has ruptured membranes and labor is progressing rapidly, or if she declines a cesarean birth. Intravenous zidovudine is recommended for all HIV-infected pregnant women during the intrapartum period. The drug is administered 3 hours before a scheduled cesarean birth and continued until the baby is born. It should be given during labor if the woman is having a vaginal birth (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010). Fetal scalp electrode and scalp pH sampling should be avoided because these procedures may result in inoculation of the virus into the fetus. Similarly the use of forceps or vacuum extractor should be avoided when possible. Infants should receive oral zidovudine for 6 weeks after birth. Avoidance of breastfeeding is recommended in the United States and most developed countries (American Academy of Pediatrics Committee on Pediatric AIDS, 2008).

Women who have HIV but who are without symptoms may have an unremarkable postpartum course. Immunosuppressed women with symptoms may be at increased risk for postpartum urinary tract infections (UTIs), vaginitis, postpartum endometritis, and poor wound healing. Good perineal hygiene should be stressed. Women who are HIV positive but who were not on antiretroviral drugs before pregnancy should be tested in the postpartum period to determine whether therapy that was initiated in pregnancy should be continued (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010). After the initial bath the newborn can be with the mother. In planning for discharge, comprehensive care and support services need to be arranged. After discharge the woman and her infant are referred to physicians who are experienced in the treatment of HIV and AIDS and associated conditions for intensive monitoring and follow-up (Panel on Treatment of HIV-Infected Pregnant Women and Prevention of Perinatal Transmission, 2010).

Vaginal Infections

Vaginal discharge and itching of the vulva and vagina are among the most common reasons a woman seeks help from a health care provider. More women complain of vaginal discharge than any other gynecologic symptom. Women who have adequate endogenous or exogenous estrogen have vaginal secretions. Vaginal discharge resulting from infection must be distinguished from normal secretions. Normal vaginal secretions (or leukorrhea) are clear to cloudy in appearance. The discharge may turn yellow after drying; is slightly

slimy; is nonirritating; and has a mild, inoffensive odor. Normal vaginal secretions are acidic, with a pH range of 4 to 5. The amount of leukorrhea differs with phases of the menstrual cycle, with greater amounts occurring at ovulation and just before menses. Leukorrhea is also increased during pregnancy. Normal vaginal secretions contain lactobacilli and epithelial cells.

Vaginitis, or abnormal vaginal discharge, is an infection caused by a microorganism. The most common vaginal infections are bacterial vaginosis (BV), candidiasis, and trichomoniasis. Although streptococcus B is considered normal vaginal flora, it may also cause infection. Vulvovaginitis (i.e., inflammation of the vulva and vagina) may be caused by vaginal infection; copious leukorrhea, which can cause maceration of tissues; and chemical irritants, allergens, and foreign bodies, which may produce inflammatory reactions.

Bacterial Vaginosis

BV, formerly called *nonspecific vaginitis, Haemophilus vaginitis,* or *Gardnerella,* is the most common type of symptomatic vaginitis today (Eckert and Lentz, 2012). It is associated with preterm labor and birth. The exact cause of BV is unknown. It is a syndrome in which normal, hydrogen peroxide–producing lactobacilli are replaced with high concentrations of anaerobic bacteria (e.g., *Gardnerella, Mobiluncus*). With the increase of anaerobes, the level of vaginal amines is raised, and the normal acidic pH of the vagina is altered. Epithelial cells slough, and numerous bacteria attach to their surfaces (clue cells). When the amines are volatilized, the characteristic odor of BV occurs.

Many women with BV complain of a characteristic "fishy odor." The odor may be noticed by the woman or her partner after heterosexual intercourse because semen releases the vaginal amines. When present, the BV discharge is usually profuse; thin; and white, gray, or milky in appearance. Some women also may experience mild irritation or pruritus.

Screening and Diagnosis. A focused history may help distinguish BV from other vaginal infections if the woman is symptomatic. Reports of fishy odor and increased thin vaginal discharge are most significant, and a report of increased odor after intercourse is also suggestive of BV. You should question women with previous occurrence of similar symptoms, diagnosis, and treatment because women with BV often have been treated incorrectly because of misdiagnosis.

Microscopic examination of vaginal secretions is always performed (Table 4-4). Both normal saline and 10% potassium hydroxide (KOH) smears are made. The presence of clue cells (vaginal epithelial cells coated with bacteria) on wet saline smear is highly diagnostic because the phenomenon is specific to BV. Test vaginal secretions for pH and amine odor. Nitrazine paper is sensitive enough to detect a pH of 4.5 or greater. The fishy odor of BV will be released when KOH is added to vaginal secretions on the lip of the withdrawn speculum.

Management. Treatment of BV with oral metronidazole (Flagyl) is most effective (CDC, 2010a), although vaginal preparations (e.g., metronidazole gel, clindamycin cream) are also used. Side effects of metronidazole are numerous, including sharp, unpleasant metallic taste in the mouth; furry tongue; central nervous system reactions; and urinary tract disturbances. When the woman is taking oral metronidazole, advise her to avoid drinking alcoholic beverages or she will experience the severe side effects of abdominal distress, nausea, vomiting, and headache. Gastrointestinal symptoms are common whether alcohol is consumed or not. Treatment of sexual partners is not recommended routinely (CDC, 2010a).

TABLE 4-4 WET SMEAR TESTS FOR VAGINAL INFECTIONS

INFECTION	TEST	POSITIVE FINDINGS
Trichomoniasis	Saline wet smear (vaginal secretions mixed with normal saline on a glass slide)	Presence of many white blood cell protozoa
Candidiasis	Potassium hydroxide (KOH) preparation (vaginal secretions mixed with KOH on a glass slide)	Presence of hyphae and pseudohyphae (buds and branches of yeast cells)
Bacterial vaginosis	Normal saline smear	Presence of clue cells (vaginal epithelial cells coated with bacteria)
	Whiff test (vaginal secretions mixed with KOH)	Release of fishy odor

Several adverse outcomes are associated with BV during pregnancy: preterm labor and birth, premature rupture of the membranes, intraamniotic infection, and postpartum endometritis. Therefore pregnant women should be treated to relieve vaginal symptoms and the signs of infection (CDC, 2010a).

Metronidazole is not recommended if the woman is breastfeeding. If it is necessary to prescribe it, she can suspend breastfeeding temporarily (pump and discard milk to maintain supply) and resume it 12 to 24 hours after taking the last dose.

Candidiasis

Vulvovaginal candidiasis, or yeast infection, is the second most common type of vaginal infection in the United States. Although vaginal candidiasis infections are common in healthy women, those seen in women with HIV infection are often more severe and persistent. Genital candidiasis lesions may be painful, and coalescing ulcerations necessitate continuous prophylactic therapy.

The most common organism is *Candida albicans.* It is estimated that 90% of yeast infections in women are caused by this organism. However, in the past 10 years the incidence of non–*C. albicans* infections has increased steadily. Women with chronic or recurrent infections often are infected with a higher percentage of non–*C. albicans* species than are women with their first infection or who have few recurrences (Eckert and Lentz, 2012).

Numerous factors have been identified as predisposing a woman to yeast infections. These include antibiotic therapy, particularly broad-spectrum antibiotics such as ampicillin, tetracycline, cephalosporins, and metronidazole; diabetes, especially when uncontrolled; pregnancy; obesity; diets high in refined sugars or artificial sweeteners; use of corticosteroids and exogenous hormones; and immunosuppressed states. Clinical observations and research have suggested that tight-fitting clothing and underwear or pantyhose made of nonabsorbent materials create an environment in which a vaginal fungus can grow.

The most common symptom of yeast infection is vulvar and possibly vaginal pruritus. The itching may be mild or intense, interfere with rest and activities, and occur during or after

intercourse. Some women report a feeling of dryness. Others may have painful urination as the urine flows over the vulva. The latter usually occurs in women who have **excoriations** resulting from scratching. Most often the discharge is thick, white, lumpy, and cottage cheese like. The discharge may be found in patches on the vaginal walls, cervix, and labia. Commonly the vulva is red and swollen, as are the labial folds, vagina, and cervix. Although there is no odor characteristic of yeast infections, sometimes a yeasty or musty smell is noted.

Screening and Diagnosis. In addition to noting the woman's symptoms, their onset, and their course, the history is a valuable screening tool for identifying predisposing risk factors. Physical examination should include a thorough inspection of the vulva and vagina. A speculum examination is always done. Commonly saline and KOH wet smear and vaginal pH are obtained (see Table 4-4). Vaginal pH is normal (less than 4.5) with a yeast infection. The characteristic pseudohypha (bud or branching of a fungus) may be seen on a wet smear done with normal saline; however, they may be confused with other cells and artifacts (CDC, 2010a).

Management. A number of antifungal preparations are available for the treatment of *C. albicans.* Many of these medications (e.g., miconazole [Monistat] and clotrimazole [Gyne-Lotrimin]) are available as over-the-counter (OTC) agents. Exogenous lactobacillus (in the form of dairy products [yogurt] or powder, tablet, capsule, or suppository supplements) and garlic have been suggested for prevention and treatment of vulvovaginal candidiasis; but research is inconclusive, and no recommendations have been developed for use in practice (Eckert and Lentz, 2012). The first time a woman suspects that she may have a yeast infection, she should see a health care provider for confirmation of the diagnosis and treatment recommendation. If she has another infection, she may wish to purchase an OTC preparation and self-treat. If she elects to do this, she should always be counseled to seek care for numerous recurrent or chronic yeast infections. If vaginal discharge is extremely thick and copious, vaginal debridement with a cotton swab followed by application of vaginal medication may be effective.

Women who have extensive irritation, swelling, and discomfort of the labia and vulva may find sitz baths helpful in decreasing inflammation and increasing comfort. Adding colloidal oatmeal powder to the bath may also increase the woman's comfort. Not wearing underpants to bed may help decrease symptoms and prevent recurrences. Completing the full course of treatment prescribed is essential to removing the pathogen. Medication should be continued even during menstruation. Women should be counseled not to use tampons during menses because the medication will be absorbed by the tampon. If possible, intercourse is avoided during treatment; if this is not feasible, the woman's partner should use a condom to prevent introduction of more organisms. Suggested measures to prevent genital tract infections are in the Patient Teaching box.

PATIENT TEACHING

Prevention of Genital Tract Infections in Women

- Practice genital hygiene.
- Choose underwear or hosiery with a cotton crotch.
- Avoid tight-fitting clothing (especially tight jeans).
- Select cloth car seat covers instead of vinyl.
- Limit the time spent in damp exercise clothes (especially swimsuits, leotards, and tights).
- Limit exposure to bath salts or bubble bath.
- Avoid colored or scented toilet tissue.
- If sensitive, discontinue use of feminine hygiene deodorant sprays.
- Use condoms.
- Void before and after intercourse.
- Decrease dietary sugar.
- Drink yeast-active milk and eat yogurt (with lactobacilli).
- Do not douche.

Trichomoniasis

Trichomonas vaginalis is almost always an STI and is also a common cause of vaginal infection (5% to 50% of all vaginitis) and discharge (Eckert and Lentz, 2012).

Trichomoniasis is caused by *T. vaginalis,* an anaerobic, one-celled protozoan with characteristic flagella. Although trichomoniasis may be asymptomatic, women commonly experience characteristically yellowish-to-greenish, frothy, mucopurulent, copious, malodorous discharge. Inflammation of the vulva, vagina, or both may be present; and the woman may complain of irritation and pruritus. Dysuria and dyspareunia are often present. Typically the discharge worsens during and after menstruation. The cervix and vaginal walls demonstrate characteristic "strawberry spots" or tiny petechiae in less than 10% of women, and the cervix may bleed on contact. In severe infections the vaginal walls, the cervix, and occasionally the vulva are acutely inflamed.

Screening and Diagnosis. In addition to obtaining a history of current symptoms, obtain a thorough sexual history. Note any history of similar symptoms in the past and treatment used. Determine whether the woman's partner or partners were treated and if she has had subsequent relations with new partners.

A speculum examination is always performed, even though it may be uncomfortable for the woman. Any of the classic signs may or may not be seen on physical examination. The typical one-celled flagellate trichomonads are easily distinguished on a normal saline wet preparation (see Table 4-4). The pH of the discharge is greater than 5.0. Because trichomoniasis is an STI, once diagnosis is confirmed, the appropriate laboratory studies for other STIs should be carried out.

Management. The recommended treatment is metronidazole or tinidazole orally in a single dose (CDC, 2010a). Although the male partner is usually asymptomatic, he should receive treatment also because he often harbors the trichomonads in the urethra or prostate. Nurses need to discuss the importance of partner treatment with their patients. If partners are not treated, the infection will likely recur.

Women with trichomoniasis need to understand the sexual transmission of this disease. The woman should know that the organism can be present without symptoms, perhaps for several months, and that determining when she became infected is impossible.

Group B Streptococcus

Group B streptococcus (GBS) may be considered a normal vaginal flora in a woman who is not pregnant. It is present in 9% to 23% of healthy pregnant women. However, GBS infection is associated with poor pregnancy outcomes. These infections are an important factor in perinatal and neonatal morbidity and mortality, usually resulting from vertical transmission from the birth canal of the infected mother to the infant during birth (Cunningham, Leveno, Bloom, et al., 2010).

Risk factors for neonatal GBS infection include positive prenatal culture for GBS in the current pregnancy; preterm birth of less than 37 weeks of gestation; premature rupture of membranes for longer than 18 hours; intrapartum maternal fever higher than 38° C (100.4° F); and a positive history for early-onset neonatal GBS (Cunningham, Leveno, Bloom, et al., 2010).

To decrease the risk of neonatal GBS infection, it is recommended that all women be screened at 35 to 37 weeks of gestation for GBS using a rectovaginal culture and that intravenous antibiotic prophylaxis (IAP) be offered to all who test positive. If a culture is not available at onset of labor or if risk factors are present, IAP is also offered. It is not recommended before a cesarean birth if labor or rupture of membranes has not occurred. The recommended treatment is penicillin G, 5 million units in an intravenous loading dose, and then 2.5 million units intravenously every 4 hours during labor. Ampicillin, 2 g intravenous loading dose, followed by 1 g intravenously every 4 hours, is an alternative therapy (CDC, 2010b).

Effects of Sexually Transmitted Infections on Pregnancy and the Fetus

STIs in pregnancy are responsible for significant morbidity and mortality. Some consequences of maternal infection such as infertility and sterility last a lifetime. Congenitally acquired infection may affect a child's length and quality of life. Table 4-5 describes the effects of several common STIs on pregnancy and the fetus. It is difficult to predict these effects with certainty. Factors such as co-infection with other STIs and at what point in pregnancy the infection was treated can affect outcomes.

Infection Control

Infection control measures are essential to protect care providers and prevent nosocomial infection of patients, regardless of the infectious agent. The risk for occupational transmission varies with the disease. Even when the risk is low as with HIV, the existence of any risk warrants reasonable precautions. Precautions against airborne disease transmission are available in all health care agencies. **Standard Precautions** (precautions to use in care of all persons for infection control) are listed in Box 4-4.

TABLE 4-5 PREGNANCY AND FETAL EFFECTS OF COMMON SEXUALLY TRANSMITTED INFECTIONS

INFECTION	MATERNAL EFFECTS	FETAL EFFECTS
Chlamydia	Premature rupture of membranes Preterm labor Postpartum endometritis	Low birth weight
Gonorrhea	Miscarriage Preterm labor Amniotic infection syndrome Chorioamnionitis Postpartum endometritis Postpartum sepsis Premature rupture of membranes	Preterm birth IUGR
Group B streptococci	Urinary tract infection Chorioamnionitis Postpartum endometritis Sepsis Meningitis (rare)	Preterm birth
Herpes simplex virus	Intrauterine infection (rare)	Congenital infection (rare)
Human papillomavirus (HPV)	Dystocia from large lesions Excessive bleeding from lesions after birth trauma	
Syphilis	Miscarriage Preterm labor	IUGR Preterm birth Stillbirth Congenital infection

PROBLEMS OF THE BREAST

Benign Problems

Fibrocystic Changes

Approximately 50% of women experience a breast problem at some point in their adult life. The most common benign breast problem is fibrocystic changes (Katz and Dotters, 2012). Fibrocystic changes occur in varying degrees in breasts of healthy women. The etiologic agent responsible for these changes has not been found. One theory is that estrogen excess and progesterone deficiency in the luteal phase of the menstrual cycle may cause changes in breast tissue.

Fibrocystic changes are characterized by lumpiness, with or without tenderness, in both breasts. Single simple cysts can also occur. Symptoms usually develop approximately a week before menstruation begins and subside approximately a week after menstruation ends. Symptoms include dull heavy pain and a sense of fullness and tenderness often in the upper outer quadrants of the breasts. Physical examination may reveal excessive nodularity that many describe as feeling similar to a "plateful of peas" (Katz and Dotters, 2012). Larger cysts are often described as feeling like water-filled balloons. Women in their twenties report the most severe pain. Women in their thirties have premenstrual pain and tenderness; small multiple nodules are usually present. Women in their forties usually do not report severe pain, but cysts are tender and often regress in size (Katz and Dotters, 2012).

Steps in the workup of a breast lump may begin with ultrasonography to determine whether it is fluid filled or solid. Fluid-filled cysts are aspirated, and the woman is monitored on a routine basis for the development of other cysts. If the lump is solid, a mammogram is obtained if the woman is older than age 50 years. A fine-needle aspiration (FNA) is performed, regardless of the woman's age, to determine the nature of the lump (Katz and Dotters, 2012).

Management depends on the severity of the symptoms. Women who have severe cyclic breast pain may find relief with eating dietary flaxseed (Chase, Wells, and Eley, 2011). Although research findings are contradictory, some practitioners advocate reducing consumption or eliminating methylxanthines (e.g., colas, coffee, tea,

BOX 4-4 STANDARD PRECAUTIONS

Medical history and examination cannot reliably identify all persons infected with human immunodeficiency virus (HIV) or other bloodborne pathogens. Therefore Standard Precautions should be used consistently in the care of all persons. These precautions apply to blood; body fluids; and all secretions and excretions, except sweat, nonintact skin, and mucous membranes. The following infection-control practices should be applied during the delivery of health care to reduce the risk of transmission of microorganisms from known and unknown sources of infection (Seigel, Rhinehart, Jackson, et al., and the Healthcare Infection Control Practices Advisory Committee, 2007):

1. *Hand hygiene.* During the delivery of health care, avoid unnecessary touching of surfaces in close proximity to the patient to prevent both contamination of clean hands from environmental surfaces and transmission of pathogens from contaminated hands to surfaces. Wash dirty or contaminated hands with either a nonantimicrobial or an antimicrobial soap and water. If hands are not visibly soiled, decontaminate them with an alcohol-based hand rub, or they may be washed with an antimicrobial soap and water. Perform hand hygiene (1) before having direct contact with patients; (2) after contact with blood, body fluids, excretions, mucous membranes, nonintact skin, or wound dressings; (3) after contact with a patient's intact skin (e.g., when taking a pulse or blood pressure or lifting a patient); (4) if hands will be moving from a contaminated to a clean body site during patient care; (5) after contact with inanimate objects (including medical equipment) in the immediate vicinity of the patient; and (6) after removing gloves. Wash hands with nonantimicrobial soap and water or with antimicrobial soap and water if contact with spores (e.g., *Clostridium difficile* or *Bacillus anthracis*) is likely to have occurred. The physical action of washing and rinsing hands under such circumstances is recommended because alcohols, chlorhexidine, iodophors, and other antiseptic agents have poor activity against spores. Do not wear artificial fingernails or extenders if duties include direct contact with patients at high risk for infection and associated adverse outcomes.
2. *Personal protective equipment (PPE).* Observe the following principles of use:
   - *Gloves.* Wear gloves when a reasonably anticipated possibility exists that contact with blood or other potentially infectious materials, mucous membranes, nonintact skin, or potentially contaminated intact skin (e.g., of a patient incontinent of stool or urine) might occur. Gloves should be worn during infant eye prophylaxis, care of the umbilical cord, circumcision site, parenteral procedures, diaper changes, contact with colostrum, and postpartum assessments. Wear gloves with fit and durability appropriate to the task. Remove gloves after contact with a patient or the surrounding environment (including medical equipment), using proper technique to prevent hand contamination. Do not wear the same pair of gloves for the care of more than one patient. Change gloves during patient care if the hands will move from a contaminated (e.g., perineal area) to a clean (e.g., face) body site.
   - *Gowns.* Wear a gown that is appropriate to the task to protect the skin and prevent soiling or contamination of clothing during procedures and patient-care activities when contact with blood, body fluids, secretions, or excretions is anticipated. Remove the gown and perform hand hygiene before leaving the patient's environment. Do not reuse gowns, even for repeated contacts with the same patient. Routine donning of gowns on entrance into a high risk unit (e.g., intensive care unit [ICU], neonatal intensive care unit [NICU]) is not indicated.
   - *Mouth, nose, eye protection.* Use PPE to protect the mucous membranes of the eyes, nose, and mouth during procedures and patient-care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, and excretions. Select masks, goggles, face shields, and combinations of each according to the need anticipated by the task performed.
   - *Respiratory hygiene and cough etiquette.* Post signs at entrances and in strategic places (e.g., elevators, cafeterias) within ambulatory and inpatient settings with instructions to patients and other persons with symptoms of a respiratory infection to cover their mouth and nose when coughing or sneezing, use and dispose of tissues, and perform hand hygiene after hands have been in contact with respiratory secretions. Provide tissues and no-touch receptacles (e.g., foot pedal–operated lid or open, plastic-lined wastebasket) for disposal of tissues. Provide resources and instructions for performing hand hygiene in or near waiting areas in ambulatory and inpatient settings; provide conveniently located dispensers of alcohol-based hand rubs and, where sinks are available, supplies for handwashing. During periods of increased prevalence of respiratory infections in the community, offer masks to coughing patients and other symptomatic persons (e.g., persons who accompany ill patients) on entry into the facility and encourage them to maintain special separation, ideally a distance of at least 3 feet, from others in common waiting areas.
3. *Safe injection practices.* The following recommendations apply to the use of needles, cannulas that replace needles, and, where applicable, intravenous delivery systems:
   - Use aseptic technique to prevent contamination of sterile injection equipment. Needles, cannulas, and syringes are sterile, single-use items; they should not be reused for another patient. Use fluid infusion and administration sets (i.e., intravenous bags, tubing, and connectors) for one patient only and dispose appropriately after use. Use single-dose vials for parenteral medications whenever possible. If multidose vials must be used, both the needle (or cannula) and the syringe used to access the multidose vial must be sterile. Do not keep multidose vials in the immediate patient treatment area and store in accordance with manufacturer recommendations; discard if sterility is compromised or questionable.

Data from Siegel JD, Rhinehart E, Jackson M, et al, and the Healthcare Infection Control Practices Advisory Committee: *Guideline for isolation precautions: preventing transmission of infectious agents in healthcare settings*, 2007, www.cdc.gov/ncidod/dhqp/pdf/isolation2007.pdf.

chocolate) and tobacco (Chase, Wells, and Eley, 2011; Katz and Dotters, 2012).

Women may report decreased symptoms with such measures as eating a low-fat diet, decreasing sodium intake, or taking mild diuretics shortly before menses; but supporting evidence is lacking (Chase, Wells, and Eley, 2011). Other pain-relief measures that include taking analgesics or NSAIDs, wearing a supportive bra, and applying heat or cold to the breasts are supported by research (Katz and Dotters, 2012).

Evening primrose oil and vitamin E supplements may be effective for some women, although more research is needed (Chase, Wells, and Eley, 2011). Oral contraceptives, danazol, bromocriptine, and tamoxifen have also been used with varying degrees of success (Katz and Dotters, 2012).

TABLE 4-6 COMPARISON OF COMMON MANIFESTATIONS OF BENIGN BREAST MASSES

FIBROCYSTIC CHANGES	FIBROADENOMA	LIPOMA	INTRADUCTAL PAPILLOMA	MAMMARY DUCT ECTASIA
Multiple lumps	Single lump	Single lump	Single or multiple	Mass behind nipple
Nodular	Well delineated	Well delineated	Not well delineated	Not well delineated
Palpable	Palpable	Palpable	Nonpalpable	Palpable
Movable	Movable	Movable	Nonmobile	Nonmobile
Round, smooth	Round, lobular	Round, lobular	Small, ball-like	Irregular
Firm or soft	Firm	Soft	Firm or soft	Firm
Tenderness influenced by menstrual cycle	Usually asymptomatic	Nontender	Usually nontender	Painful, burning, itching
Bilateral	Unilateral	Unilateral	Unilateral	Unilateral
May or may not have nipple discharge	No nipple discharge	No nipple discharge	Serous or bloody nipple discharge	Thick, sticky nipple discharge

Fibroadenoma

The next most common benign neoplasm of the breast is a **fibroadenoma.** It is the single most common type of tumor seen in the adolescent population, although it can also occur in women in their thirties. Fibroadenomas are discrete, usually solitary lumps averaging 2.5 cm in diameter (Katz and Dotters, 2012). Occasionally the woman with a fibroadenoma experiences tenderness in the tumor during the menstrual cycle. Fibroadenomas do not increase in size in response to the menstrual cycle as cysts do. They increase in size during pregnancy and decrease in size as the woman ages. The cause of fibroadenomas is unknown.

Diagnosis is made by reviewing patient history and physical examination. Mammography, ultrasound, or magnetic resonance imaging (MRI) helps determine the type of lesion. FNA may be used to determine underlying pathologic conditions. Surgical excision may be necessary if the lump is suspicious or if the symptoms are severe. Periodic observation of masses by professional physical examination or mammography may be all that is necessary for masses not needing surgical intervention (Katz and Dotters, 2012). Breast self-examination can be practiced by the woman between professional examinations (see Chapter 3).

Nipple Discharge

Nipple discharge is a common occurrence that concerns many women. Although most nipple discharge is physiologic, evaluate each woman who has this problem thoroughly because a small percentage will be found to have a serious endocrine disorder or malignancy. Most nipple discharge is elicited (i.e., discharge is a result of the breast being compressed or stimulated) and is usually not a concern unless the woman is postmenopausal or a mass is present in the breast (Lobo, 2012c).

Another form of breast discharge not related to malignancy is galactorrhea, a bilaterally spontaneous, milky, sticky discharge. It is a normal finding in pregnancy. It can also occur as the result of elevated prolactin levels caused by a thyroid disorder, pituitary tumor, or chest wall surgery or trauma. Obtaining a complete medication history on each woman is essential. Some tranquilizers (e.g., tricyclic antidepressants), narcotics, antihypertensive medications, and oral contraceptives can precipitate galactorrhea in some women (Lobo, 2012c).

Diagnostic tests that may be indicated include a prolactin level, a microscopic analysis of the discharge from each breast, a thyroid profile, a pregnancy test, and a mammogram (Lobo, 2012c).

Mammary Duct Ectasia

Mammary duct ectasia is an inflammation of the ducts behind the nipple. It occurs most often in perimenopausal women. In mammary duct ectasia nipple discharge is thick; sticky; and colored white, brown, green, or purple. The woman frequently experiences a burning pain, an itching, or a palpable mass behind the nipple.

The workup includes a mammogram and aspiration and culture of fluid. Treatment is usually symptomatic; mild pain relievers, warm compresses applied to the breast, or wearing a supportive bra may provide relief. If a mass is present or an abscess occurs, treatment may include a local excision of the affected duct or ducts, provided that the woman has no future plans to breastfeed (Mayo Foundation for Medical Education and Research, 2012).

Intraductal Papilloma

Intraductal papilloma is a rare benign condition that develops within the terminal nipple ducts. The cause is unknown. It usually occurs in women between ages 30 and 50. The papilloma is usually too small to be palpated, and the characteristic sign is spontaneous unilateral nipple discharge that is serous, serosanguineous, or bloody. After eliminating the possibility of malignancy, the affected segments of the ducts and breasts are surgically excised (Katz and Dotters, 2012). Table 4-6 compares manifestations of benign breast diseases.

Collaborative Care

The history should focus on risk factors for breast diseases, events related to the breast mass, and health maintenance practices. Risk factors for breast cancer are discussed later in this chapter. Information related to the breast mass should include how, when, and by whom the mass was discovered. The following patient information is documented: presence of pain, whether symptoms increase with menses, dietary habits, smoking habits, and use of oral contraceptives. The woman's emotional status, including her stress level, fears, and concerns and her ability to cope, also should be assessed.

Physical examination may include assessment of the breasts for symmetry, masses (size, number, consistency, mobility), and nipple discharge.

Nursing actions might include the following:

- Discuss the intervals for and facets of breast screening, including professional examination and mammography (see Table 3-3). Women with breast implants may need special views of the breast, and precautions might have to be taken to prevent rupturing the implant during mammography.
- Provide written educational materials.
- Encourage the verbalization of fears and concerns about treatment and prognosis.
- Provide specific information regarding the woman's condition and treatment, including dietary changes, drug therapy, comfort measures, stress management, and surgery.
- Demonstrate correct breast self-examination technique if the woman desires to practice it (see Chapter 3, p. 44).
- Describe pain-relieving strategies in detail and collaborate with the primary health care provider to ensure effective pain control.
- Encourage discussion of feelings about body image.
- Refer to a support group or stress-management resource if needed to cope with long-term consequences of benign breast conditions.

Cancer of the Breast

The United States has one of the highest rates of carcinoma in the world. After skin cancer, breast cancer is the most diagnosed cancer and the leading cause of cancer deaths in women (ACS, 2012). One in eight American women will develop breast cancer in her lifetime (National Cancer Institute, 2012). No clear method for prevention has been formulated. The prognosis for and survival of the woman are improved with early detection. Therefore women must be educated about risk factors, early detection, and screening.

Although the exact cause of breast cancer is still unknown, researchers have identified certain factors that increase a woman's risk for developing a malignancy. Box 4-5 lists these factors. The most important predictor for breast cancer is age; the risk increases as the woman ages.

Much discussion has taken place about possible links between breast cancer and hormone therapy; several large research studies, including the Women's Health Initiative, have found that the risk of breast cancer increases when a woman is taking combined estrogen and progesterone but declines quickly once therapy is stopped. No consensus about possible links has been reached (Katz and Dotters, 2012).

Studies that include a long-term study of breast implant patients implemented by the National Cancer Institute concluded that silicone breast implants did not increase the risk of breast cancer (Katz and Dotters, 2012).

Although most breast cancers are not related to genetic factors, the identification of the BRCA1 and BRCA2 genes has demonstrated the role of heredity and genetic mutations in this disease. Only approximately 5% to 10% of all breast cancers are attributed to heredity. Women who have abnormalities in the BRCA1 and BRCA2 genes have up to an 80% chance of developing breast cancer (ACS, 2012). Other genetic mutations that can cause breast cancer include mutations of the ataxia telangiectasia mutated (ATM) gene, the p53 tumor suppressor gene, the phosphatase and tensin homolog (PTEN) gene, and the checkpoint kinase 2 (CHEK2) gene (ACS, 2012).

BOX 4-5 RISK FACTORS FOR BREAST CANCER*

Risks that are not modifiable:

- Age—risk increases with age
- Previous history of breast cancer
- Family history of breast cancer, especially a mother or sister (particularly significant if premenopausal)
- Inherited genetic mutations in BRCA1 and BRCA2 genes
- Previous history of ovarian, endometrial, colon, or thyroid cancer
- High breast tissue density
- Early menarche (before age 12)
- Late menopause (after age 55)
- Previous history of benign breast disease with epithelial hyperplasia
- Race (Caucasian women have highest incidence)

Lifestyle and modifiable risks:

- Nulliparity or first pregnancy after age 30
- Not breastfeeding
- Postmenopausal use of combined estrogen-progestin replacement therapy
- Obesity after menopause
- Alcohol consumption of more than one drink per day
- Sedentary lifestyle
- Vitamin D—low levels increase risk

Data from American Cancer Society (ACS): *Breast cancer 2011,* www.cancer.org; American Cancer Society (ACS): *Cancer facts and figures,* Atlanta, 2012, American Cancer Society.
*Risk factors are cumulative (i.e., the more risk factors that are present, the greater is the likelihood of breast cancer occurring).

BOX 4-6 RISK FACTORS INCLUDED IN THE BREAST CANCER RISK ASSESSMENT TOOL

- Woman's age
- Number of first-degree relatives affected
- Age of woman at menarche
- Age of woman at first live birth
- Number of breast biopsies
- History of atypical hyperplasia in biopsy specimens

Information about breast cancer risks can be confusing, and women can overestimate or underestimate their risks. Women and health professionals can use the Breast Cancer Risk Assessment Tool to calculate risk. This tool was developed and verified by the National Cancer Institute (NCI) to predict the risk of breast cancer in 5 years and over the lifetime (to age 90) of a woman. The risk factors used are in Box 4-6. The tool is available at www.nci.nih.gov/bcrisktool/. Although the clinical applicability of risk factors has limits, screen women at increased risk at frequent intervals and help them consider changing risk factors that can be changed such as losing weight if obese and limiting alcohol intake (ACS, 2012).

Prevention

Chemoprevention is the use of medications to reduce cancer risk. Tamoxifen and raloxifene block the effect of estrogen on breast tissue. Studies have shown that these two drugs can reduce the risk of breast cancer, and the FDA has approved them for such use (ACS,

MEDICATION GUIDE

Tamoxifen (Nolvadex)

Action
Antiestrogenic effects; attaches to hormone receptors on cancer cells and prevents natural hormones from attaching to the receptors

Indications
For treatment of advanced-stage or metastatic breast cancer; for treatment of early-stage breast cancer after breast cancer surgery and radiation therapy; to reduce the incidence of breast cancer in women at high risk

Dosage
20 mg orally daily

Adverse Reactions
Common side effects include hot flashes, night sweats, nausea, vaginal bleeding or discharge, and mood swings. Hair loss is an uncommon effect. Serious side effects include deep vein thrombosis, increased risk of endometrial cancer, and stroke.

Nursing Considerations
The medication may be taken on an empty stomach or with food. Missed doses should be taken as soon as possible, but taking two doses at once is not recommended. A barrier or nonhormonal form of contraception is recommended in premenopausal women because tamoxifen may be harmful to the fetus if pregnancy should occur.

MEDICATION GUIDE

Raloxifene Hydrochloride (Evista)

Action
A selective estrogen receptor modulator, serving as an agonist and antagonist to estrogen receptor sites

Indications
Treatment and prevention of osteoporosis; reduction in the risk of invasive breast cancer in postmenopausal women with osteoporosis; and reduction of risk of invasive breast cancer in postmenopausal women at high risk for invasive breast cancer

Dosage
60 mg orally daily

Adverse Reactions
Common side effects include hot flashes, nausea, peripheral edema, joint pain, leg cramps, flu-like symptoms, sweating. Serious and life-threatening side effects can occur from existing condition. Women who have had or are at risk for a heart attack have increased risk of dying from a stroke. Risk of blood clots in the legs and lungs is increased. Raloxifene is contraindicated in women with an active or past history of venous thromboembolism.

Nursing Considerations
The medication may be taken on an empty stomach or with food. Missed doses should be taken as soon as possible, but taking two doses at once is not recommended. Counsel woman to contact her health care provider if leg pain or feeling of warmth in lower legs, swelling of hands and feet, sudden chest pain or shortness of breath, or sudden changes in vision occur. Calcium 1500 mg plus vitamin D 400 to 800 International Units daily are recommended.

2011) (see Medication Guides). The role of aromatase inhibitors (e.g., anastrozole) also is being examined to see if these drugs are effective for prevention.

Surgical prophylaxis (bilateral mastectomy, oophorectomy) can reduce the risk of breast cancer, but it should be considered only for people at very high risk (Katz and Dotters, 2012).

Screening and Diagnosis

Breast cancer in its earliest form can be detected by a mammogram before it is felt by a woman. However, estimates indicate that women detect 90% of all breast lumps. Of this 90%, only 20% to 25% are malignant. More than half of all lumps are discovered in the upper outer quadrant of the breast. The most common presenting symptom is a lump or thickening of the breast. The lump may feel hard and fixed or soft and spongy. It may have well-defined or irregular borders. It may be fixed to the skin, thereby causing dimpling to occur. A nipple discharge that is bloody or clear also may be present.

Early detection and diagnosis reduce the risk of mortality because cancer is found when it is smaller, lesions are more localized, and the tendency is to have a lower percentage of positive nodes. However, cultural factors may influence a woman's decision to participate in breast cancer screening. Knowledge of these factors and use of culturally sensitive messages and materials that appeal to the unique concerns, beliefs, and reading abilities of target groups assist the nurse in helping women overcome barriers to seeking care. For example, the ACS (2012) reported that women who are African-American, Hispanic, or Native American were less likely to get mammograms than Caucasian or Asian-American women.

Other barriers to breast cancer screening include older age, expense, lack of health insurance, fear, ignorance, and organizational barriers such as scheduling problems and lack of available services.

Clinical examination by a qualified health care provider and screening mammography (x-ray film examination of the breast) (Fig. 4-6) may aid in the early detection of breast cancers. A diagnostic mammogram is performed when a screening mammogram identifies something that needs further inspection or when the woman or examiner finds a breast symptom that is new.

When a suspicious finding on a mammogram is noted or a lump is detected, the diagnosis is confirmed by needle aspiration, a core needle biopsy, or surgical excision (Fig. 4-7). Ultrasound may also be used to assess a specific area of abnormality found during a mammogram procedure (ACS, 2012). Women need specific information regarding advantages and disadvantages of these procedures in making a decision about which one is most appropriate for them.

Laboratory examination of breast tissue determines if cancer is present and, if so, the extent. Other tests performed to determine the spread of the cancer include chest x-ray film examination, bone scan, CT, MRI, and positron emission tomography (PET scan) (ACS, 2012).

An important step in evaluating a breast cancer is to test for the presence of estrogen and progesterone receptors in the biopsied tissue. Cancer cells may contain one, both, or neither of these receptors. Breast cancers that contain estrogen receptors are often called *ER-positive* cancers, whereas those containing progesterone receptors are called *PR-positive* cancers. Women with hormone-positive tumors tend to respond better to treatment and have higher survival rates than the general population (Katz and Dotters, 2012).

FIG 4-6 Patient undergoing mammography. (Courtesy Shannon Perry, Phoenix, AZ.)

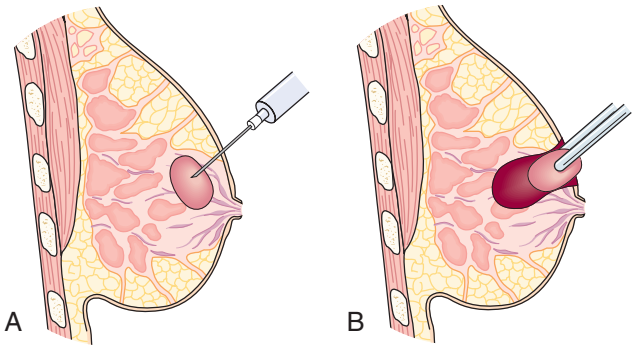

FIG 4-7 Diagnosis. **A,** Needle aspiration. **B,** Open biopsy. (Redrawn from National Women's Health Resource Center: Breast health, *Natl Womens Health Rep* 13(5):3, 1995.)

An HER2/neu test also may be performed on the biopsied breast tissue. HER2/neu is a growth-promoting hormone; and in approximately 15% to 30% of breast cancers, excessive amounts of the hormone are present, causing the cancer to be more aggressive in spreading than other types of breast cancer (ACS, 2011).

CARE MANAGEMENT

Medical Management. Controversy continues regarding the best treatment for breast cancer. Nodal involvement, tumor size, receptor status, and aggressiveness are important variables for treatment selection. Medical management of breast cancer includes surgery, breast reconstruction, radiation therapy, adjuvant hormone therapy, biologic targeted therapy, and chemotherapy. Many women face difficult decisions about the various treatment options. Box 4-7 lists questions that must be addressed in decision making.

BOX 4-7 DECISION-MAKING QUESTIONS TO ASK

1. What kind of breast cancer is it (invasive or noninvasive)?
2. What stage is cancer (i.e., how extensive is the spread)?
3. Did the cancer test positive for hormone (estrogen) (may be slower growing)?
4. Which further tests are recommended?
5. What are the treatment options? (pros and cons of each, including side effects)
6. If surgery is recommended, what will the scar look like?
7. If a mastectomy is done, can breast reconstruction be done (at the time of surgery or later)?
8. How long will the woman be in the hospital? What kind of postoperative care will she need?
9. How long will treatment last if radiation or chemotherapy is recommended? What effects can the woman expect from these treatments?
10. What community resources are available for support?

Most health care providers recommend that the malignant mass and the axillary nodes, specifically the sentinel node, be removed for staging purposes (Katz and Dotters, 2012). The treatment can be conservative or more radical. The most frequently recommended surgical approaches for the treatment of breast cancer are lumpectomy and total simple mastectomy. Breast-conserving surgery such as a **lumpectomy** (Fig. 4-8, *A*) or partial mastectomy (e.g., quadrantectomy, wide excision) (Fig. 4-8, *B*) is the removal of the breast tumor and a small amount of surrounding tissue. Sampling of axillary lymph nodes usually occurs through a separate incision at the time of these procedures, and the surgery is usually followed by radiation therapy to the remaining breast tissue (Katz and Dotters, 2012). These procedures are for the primary treatment of women with early-stage (I or II) breast cancer. Lumpectomy offers survival equivalent to that with modified radical mastectomy.

A total **simple mastectomy** (Fig. 4-8, C) is the removal of the breast containing the tumor. A **modified radical mastectomy** is the removal of the breast tissue, skin, and fascia of the pectoralis muscle and dissection of the axillary nodes. A **radical mastectomy** (Fig. 4-8, *D*), although rarely performed, is the removal of the breast and underlying pectoralis muscles and complete axillary node dissection. After surgery follow-up treatment may include radiation, chemotherapy, or hormone therapy (Katz and Dotters, 2012). The decision to include follow-up therapy is based on the stage of disease, age and menopausal status of the woman, the woman's preference, and her hormone receptor status. Follow-up treatment is usually initiated to decrease the risk of recurrence in women who have no evidence of metastasis.

Radiation is usually recommended as follow-up therapy for women who have stage I or II cancer. Radiation can be external for 5 to 6 weeks or as short as 3 weeks. Internal radiation is in the form of needles, seeds, wires, or catheters filled with a radioactive substance that is inserted into the breast near the tumor. Hormone therapy with tamoxifen, an estrogen agonist, is recommended for women over the age of 50 for at least 5 years (see Medication Guide [tamoxifen]).

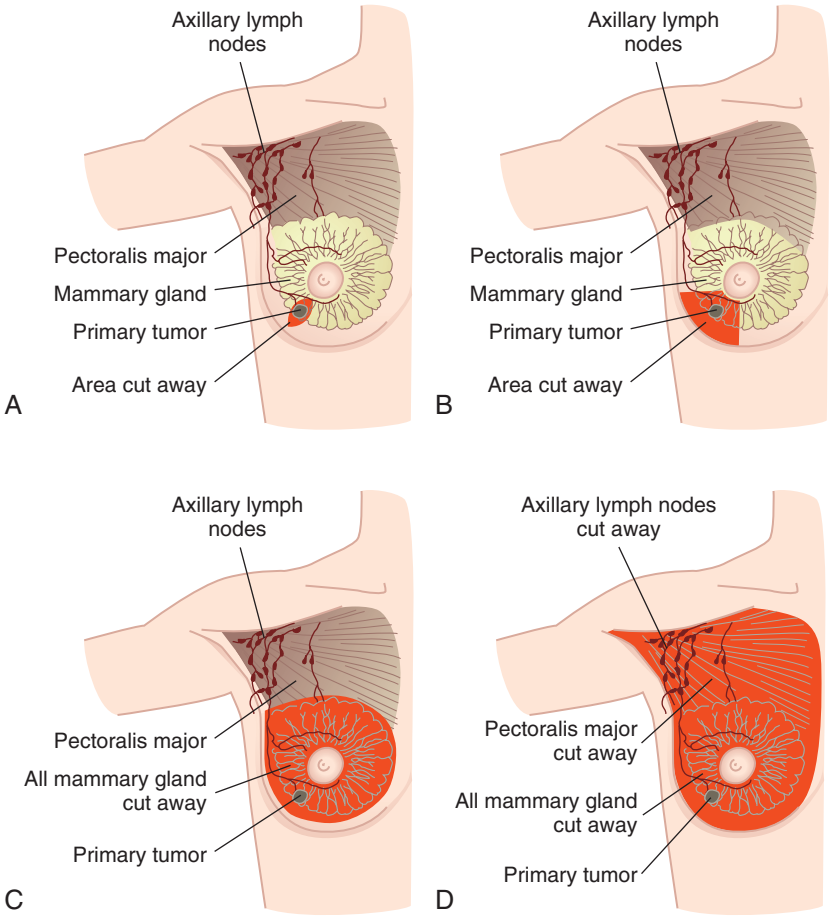

FIG 4-8 Surgical alternatives for breast cancer. **A,** Lumpectomy **B,** Partial mastectomy (quadrantectomy, wide excision). **C,** Total (simple) mastectomy. **D,** Radical mastectomy.

Aromatase inhibitors markedly suppress plasma estrogen levels in postmenopausal women by inhibiting or inactivating aromatase, the enzyme responsible for synthesizing estrogens from androgenic substrates. Aromatase inhibitors such as anastrozole, letrozole, and exemestane have shown to be effective agents in hormone therapy for breast cancer. In early-stage breast cancer, adjuvant therapy with anastrozole appears to be superior to adjuvant therapy with tamoxifen in reducing recurrence in postmenopausal women (see Medication Guide). The aromatase inhibitors appear to be well tolerated, with a lower incidence of adverse effects compared to tamoxifen (ACS, 2011).

Chemotherapy is often given to premenopausal women who have positive nodes. Therapy for more advanced tumors usually includes surgery followed by chemotherapy, radiation, or both (Katz and Dotters, 2012).

The goals of surgical breast reconstruction are achievement of symmetry and preservation of body image. Surgical reconstruction can be done immediately or at a later date. Immediate reconstruction at the time of mastectomy does not change survival rates or interfere with therapy or the treatment of recurrent disease.

The types of surgical option for breast reconstruction include implants and flap procedures. Implants are made of silicone or saline or a combination of both and can be inserted at the same time as a mastectomy or later. They are placed underneath the chest muscle versus on top of it, as in the case of breast augmentation. Silicone implants have been deemed safe and are options for women having breast reconstruction following mastectomy.

Flap procedures are done by plastic and reconstructive surgeons who specialize in microsurgery. During flap reconstruction a breast is created using tissue taken from other parts of the body such as the abdomen, back, or buttocks, or thighs, which is then transplanted to the chest by reconnecting the blood vessels to new ones in the chest region.

After a woman has recovered from initial reconstructive surgery, she may choose to have nipple and areolar reconstruction. Nipple reconstruction is achieved by using an autologous skin graft to construct a nipple, either from tissue from the remaining nipple or from a donor site (Katz and Dotters, 2012).

Nursing Care. Surgery may be performed in an outpatient surgical setting or as an inpatient procedure, depending on which type of surgery is being performed. Nursing care and teaching are focused on the perioperative period. Before surgery assess the woman's psychologic readiness, specific teaching needs related to the procedure, and what to expect after surgery. A visit from a woman who has had a similar experience may be beneficial before and after surgery.

Discuss reconstruction surgery, including the risks and benefits before the surgery if appropriate. A discussion of partial and full external prostheses also may be appropriate, including where to purchase one and the types of bras that may be worn. Local ACS

MEDICATION GUIDE

Anastrozole (Arimidex)

Action
An aromatase inhibitor; inhibits the conversion of androgens to estrogen

Indication
For adjuvant treatment of early breast cancer in postmenopausal women who have received 5 years of tamoxifen therapy; first-line treatment of postmenopausal women with hormone receptor–positive or hormone receptor–unknown locally advanced or metastatic cancer; adjuvant treatment of postmenopausal women with hormone receptor–positive early breast cancer

Dosage and Route
1 mg once a day by mouth

Adverse Reactions
Common side effects include hot flashes, nausea, increased sweating, joint or muscle pain, fluid retention, vaginal dryness, constipation, dizziness, fatigue, headache; severe side effects include severe allergic reactions (e.g., rash, hives, difficulty breathing), vomiting, chest pain, severe bone pain, calf pain or tenderness

Nursing Considerations
The medication may be taken on an empty stomach or with food. The woman should use caution if driving or using machinery because this medication may cause drowsiness or dizziness. Advise her that the medicine may decrease bone strength, increase her risk for fractures, and increase cholesterol.

units can provide sources, and volunteers of Reach to Recovery can offer hints and suggestions for wearing apparel and coping with prostheses.

Postoperative nursing care focuses on recovery. Women who had surgery in an outpatient setting usually go home within a few hours after surgery. A 24- to 48-hour stay is usual after modified radical mastectomy.

! NURSING ALERT

Avoid taking blood pressure, giving injections, or taking blood from the arm on the affected side.

The woman may have drainage tubes from the incision site that you will need to assess and drain. Incision care may include dressing changes. If postoperative arm exercises are appropriate, initiate these during the early postoperative period (Box 4-8). The woman is usually discharged to home after being given self-management instructions. Because teaching time is short, providing printed information gives the woman and her family something to refer to at home (see Patient Teaching box).

Concerns about appearance after breast surgery may affect the woman's self-concept. Before surgery the woman and her partner need information about the woman's postoperative appearance. They need to be able to discuss feelings and concerns about accepting the changes. Nurses can help the couple communicate these feelings and concerns. Information about community resources and support groups such as Reach to Recovery are often beneficial (see Community Focus box).

PATIENT TEACHING

After a Mastectomy Without Reconstruction

- Wash hands well before and after touching incision area or drains.
- Empty surgical drains twice a day and as needed, recording the date, time, drain sites (if more than one drain is present), and amount of drainage in milliliters in the diary that you will take to each surgical checkup until your drains are removed. (Before discharge you may receive a graduated container for emptying drains and measuring drainage.)
- Avoid driving, lifting more than 10 pounds, or reaching above your head until given permission by the surgeon.
- Take medications for pain as soon as pain begins.
- Perform arm exercises as directed.
- Call health care provider if inflammation of incision or swelling of the incision or the arm occurs.
- Avoid tight clothing, tight jewelry, and other causes of decreased circulation in the affected arm.
- Until drains are removed, wear loose-fitting underwear (camisole or half-slip) and clothes, pinning surgical drains inside of clothing. (You will be taught how to do this safely.)
- After drains are removed and surgical sites are healing and still tender, wear a mastectomy bra or camisole with a cotton-filled, muslin temporary prosthesis. Temporary prostheses of this type are often available from Reach to Recovery.
- Avoid depilatory creams; strong deodorants; and shaving of affected chest area, axilla, and arm.
- Sponge bathe for the first 48 hours; then you may shower. Thoroughly dry yourself afterward and reapply fresh dressings.
- Return to the surgeon's office for incision check, drain inspection, and possible drain removal as directed.
- Contact Reach to Recovery or a breast center nursing staff member for assistance in obtaining external prosthesis and lingerie when dressings, drains, and staples are removed and wound is healing and nontender.
- Contact insurance company for information about coverage of prosthesis and wig if needed. Obtain prescriptions for prosthesis and wig to submit with receipts of purchase for these items to the insurance company. If insurance does not pay for these items, contact hospital or agency social worker or local American Cancer Society for assistance.
- Practice BSE of unaffected side and affected surgical site and axilla.
- Keep follow-up visits for professional examination, mammography, and testing to detect recurrent breast cancer.
- Expect decreased sensation and tingling at incision sites and in the affected arm for weeks to months after surgery.
- Resume sexual activities as desired.
- Participate in breast cancer survivor support group if desired.
- Encourage mother, sisters, and daughters (if applicable) to learn and practice BSE and have annual professional breast examinations and mammography (if appropriate).

Additional Nursing Care for Women Undergoing Mastectomy with Reconstruction

- Apply no tight compression of the reconstructed breasts until approved by the plastic surgeon.
- Wear loosely fitting garments for first 3 to 4 weeks.
- Know that surgery is still a work in progress and that final cosmetic result of reconstruction takes many weeks.
- Assess skin for potential of poor peripheral circulation that may cause skin necrosis and report any skin changes immediately.
- See drain care instructions under axillary dissection section.

BSE, Breast self-examination.

BOX 4-8 EXERCISES AFTER BREAST SURGERY

It is important to talk to your physician before starting any exercises. A physical or occupational therapist can help design an exercise program for you.

Exercises in Lying Position

These exercises should be performed on a bed or the floor while lying on your back with your knees and hips bent, feet flat.

Wand Exercise

This exercise helps increase the forward motion of the shoulders. You will need a broom handle, yardstick, or other similar object to perform it.

- Hold the wand in both hands with palms facing up.
- Lift the wand up over your head (as far as you can), using your unaffected arm to help lift it until you feel a stretch in your affected arm.
- Hold for 5 seconds.
- Lower arms and repeat 5 to 7 times.

Elbow Winging

This exercise helps increase the mobility of the front of your chest and shoulder. It may take several weeks of regular exercise before your elbows will get close to the bed (or floor).

- Clasp your hands behind your neck with your elbows pointing toward the ceiling.
- Move your elbows apart and down toward the bed (or floor).
- Repeat 5 to 7 times

Exercises in Sitting Position

Shoulder Blade Stretch

This exercise helps increase the mobility of the shoulder blades.

- Sit in a chair very close to a table with your back against the chair back.
- Place the unaffected arm on the table with your elbow bent and palm down. Do not move this arm during the exercise.
- Place the affected arm on the table, palm down with your elbow straight.
- Without moving your trunk, slide the affected arm toward the opposite side of the table. You should feel your shoulder blade move as you do this.
- Relax your arm and repeat 5 to 7 times.

Shoulder Blade Squeeze

This exercise also helps increase the mobility of the shoulder blade.

- Facing straight ahead, sit in a chair in front of a mirror without resting on the back of the chair.
- Arms should be at your sides with elbows bent.
- Squeeze shoulder blades together, bringing your elbows behind you. Keep your shoulders level as you do this exercise. Do not lift them up toward your ears.
- Return to the starting position and repeat 5 to 7 times.

Side Bending

This exercise helps increase the mobility of the trunk/body.

- Clasp your hands together in front of you and lift your arms slowly over your head, straightening your arms.
- When your arms are over your head, bend your trunk to the right while bending at the waist and keeping your arms overhead.
- Return to the starting position and bend to the left.
- Repeat 5 to 7 times.

Exercises in Standing Position

Chest Wall Stretch

This exercise helps stretch the chest wall.

- Stand facing a corner with toes approximately 8 to 10 inches from the corner.
- Bend your elbows and place forearms on the wall, one on each side of the corner. Your elbows should be as close to shoulder height as possible.
- Keep your arms and feet in position and move your chest toward the corner. You will feel a stretch across your chest and shoulders.
- Return to starting position and repeat 5 to 7 times.

Shoulder Stretch

This exercise helps increase the mobility in the shoulder.

- Stand facing the wall with your toes approximately 8 to 10 inches from it.
- Place your hands on the wall. Use your fingers to "climb the wall," reaching as high as you can until you feel a stretch.
- Return to starting position and repeat 5 to 7 times.

Modified from American Cancer Society: *Exercises after breast surgery*, 2010, www.cancer.org/docroot/CRI/content/CRI_2_6x_Exercises_After_Breast_Surgery.asp?sitearea=CRI&viewmode=print&.

COMMUNITY FOCUS

Reach to Recovery

Check the Internet for the American Cancer Society's *(www.cancer.org)* Reach to Recovery program. Identify the services provided by the program and the requirements to become a volunteer. Visit the women's clinic in a local community health agency. Are materials about the Reach to Recovery program visible in the waiting areas? Talk to one of the nurses who works in the clinic (make an appointment for this conversation). What does she know about Reach to Recovery? Does she refer her patients to this program? What is her evaluation of the program? Has she met any of the volunteers? Do her patients have positive things to say about the program?

KEY POINTS

- Menstrual disorders diminish the quality of life for affected women and their families.
- Primary dysmenorrhea is a condition associated with ovulatory cycles and is related to the release of prostaglandins with menses.
- PMS is a disorder that begins in the luteal phase of the menstrual cycle and resolves with the onset of menses.
- PMS is a disorder with both psychologic and physiologic characteristics.
- Endometriosis is characterized by dysmenorrhea; infertility; and, less often, alterations in menstrual cycle bleeding and dyspareunia.
- Reduced risky sexual practices are key STI prevention strategies.

- HIV is transmitted through body fluids, primarily blood, semen, and vaginal secretions.
- Prevention of mother-to-newborn HIV transmission is most effective when the woman receives antiretroviral drugs during pregnancy and labor and birth and the infant also receives the drugs after the birth.
- HPV is the most common viral STI.
- Syphilis has reemerged as a common STI, affecting more African-American women than any other ethnic group.
- Chlamydia is the most common STI in U.S. women and the most common cause of PID.
- Young sexually active women who do not practice reduced-risk sexual behaviors and have multiple partners are at greatest risk for STIs and HIV infection.
- STIs are responsible for substantial morbidity and mortality, personal suffering, and a heavy economic burden in the United States.
- The development of breast neoplasms, whether benign or malignant, can have a significant physical and emotional effect on the woman and her family.
- The risk of U.S. women developing breast cancer is one in eight.
- Clinical breast examinations by a health care provider and routine screening mammograms are recommended for early detection of breast cancer.
- The primary therapy for most women with stage I or II breast cancer is breast-conserving surgery with axillary or sentinel lymph node sampling followed by radiation therapy.
- Tamoxifen is a common adjuvant therapy for breast cancers that are estrogen-receptor positive.

CHAPTER

5

Infertility, Contraception, and Abortion

Peggy Mancuso

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- List common causes of infertility.
- Discuss the psychologic impact of infertility.
- Describe common diagnoses and treatments for infertility.
- Compare reproductive alternatives for couples experiencing infertility.
- Identify the advantages and disadvantages of the following methods of contraception: fertility awareness methods, barrier methods, hormonal methods, intrauterine devices, and sterilization.
- Explain common nursing interventions that facilitate contraceptive use.
- Describe the techniques used for medical and surgical interruption of pregnancy.
- Recognize ethical, legal, cultural, and religious considerations of infertility, contraception, and elective abortion.

INFERTILITY

Incidence

Infertility is a serious concern that affects quality of life of 10% to 15% of reproductive-age couples (American Society for Reproductive Medicine [ASRM], 2012). Commonly **infertility** is considered to be a diagnosis for couples who have not achieved pregnancy after 1 year of regular, unprotected intercourse when the woman is less than 35 years of age or after 6 months when the woman is older than 35 (Practice Committee of the ASRM, 2008). Fecundity is the term used to describe the chance of achieving pregnancy and subsequent live birth within one menstrual cycle. Fecundity averages 20% in couples who are not experiencing reproductive problems.

The prevalence of infertility is relatively stable among the overall population; although, as the U.S. population ages, the numbers of infertile women will decline with the decrease in numbers of reproductive-age women. Infertility increases with the age of the woman, with fertility rates in women ages 40 to 45 being 95% lower than women ages 20 to 24. Probable causes of infertility include the trend toward delaying pregnancy until later in life, a time when fertility decreases naturally and the prevalence of diseases such as endometriosis and ovulatory dysfunction increases. Questions exist regarding whether there has been an increase in male infertility or whether male infertility is more readily identified because of improvements in diagnosis.

For the couple experiencing infertility, diagnosis and treatment strategies require considerable physical, emotional, and financial investment over an extended period of time. Feelings connected with infertility are many and complex. The origins of some of these feelings are myths, superstitions, misinformation, or magical thinking about the causes of infertility. Other feelings of anxiety and helplessness arise from the need to undergo many tests and examinations and from a perception of being "different" from others (RESOLVE, 2012). Nurses who care for infertile couples should consider the following four goals:

- Provide the couple with accurate information about human reproduction, infertility treatments, and prognosis for pregnancy. Dispel any myths or inaccuracies from friends or the mass media that the couple may believe to be true.
- Help the couple and the health care team accurately identify and treat possible causes of infertility.
- Provide emotional support. The couple may benefit from anticipatory guidance, counseling, and support group meetings, either face-to-face or online. The organization RESOLVE (www.resolve.org) provides online support, advocacy, and education about infertility for both the infertility community and health care providers.
- Guide and educate those who fail to conceive biologically as a couple about other forms of treatment such as in vitro fertilization (IVF), donor eggs or semen, surrogate

motherhood, and adoption. Support the couple in their decisions regarding their future family.

Nurses should also remember that among healthy women and men promotion of normal reproduction and prevention of infertility can be achieved if both partners maintain a normal body mass index (BMI) and avoid sexually transmitted infections (STIs) and exposures to substances or habits (such as smoking) that impair reproductive ability. As they make plans for their future family, adults should also know that realistically fertility decreases with age.

Factors Associated with Infertility

Although exact percentages vary somewhat with populations, approximately 80% of couples have an identifiable cause of infertility, with about 40% of these causes related to factors in the female partner, 40% related to factors in the male partner, and 20% related to factors in both partners. About 20% or more couples will experience unexplained or idiopathic causes of infertility (ASRM, 2012). Nevertheless the focus of infertility treatment has shifted from attempting to correct a specific pathology to recommending and initiating the treatment that is most effective in achieving pregnancy for this unique couple at this time in their reproductive life span. Assisted reproductive technologies (ARTs) have proven to be effective, even in couples who experience unexplained infertility.

Unassisted human conception requires a normally developed reproductive tract in both the male and female partners. For simplification, each live birth necessitates synchronization of the following:

- The male must deposit semen with sperm that has the capacity to fertilize an egg close to the cervix at the time of ovulation. The sperm must be able to ascend through the uterus and fallopian tubes (male factor).
- The cervix must be sufficiently open to allow semen to enter the uterus and provide a nurturing environment for sperm (cervical factor).
- The fallopian tubes must be able to capture the ovum, transport semen to the ovum, and transport the fertilized embryo to the uterus (tubal factor).
- Ovulation of a healthy oocyte must occur, ideally within the parameters of a regular, predictable menstrual cycle (ovarian factor).
- The uterus must be receptive to implantation of the embryo and capable of nourishing the growth and development of the fetus throughout the normal duration of pregnancy (uterine factor).

An alteration in one or more of these structures, functions, or processes results in some degree of impaired fertility. Boxes 5-1 and 5-2 list factors affecting female and male infertility.

For ovulation to occur, both partners must have normal, intact hypothalamic-pituitary-gonadal hormonal axes that support the formation of sperm in the male and ova in the female. Sperm can remain viable within a woman's reproductive tract for at least 3 days and for as long as 5 days. The oocyte can only be successfully fertilized for 12 to 24 hours after ovulation (Fritz and Speroff, 2011c). The couple seeking pregnancy should be taught about the menstrual cycle and ways to detect ovulation (see Chapter 3). They should be counseled to have intercourse 2 to 3 times a week; or, if timed intercourse does not increase anxiety, they should be encouraged to engage in intercourse the day before and the day of ovulation. Fertility decreases markedly 24 hours after ovulation.

BOX 5-1 FACTORS AFFECTING FEMALE FERTILITY

Ovarian Factors
- Developmental anomalies
- Anovulation—primary
  - Pituitary or hypothalamic hormone disorders
  - Adrenal gland disorders (rare)
  - Congenital adrenal hyperplasia (rare)
- Anovulation—secondary
  - Disruption of hypothalamic-pituitary-ovarian axis
  - Anorexia
  - Insufficient body fat in athletic women
  - Increased prolactin levels
  - Thyroid disorders
  - Premature ovarian failure
  - Polycystic ovarian disorder
- Medications
  - Oral contraceptives
  - Progestins
  - Antidepressant and antipsychotic drugs
  - Corticosteroids
  - Chemotherapy

Tubal/Peritoneal Factors
- Developmental anomalies of the tubes (see Fig. 5-1)
- Reduced tubal motility
- Inflammation within the tube
- Tubal adhesions
- Disruption caused by tubal pregnancy
- Endometriosis

Uterine Factors
- Developmental anomalies of the uterus (see Fig. 5-1)
- Endometrial and myometrial fibroid tumors
- Asherman's syndrome (uterine adhesions or scar tissue)

Vaginal-Cervical Factors
- Vaginal-cervical infections
- Cervical mucus inadequate
- Isoimmunization (development of sperm antibodies)

Other Factors
- Nutritional deficiencies
- Obesity
- Thyroid dysfunction (hyperthyroidism and hypothyroidism)
- Idiopathic conditions

CARE MANAGEMENT

The nurse assists in the assessment and education of the infertile couple. As part of the assessment process he or she obtains information from the couple through interview and physical examination, including if this couple's situation is one of primary (never experienced pregnancy) or secondary (previous pregnancy) infertility. Religious, cultural, and ethnic data may place restrictions on use of available treatments. Box 5-3 describes some of the concerns related to religion that may affect the couple's choices regarding infertility treatment. The Cultural Competence box notes cultural rituals and beliefs regarding fertility. In addition, the nurse obtains and monitors results of diagnostic testing. Some of the information and data needed to investigate impaired fertility are of a sensitive, personal

BOX 5-2 FACTORS AFFECTING MALE FERTILITY

Hormonal Disorders

- Congenital disorders
- Tumors of the pituitary and hypothalamus
- Trauma to the pituitary or hypothalamus
- Hyperprolactinemia
- Excess of androgens, estrogen, cortisol
- Drugs and substance abuse (recreational and prescribed drugs)
- Chronic illnesses
- Nutritional deficiencies
- Obesity
- Endocrine disorders (e.g., diabetes)

Testicular Factors

- Congenital disorders
- Undescended testes
- Hypospadias
- Varicocele
- Viral infections (e.g., mumps)
- Sexually transmitted infections (gonorrhea, chlamydial infection)
- Obstructive lesions of the epididymis and vas deferens
- Environmental toxins
- Trauma
- Torsion
- Castration
- Systemic illnesses
- Changes in sperm from cigarette smoking or use of heroin, marijuana, amyl nitrate, butyl nitrate, ethyl chloride, or methaqualone
- Decrease in libido from use of heroin, methadone, selective serotonin reuptake inhibitors, or barbiturates
- Impotence from use of alcohol or antihypertensive medications
- Antisperm antibodies

Factors Associated with Sperm Transport

- Drugs
- Sexually transmitted infections of the epididymis
- Ejaculatory dysfunction
- Premature ejaculation

Idiopathic Male Infertility

BOX 5-3 RELIGIOUS CONSIDERATIONS CONCERNING INFERTILITY

The health care provider must always be aware of civil laws and religious proscriptions about sexual activities. Conservative and reform Jewish couples accept most infertility treatment; however, the Orthodox Jewish husband and wife may face problems in infertility investigation and management because of religious laws that govern marital relations. For example, according to Jewish law the Orthodox couple may not engage in marital relations during menstruation and through the following seven "preparatory days." The wife then is immersed in a ritual bath *(Mikvah)* before relations can resume. Fertility problems can arise when the woman has a short cycle (i.e., a cycle of 24 days or fewer, when ovulation would occur on day 10 or earlier).

The Roman Catholic Church regards the embryo as a human being from the first moment of existence. Therefore technical procedures such as in vitro fertilization (IVF), therapeutic donor insemination, and freezing embryos are not accepted or endorsed.

Other religious groups may have ethical concerns about infertility tests and treatments. For example, most Protestant denominations and Muslims usually support infertility management as long as IVF is done with the husband's sperm, there is no reduction of fertilized embryos after implantation, and insemination is done with the husband's sperm. These groups are less supportive of surrogacy and use of donor sperm and eggs. Christian Scientists do not permit surgical procedures or IVF but do permit insemination with husband and donor sperm.

Care providers should seek to understand the woman's spirituality and how beliefs affect her perception of health care, especially in relation to infertility. Women may wish to seek infertility treatment but have questions about proposed diagnostic and therapeutic procedures because of religious proscriptions. These women are encouraged to consult their minister, rabbi, priest, or other spiritual leader for advice.

Data from D'Avanzo C: *Mosby's pocket guide to cultural health assessment*, ed 4, St Louis, 2008, Mosby.

BOX 5-4 INSURANCE COVERAGE FOR INFERTILITY

As of October 2012, only 15 states had mandated some form of insurance coverage for infertility. These mandates included in vitro fertilization in some states, whereas others only covered some diagnostic tests. Some states require health maintenance organizations (HMOs) to cover some costs, whereas in others HMOs are exempt. Patients need information about what they can expect from their insurers. For questions about an individual state, call the state Insurance Commissioner's office. The website for the American Society for Reproductive Medicine (www.asrm.org) has more complete information.

nature. The couple may experience feelings of invasion of privacy, and the nurse must exercise tact and express concern for their well-being throughout the interview. The tests and examinations associated with infertility diagnosis and treatment are occasionally painful and often intrusive. The couple's intimacy and feelings of romantic attachment are often impaired as they engage in this process. A high level of motivation is needed to endure the investigation and subsequent treatment. Because multiple factors involving both partners are common, the investigation of impaired fertility is conducted systematically and simultaneously for both male and female partners (see Cultural Competence box). Both partners must be interested in the solution to the problem. The medical investigation requires time (3 to 4 months) and considerable financial expense. Box 5-4 describes the status of insurance coverage for infertility treatment.

Assessment of Female Infertility

Evaluation for infertility should be offered to couples who have failed to become pregnant after 1 year of regular intercourse or after 6 months if the woman is over 35. Investigation of impaired fertility begins for the woman with a complete history and physical examination. A complete general physical examination should include height and weight and estimation of BMI. Both obesity and being underweight are associated with anovulation disorders. Signs and symptoms of androgen excess such as excess body hair or pigmentation changes should be noted. The general physical examination is followed by a specific assessment of the reproductive tract. A history of infections of the genitourinary tract and any signs of infections, especially STIs that could impair tubal patency, should be assessed.

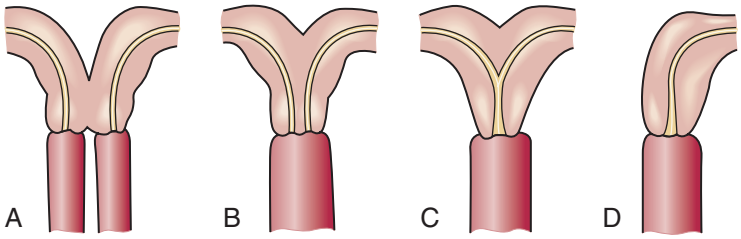

FIG 5-1 Abnormal uterus. **A,** Complete bicornuate uterus with vagina divided by a septum. **B,** Complete bicornuate uterus with normal vagina. **C,** Partial bicornuate uterus with normal vagina. **D,** Unicornuate uterus.

CULTURAL COMPETENCE

Fertility and Infertility

Worldwide cultures continue to use symbols and rites that celebrate fertility. One fertility rite that persists today is the custom of throwing rice at the bride and groom. Other fertility symbols and rites include passing out congratulatory cigars, candy, or pencils by a new father and baby showers held in anticipation of a child's birth.

In many cultures the responsibility for infertility is usually attributed to the woman. A woman's inability to conceive may be caused by previous sins, evil spirits, or personal inadequacies. In some cultures male virility remains in question until a man demonstrates his ability to reproduce by having at least one child (D'Avanzo, 2008).

Bimanual examination of internal organs may reveal lack of mobility of the uterus or abnormal contours of the uterus and tubes. A woman may have an abnormal uterus and tubes (Fig. 5-1) as a result of congenital abnormalities during fetal development). These uterine abnormalities increase risk for early pregnancy loss.

Laboratory data, including routine urine and blood tests, are collected. The initial clinic visit serves as a preconceptual visit and as initial assessment of possible causes of infertility. The woman should be taking folic acid supplements, and all immunizations should be current to prepare for possible pregnancy.

Diagnostic Testing. The basic infertility survey of the female involves evaluation of the cervix, uterus, tubes, and peritoneum; detection of ovulation; and hormone analysis. Timing and descriptions of common tests are presented in Table 5-1. Previous status regarding ovulation can be evaluated through menstrual history, serum hormone studies, and use of an ovulation predictor kit. If the woman is over age 35, the clinician may choose to assess "ovarian reserve" or how many potential ova remain within the ovaries. A common evaluation of ovarian reserve is measurement of follicle-stimulating hormone (FSH) levels on the third day of the menstrual cycle. The uterus and fallopian tubes can be visualized for abnormalities and tubal patency through hysterosalpingogram (x-ray film examination of the uterine cavity and tubes after instillation of radiopaque contrast material through the cervix). If the woman is at risk for endometriosis (implants of endometrial tissue outside of the uterus) or adhesions, diagnostic laparoscopy may be indicated. Test findings favorable for fertility are summarized in Box 5-5.

Assessment of Male Infertility

The systematic investigation of infertility in the male patient begins with a thorough history and physical examination. Assessment of the male patient proceeds in a manner similar to that of the female patient, starting with noninvasive tests.

Diagnostic Testing and Semen Analysis. The basic test for male infertility is **semen analysis.** A complete semen analysis, study of the effects of cervical mucus on sperm forward motility and survival, and evaluation of the ability of the sperm to penetrate an ovum provide basic information. Sperm counts vary from day to day and depend on emotional and physical status and sexual activity. Therefore a single analysis may be inconclusive. A minimum of two analyses must be performed several weeks apart to assess male fertility.

Semen is collected by ejaculation into a clean container or a plastic sheath that does not contain a spermicidal agent. The specimen is usually collected by masturbation following 2 to 7 days of abstinence from ejaculation. The semen is examined at the collection site or taken to the laboratory in a sealed container within 2 hours of ejaculation. Exposure to excessive heat or cold is avoided. Commonly accepted values for semen characteristics are given in Box 5-6. If results are in the fertile range, no further sperm evaluation is necessary. If results are not within this range, the test is repeated. If subsequent results are still in the subfertile range, further evaluation is needed to identify the problem.

Hormone analyses are done for testosterone, gonadotropin, FSH, and luteinizing hormone (LH). The sperm penetration assay and other alternative tests can be used to evaluate the ability of sperm to penetrate an egg. Testicular biopsy may be warranted. Scrotal ultrasound can be used to examine the testes for presence of **varicoceles** and identify abnormalities in the scrotum and spermatic cord. Transrectal ultrasound is used to evaluate the ejaculatory ducts, seminal vesicles, and vas deferens.

Psychosocial Considerations

Infertility is recognized as a major life stressor that can affect self-esteem; relations with the spouse, family, and friends; and careers. Psychologic responses to the diagnosis of infertility may tax a couple's capacity for giving and receiving physical and sexual closeness. The prescriptions and proscriptions for achieving conception may add tension to a couple's sexual functioning. They may report decreased desire for intercourse, orgasmic dysfunction, or midcycle erectile disorders.

To be able to deal comfortably with a couple's sexuality, nurses must be comfortable with their own sexuality so they can better help couples understand why aspects of a private act, lovemaking, need to be shared with health care professionals. Nurses need current factual knowledge about human sexual practices and must be accepting of the preferences and activities of others without being judgmental. They must be skilled in interviewing and therapeutic use of self, sensitive to the nonverbal cues of others, and

TABLE 5-1 GENERAL TESTS FOR IMPAIRED FERTILITY

TEST OR EXAMINATION	TIMING (MENSTRUAL CYCLE DAYS)	RATIONALE
Hysterosalpingogram (HSG) (uterine abnormalities, tubal patency)	7-10	Late follicular, early proliferative phase; will not disrupt a fertilized ovum; may open uterine tubes before time of ovulation
Chlamydia immunoglobulin G antibodies (tubal patency)	Variable	Negative antibody test may indicate tubal patency assessment (HSG); not needed in low risk women
Hysterosalpingo-contrast sonography (uterine abnormalities, tubal patency)	7-10	Late follicular, early proliferative phase; will not disrupt a fertilized ovum; evaluates tubal patency, uterine cavity, and myometrium
Serum progesterone (ovulation)	7 days before expected menses	Midluteal-phase progesterone levels; check adequacy of corpus luteum progesterone production
Assessment of cervical mucus (ovulation)	Variable, ovulation	Cervical mucus should have low viscosity, high spinnbarkeit (ability to stretch) during ovulation
Basal body temperature (ovulation)	Chart entire cycle	Elevation occurs in response to progesterone; documents ovulation
Urinary ovulation predictor kit (ovulation)	Variable, ovulation	Detects timing of lutein hormone surge before ovulation
Semen analysis (male factor)	2 to 7 days after abstinence	Detects ability of sperm to fertilize egg
Sperm penetration assay (male factor)	After 2 days but ≤1 wk of abstinence	Evaluation of ability of sperm to penetrate egg
Follicle-stimulating hormone (FSH) level (ovarian reserve)	Day 3	High FSH levels (>20) indicate that pregnancy will not occur with woman's own eggs; value <10 indicates adequate ovarian reserve
Clomiphene citrate challenge test (CCCT) (ovarian reserve)	Administer clomiphene 100 mg days 3 through 10	Assess FSH on days 3 and 10 in presence of clomiphene stimulation; high FSH levels (>20) indicate that pregnancy will not occur with woman's own eggs; FSH <15 suggestive of adequate ovarian reserve

BOX 5-5 SUMMARY OF FINDINGS FAVORABLE TO FERTILITY

1. Follicular development, ovulation, and luteal development are supportive of pregnancy:
   a. Basal body temperature (presumptive evidence of ovulatory cycles) is biphasic, with temperature elevation that persists for 12 to 14 days before menstruation.
   b. Cervical mucus characteristics change appropriately during phases of the menstrual cycle.
   c. Days 3 to 10 follicle-stimulating hormone (FSH) levels are low enough to verify presence of adequate ovarian follicles.
   d. Day 3 estradiol levels are low enough to verify presence of adequate ovarian follicles.
   e. Woman reports a history of regular, predictable menses with consistent premenstrual and menstrual symptoms.
2. The luteal phase is supportive of pregnancy:
   a. Levels of plasma progesterone are adequate to indicate ovulation.
   b. Luteal phase of menstrual cycle is of sufficient duration to support pregnancy.
3. Cervical factors are receptive to sperm during expected time of ovulation:
   a. Cervical os is open.
   b. Cervical mucus is clear, watery, abundant, and slippery and demonstrates good spinnbarkeit and arborization (fern pattern) at time of ovulation.
   c. Cervical examination reveals no lesions or infections.
4. The uterus and uterine tubes support pregnancy:
   a. Uterine and tubal patency are documented by (1) spillage of dye into the peritoneal cavity, and (2) outlines of uterine and tubal cavities of adequate size and shape with no abnormalities.
   b. Laparoscopic examination verifies normal development of internal genitals and absence of adhesions, infections, endometriosis, and other lesions.
5. The male partner's reproductive structures are normal:
   a. There is no evidence of developmental anomalies of penis, testicular atrophy, or varicocele (varicose veins on the spermatic vein in the groin).
   b. There is no evidence of infection in prostate, seminal vesicles, and urethra.
   c. Testes are more than 4 cm in largest diameter.
6. Semen is supportive of pregnancy:
   a. Sperm (number per milliliter) are adequate in ejaculate.
   b. Most sperm show normal morphology.
   c. Most sperm are motile, forward moving.
   d. No autoimmunity exists.
   e. Seminal fluid is normal.

BOX 5-6 SEMEN ANALYSIS

- Semen volume at least 1.5 L
- Semen pH 7.2 or higher
- Sperm density greater than 15 million/mL
- Total sperm count greater than 39 million per ejaculate
- Normal morphologic features greater than 4% (normal oval)
- Motility (important consideration in sperm evaluation)—percentage of forward-moving sperm estimated with respect to abnormally motile and nonmotile sperm, 40%
- Liquification—usually within 15 minutes but no longer than 60 minutes

Source: World Health Organization (WHO): *Laboratory manual for the examination of human semen,* ed 5, Geneva, 2010, WHO.
NOTE: These values are not absolute but are only relative to final evaluation of the couple as a single reproductive unit. Values also differ according to source used as a reference.

CRITICAL THINKING CASE STUDY

Infertility

Diane is a 39-year-old accountant who has recently married for the first time. Charles is 41 and has two children from a previous marriage. Diane has a history of amenorrhea when she was in college and a member of the track team. Currently her menstrual periods are irregular. She wants to have a baby "before it's too late," and she and Charles have been having unprotected sex for almost a year. They have come to the fertility clinic today for an evaluation. Diane tells the nurse that she has heard a lot about the success of in vitro fertilization (IVF) and wants to know if she will be able to have it performed. How should the nurse respond to Diane's comments and questions?

1. Evidence—Is evidence sufficient to draw conclusions about what response the nurse should give?
2. Assumptions—Describe underlying assumptions about the following issues:
   a. Age and fertility
   b. Infertility as a major life stressor
   c. Success rates for IVF pregnancy and birth
   d. Causes of female infertility
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

knowledgeable regarding each couple's sociocultural and religious beliefs (see Critical Thinking Case Study).

The couple facing infertility exhibit behaviors of the grieving process such as those associated with other types of loss. The loss of one's genetic continuity with the generations to come can provoke decreased self-esteem, a sense of inadequacy as a woman or a man, and feelings of loss of control over personal destiny. Infertile individuals can perceive greater dissatisfaction with their marriages. Not all people have all the reactions described, nor can it be predicted how long any reaction will last for an individual.

If the couple does not conceive, they should be assessed regarding their desire to be referred for help with adoption, donor eggs or semen, surrogacy, or other reproductive alternatives. The couple may choose to continue in a childfree state. Both health care providers and patients should have a list of agencies, support groups, and other resources within their community such as the ASRM (www.asrm.org) and RESOLVE (www.resolve.org).

Nonmedical Treatments

Both men and women can benefit from healthy lifestyle changes that result in a BMI within the normal range; moderate daily exercise; and abstinence from alcohol, nicotine, and recreational drugs. For the woman with a BMI >27 and polycystic ovary syndrome, losing just 5% to 10% of body weight can restore ovulation within 6 months. Anovulatory women with a BMI <17 who have eating disorders or intense exercise regimens benefit from weight gain. Nevertheless, this population sometimes is reluctant to alter their behaviors, and counseling should be advised.

Simple changes in lifestyle may be effective in the treatment of subfertile men. Only water-soluble lubricants should be used during intercourse because many commonly used lubricants contain spermicides or have spermicidal properties. High scrotal temperatures can be caused by daily hot tub baths or saunas that keep the testes at temperatures too high for efficient spermatogenesis. These conditions lead to only lessened fertility and should not be used as a means of contraception.

Most herbal remedies have not been proven clinically to promote fertility or to be safe in early pregnancy and should be taken by the woman only as prescribed by a physician or nurse-midwife who has expertise in herbology. Relaxation, osteopathy, stress management (e.g., aromatherapy, yoga), and nutritional and exercise counseling have been reported to increase pregnancy rates in some women. Herbs to avoid while trying to conceive include licorice root, yarrow, wormwood, ephedra, fennel, goldenseal, lavender, juniper, flaxseed, pennyroyal, passionflower, wild cherry, cascara, sage, thyme, and periwinkle. All supplements or herbs should be purchased from trusted sources to ensure that they do not contain contaminants.

Medical Therapy

One goal of infertility assessment and treatment is to determine which couples could respond to conventional therapies in a timely manner. Another goal is to refer couples who will need ARTs to conceive early in the process. In general, any fertility treatment is more likely to result in a live birth in women who are younger than age 35, with successful outcomes decreasing for women over age 40.

Pharmacologic therapy for female infertility is often directed at treating ovulatory dysfunction by either stimulating or enhancing ovulation so more oocytes mature. These medications include (a) clomiphene citrate as initial therapy for many women with intermittent anovulation; (b) a combination of clomiphene and metformin for women with anovulation and insulin resistance; (c) human menopausal gonadotropin (HMG), FSH, and recombinant FSH (rFSH) to stimulate follicle formation in women who do not respond to clomiphene therapies; (d) human chorionic gonadotropin to induce ovulation when follicles are ripe, (e) gonadotropin-releasing hormone (GnRH) agonists at the beginning of a cycle to sequence HMG therapies, (f) progesterone to support the luteal phase of the cycle, and (g) bromocriptine (Parlodel) for women who have excess prolactin (see Medication Guide).

Treatment of certain medical conditions can result in improved fertility. The woman who is hypothyroid benefits from thyroid hormone supplementation. Treatment of endometriosis could include trials of danazol, progesterone, continuous combined oral contraceptives, or GnRH agonists to suppress menstruation and shrink endometrial implants. This regimen would be followed by

MEDICATION GUIDE

Selected Infertility Medications

DRUG	INDICATION	MECHANISM OF ACTION	DOSAGE	COMMON SIDE EFFECTS
Clomiphene citrate	Ovulation induction, treatment of luteal-phase inadequacy	Thought to bind to estrogen receptors in the pituitary, blocking them from detecting estrogen	Tablets, starting with 50 mg/day by mouth for 5 days beginning on fifth day of menses; if ovulation does not occur, may increase dose next cycle; variable dosage	Vasomotor flushes, abdominal discomfort, nausea and vomiting, breast tenderness, ovarian enlargement
Menotropins (human menopausal gonadotropins)	Ovarian follicular growth and maturation	LH and FSH in 1:1 ratio, direct stimulation of ovarian follicle; given sequentially with hCG to induce ovulation	IM injections; dosage regimen variable based on ovarian response Initial dose is 75 International Units of FSH and 75 International Units of LH (1 ampule) daily for 7-12 days followed by 10,000 International Units hCG	Ovarian enlargement, ovarian hyperstimulation, local irritation at injection site, multifetal gestations
Follitropins (purified FSH)	Treatment of polycystic ovarian disease; follicle stimulation for assisted reproductive techniques	Direct action on ovarian follicle	Subcutaneous or IM injections; dosage regimen variable	Ovarian enlargement, ovarian hyperstimulation, local irritation at injection site, multifetal gestations
Human chorionic gonadotropin (hCG)	Ovulation induction	Direct action on ovarian follicle to stimulate meiosis and rupture of the follicle	5000-10,000 International Units IM 1 day after last dose of menotropins; dosage regimen variable	Local irritation at injection site; headaches, irritability, edema, depression, fatigue
GnRH agonists (nafarelin acetate, leuprolide acetate)	Treatment of endometriosis, uterine fibroids	Desensitization and downward regulation of GnRH receptors of pituitary, resulting in suppression of LH, FSH, and ovarian function	Nafarelin, 200 mcg (1 spray) intranasally twice daily for 6 months; leuprolide acetate 3.75 mg IM every month for 3 to 6 months	Nafarelin—irritation, nosebleeds Both nafarelin and leuprolide—hot flashes, vaginal dryness, myalgia and arthralgia, headaches, mild bone loss (usually reversible within 12-18 months after treatment)
Progesterone	Treatment of luteal-phase inadequacy	Direct stimulation of endometrium	Vaginal gel 8%, 1 prefilled applicator per day; after ovulation induction, continue through 10-12 weeks of pregnancy	Breast tenderness, local irritation, headaches
GnRH antagonists (ganirelix acetate, cetrorelix acetate)	Controlled ovarian stimulation for infertility treatment	Suppress gonadotropin secretion, inhibit premature LH surges in women undergoing ovarian hyperstimulation	250 mcg daily subcutaneously, usually in the early to midfollicular phase of the menstrual cycle; usually followed by hCG administration	Abdominal pain, headache, vaginal bleeding, irritation at the injection site
Metformin	Restores cyclic ovulation and menses in many women with polycystic ovary disease	Induces ovulation through reducing insulin resistance, thus affecting gonadotropins and androgens; simulates the ovary	Initial dose is 500 mg and titrated up over several weeks to 1500 mg/day; administered orally	Nausea, vomiting, diarrhea, lactic acidosis, liver dysfunction
Letrozole	Ovulation induction	Aromatase inhibitor that inhibits E_2 production, which causes an increase in LH:FHS ratio	2.5- to 5-mg tablets administered orally for 5 days beginning on cycle day 3 to 5	Hot flashes, headaches, breast tenderness; may increase risk of congenital anomalies

Data from American Society for Reproductive Medicine (ASRM). *Medications for inducing ovulation: A patient guide, 2012,* www.asrm.org/Factsheetsandbooklets/; Facts and Comparisons. *A to Z drug facts,* 2013, www.factsandcomparisons.com; and Lobo, R: Infertility: Etiology, diagnostic evaluation, management, prognosis. In Lentz G, Lobo R, Gershenson D, Katz V, editors: *Comprehensive gynecology*, ed 6, Philadelphia, 2012, Mosby.

ovulation induction. Adrenal hyperplasia is treated with prednisone. Any infections present in the infertile couple should be treated with appropriate antimicrobial formulations.

Clomiphene citrate (with the possible addition of metformin) is often the initial pharmacologic treatment of the infertile woman because it is inexpensive and the side effect profile is less than other medications that induce ovulation. There is an increased risk of twins with clomiphene therapy.

The more powerful medications used to induce ovulation include GnRH agonists followed by gonadotropin therapy. These medications are extremely potent and require daily ovarian ultrasonography and monitoring of estradiol levels to prevent hyperstimulation of the ovaries. The incidence of multiple pregnancies with the use of these medications is greater than 25%. Combinations of these medications are used with ART to stimulate ovulation before harvesting eggs.

Drug therapy may be indicated for male infertility. As with women, problems with the thyroid or adrenal glands are corrected with appropriate medications. Infections are identified and treated with antimicrobials. FSH, HMG, and clomiphene may be used to stimulate spermatogenesis in men with hypogonadism. Men who do not respond to these therapies are candidates for intracytoplasmic sperm injection (ICSI), which is a procedure that injects sperm directly into the egg as part of IVF. ICSI has enabled men with very low sperm counts to achieve biologic reproduction.

The primary care provider is responsible for fully informing patients about the prescribed medications. The nurse must be ready to answer patients' questions and confirm their understanding of the drug, its administration, potential side effects, and expected outcomes. Because information varies with each drug, the nurse must consult the medication package inserts, pharmacology references, health care provider, and pharmacist as necessary. The nurse should also provide anticipatory guidance regarding the time given for a medication trial before referral to a specialist in ART would be indicated if the couple wants to continue to attempt to become pregnant.

Surgical Therapies

A number of surgical procedures can be used for problems causing female infertility. Ovarian tumors must be excised. Whenever possible, functional ovarian tissue is left intact. Scar tissue adhesions caused by chronic infections may cover much of the ovary. These adhesions usually necessitate surgery to free and expose the ovary so ovulation can occur.

Hysterosalpingography is useful for identification of tubal obstruction and also for the release of blockage as demonstrated in Fig. 5-2. During laparoscopy delicate adhesions may be divided and removed, and endometrial implants may be destroyed by electrocoagulation or laser, as illustrated in Fig. 5-3. Laparotomy and microsurgery may be required for extensive repair of the damaged tube. Prognosis depends on the degree to which tubal patency and function can be restored. In general laparoscopic surgery for tubal patency is most effective in younger women with distal tubal damage. Older women or those with significant proximal disease should be referred for ARTs that bypass the fallopian tube.

In women with uterine abnormalities reconstructive surgery (e.g., the unification operation for bicornuate uterus) can improve the ability to conceive and carry a fetus to term. Surgical removal of tumors or fibroids involving the endometrium or muscular walls of the uterus could also improve the woman's chance of conceiving and maintaining a pregnancy to viability, depending on the location and size of the fibroid or tumor. Surgical treatment of uterine tumors or maldevelopment that results in successful pregnancy usually necessitates birth by cesarean surgery near term gestation because the enlarging uterus can rupture as a result of weakness in the area of reconstructive surgery.

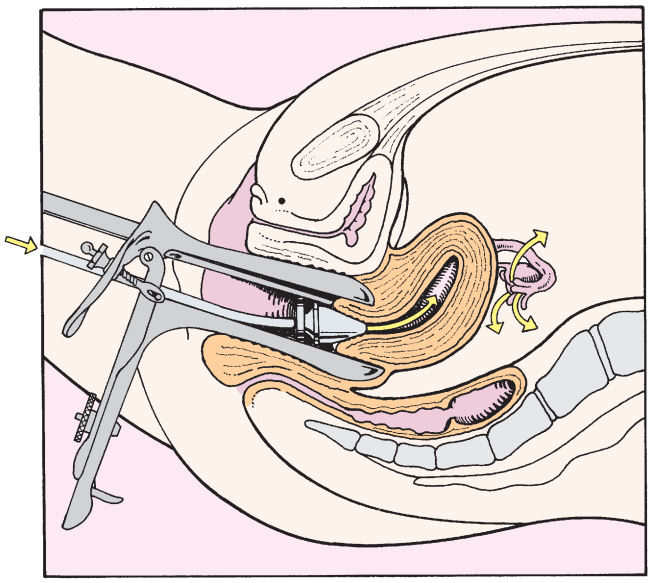

FIG 5-2 Hysterosalpingography. Note that the contrast medium flows through the intrauterine cannula and out through the uterine tubes.

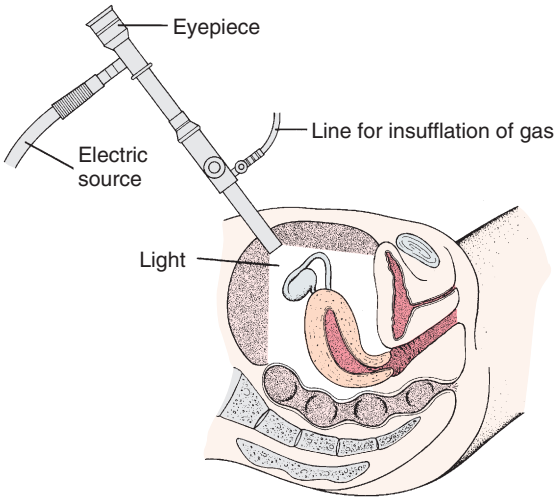

FIG 5-3 Laparoscopy.

Chronic inflammation and infection can be eliminated by radial chemocautery (destruction of tissue with chemicals) or thermocautery (destruction of tissue with heat, usually electrical) of the cervix, cryosurgery (destruction of tissue by application of extreme cold, usually liquid nitrogen), or conization (excision of a cone-shaped piece of tissue from the endocervix). When the cervix has been deeply cauterized or frozen or when extensive conization has been performed, the cervix may produce less mucus. Therefore the absence of a mucus bridge from the vagina to the uterus can make sperm migration difficult or impossible. Therapeutic intrauterine insemination may be necessary to carry the sperm directly through the internal os of the cervix.

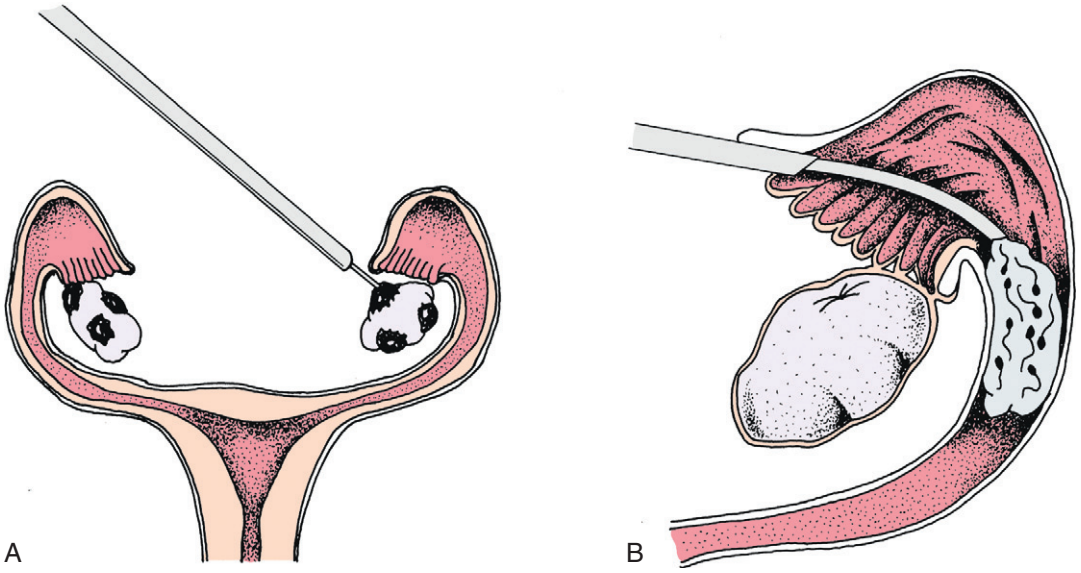

FIG 5-4 Gamete intrafallopian transfer (GIFT). **A,** Through laparoscopy a ripe follicle is located, and fluid containing the egg is removed. **B,** The sperm and egg are placed separately in the uterine tube, where fertilization occurs.

Surgical procedures may also be used for problems causing male infertility. Surgical repair of varicocele has been relatively successful in increasing sperm count but not fertility rates. Microsurgery to reanastomose (restore tubal continuity) the sperm ducts after vasectomy can restore fertility.

Assisted Reproductive Therapies

The Centers for Disease Control and Prevention (CDC) (2012) defines **assisted reproductive technology (ART)** as fertility treatments in which both eggs and sperm are handled. In general these treatments involve removing the eggs from the woman, fertilizing the eggs in the laboratory, and returning the embryo or embryos to the woman or surrogate carrier. The CDC reported that in 2010 there were approximately 147,260 ART cycles with 47,090 births and 61,564 infants (some multiple births) from these cycles. Although the use of ART is still relatively rare compared to the potential demand, its use has doubled over the past decade. Births that were conceived through ART comprise over 1% of all infants born in the United States every year.

Some of the ARTs for treatment of infertility include in vitro fertilization–embryo transfer (IVF-ET), gamete intrafallopian transfer (GIFT) (Fig. 5-4), zygote intrafallopian transfer (ZIFT), ovum transfer (oocyte donation), embryo adoption, embryo hosting and surrogate motherhood, therapeutic donor insemination (TDI), intracytoplasmic sperm injection (ICSI), assisted embryo hatching, and preimplantation genetic diagnosis (PGD). Table 5-2 describes these procedures and the possible indications for ARTs. Donor sperm and donor eggs can be used with ARTs. In addition, surrogates may carry the couple's biologic child. ARTs are associated with many ethical and legal issues (Box 5-7).

The lack of or misleading information about success rates and the risks and benefits of treatment alternatives prevent couples from making informed decisions. Nurses can provide information so couples have an accurate understanding of their chances for a successful pregnancy and live birth. Nurses also can provide anticipatory guidance about the moral and ethical dilemmas regarding the use of ARTs. If a couple is fortunate enough to have multiple embryos available, they may choose to preserve these for later implantation, which could have legal implications.

LEGAL TIP: Cryopreservation of Human Embryos
Couples who have excess embryos frozen for later transfer must be fully informed before consenting to the procedure and make decisions regarding the disposal of embryos in the event of death or divorce and a decision at a later time if they no longer want the embryos.

Complications

Other than the established risks associated with laparoscopy and general anesthesia, few risks are associated with IVF-ET, GIFT, and ZIFT. The more common transvaginal needle aspiration requires only local or intravenous analgesia. Congenital anomalies occur no more frequently than among naturally conceived embryos. Multiple gestations are more likely and are associated with increased risks for both the mother and fetuses. Nevertheless, ectopic pregnancies do occur more often and pose significant maternal risk. There is no increase in maternal or perinatal complications with TDI and the same frequencies of anomalies (about 5%) and obstetric complications (between 5% and 10%) that accompany natural insemination (through sexual intercourse).

Preimplantation Genetic Diagnosis

PGD is a form of early genetic testing designed to eliminate embryos with serious genetic diseases before implantation through one of the ARTs and to avoid future termination of pregnancy for genetic reasons. Micromanipulation allows removal of a single cell from a multicellular embryo for genetic study (i.e., embryo biopsy) (Fritz and Speroff, 2011c). PGD is used clinically in over 20 centers around the world. Couples must be counseled about their options and choices and the implications of their choices when genetic analysis is considered.

TABLE 5-2 ASSISTED REPRODUCTIVE THERAPIES

PROCEDURE	DEFINITION	INDICATIONS
In vitro fertilization–embryo transfer (IVF-ET)	A woman's eggs are collected from her ovaries, fertilized in the laboratory with sperm, and transferred to her uterus after normal embryo development has occurred.	Tubal disease or blockage; severe male infertility; endometriosis; unexplained infertility; cervical factor; immunologic infertility
Gamete intrafallopian transfer (GIFT)	Oocytes are retrieved from the ovary, placed in a catheter with washed motile sperm, and immediately transferred into the fimbriated end of the uterine tube. Fertilization occurs in the uterine tube.	Same as for IVF-ET, except there must be normal tubal anatomy, patency, and absence of previous tubal disease in at least one uterine tube
IVF-ET and GIFT with donor sperm	This process is the same as described previously except in cases where the husband's fertility is severely compromised and donor sperm can be used; if donor sperm are used, the wife must have indications for IVF and GIFT.	Severe male infertility; azoospermia; indications for IVF-ET or GIFT
Zygote intrafallopian transfer (ZIFT)	This process is similar to IVF-ET; after IVF the ova are placed in one uterine tube during the zygote stage.	Same as for GIFT
Donor oocyte	Eggs are donated by an IVF procedure, and the donated eggs are inseminated. The embryos are transferred into the recipient's uterus, which is hormonally prepared with estrogen/progesterone therapy.	Early menopause; surgical removal of ovaries; congenitally absent ovaries; autosomal or sex-linked disorders; lack of fertilization in repeated IVF attempts because of subtle oocyte abnormalities or defects in oocyte-spermatozoa interaction
Donor embryo (embryo adoption)	A donated embryo is transferred to the uterus of an infertile woman at the appropriate time (normal or induced) of the menstrual cycle.	Infertility not resolved by less aggressive forms of therapy; absence of ovaries; male partner azoospermic or severely compromised
Gestational carrier (embryo host); surrogate mother	A couple undertakes an IVF cycle, and the embryo(s) is/are transferred to another woman's uterus (the carrier), who has contracted with the couple to carry the baby to term. The carrier has no genetic investment in the child. Surrogate motherhood is a process by which a woman is inseminated with semen from the infertile woman's partner and then carries the baby until birth.	Congenital absence or surgical removal of uterus; reproductively impaired uterus, myomas, uterine adhesions, or other congenital abnormalities; medical condition that might be life threatening during pregnancy (e.g., diabetes; immunologic problems; or severe heart, kidney, or liver disease)
Therapeutic donor insemination (TDI)	Donor sperm are used to inseminate the female partner.	Male partner is azoospermic or has very low sperm count; couple has genetic defect; male partner has antisperm antibodies
Intracytoplasmic sperm injection	One sperm cell is selected to be injected directly into the egg to achieve fertilization. It is used with IVF.	Same as TDI
Assisted hatching	The zona pellucida is penetrated chemically or manually to create an opening for the dividing embryo to hatch and implant into the uterine wall.	Recurrent miscarriages; to improve implantation rate in women with previously unsuccessful IVF attempts; advanced age

Data from American Society for Reproductive Medicine: *Assisted reproductive technologies,* 2011, www.asrm.org.

BOX 5-7 ISSUES TO BE ADDRESSED BY INFERTILE COUPLES BEFORE TREATMENT

- Risks of multiple gestation
- Possible need for multifetal reduction
- Possible need for donor oocytes, sperm, or embryos or for gestational carrier (surrogate mother)
- Whether or how to disclose facts of conception to offspring
- Freezing embryos for later use
- Possible risks of long-term effects of medications and treatment on women, children, and families

Adoption

Couples may choose to build their family by adopting children who are not their own biologically. With increased availability of birth control and abortion and an increase in single mothers who choose to keep their babies, the availability of healthy newborn infants in the United States is limited. Infants with diverse ethnic and racial heritages, infants with special needs, older children, and foreign adoptions are other options (Fig. 5-5).

Couples who decide to adopt a child have decided that being a parent is more important than the actual process of birthing the child. The birth process is a very small aspect of having a baby and becoming a parent. So much emphasis is placed on being pregnant and having a child composed of one's own genetic makeup that the

FIG 5-5 After two miscarriages this couple chose foreign adoption. (Courtesy Shannon Perry, Phoenix, AZ.)

focus of the reason to have a child is not clear. The question to be answered by couples who want to adopt is, "Do you want to give birth to a baby, or do you want to become parents?"

CONTRACEPTION

The CDC noted that the capability of Americans to engage in effective family planning as a result of the modern era of contraception was one of the 10 greatest public health achievements of the 20th century. Nevertheless, nearly half of all U.S. pregnancies are not planned (Finer and Zolna, 2011). Among adolescent women approximately 80% of those who became pregnant did not intend to do so (Fritz and Speroff, 2011b). The nurse can play a vital role in preventing unwanted pregnancy through counseling and education regarding family planning, contraception, and effective birth control. Family planning is the conscious decision about when to conceive or to avoid pregnancy throughout the reproductive years. **Contraception** is defined as the intentional prevention of pregnancy during sexual intercourse. Birth control is the device and/or practice used to decrease the risk of conceiving or bearing offspring.

With the wide assortment of birth control options available, it is possible for a woman to use several different contraceptive methods at various stages throughout her fertile years. Nurses interact with the couple to compare and contrast available contraceptive options. Factors to consider include reliability, relative cost of the method, any protection from STIs, the individual's comfort level with the method, and the partner's willingness to use a particular birth control method. Those who use contraception can still be at risk for pregnancy if their choice of contraceptive method results in a method that is not used correctly. Providing adequate instruction about how to use a contraceptive method, when to use a backup method, and when to use emergency contraception (EC) can decrease the risk of unintended pregnancy. The Community Focus box presents information about contraceptive education.

CARE MANAGEMENT

A multidisciplinary approach may help a woman choose and correctly use an appropriate contraceptive method. Nurses, nurse-midwives, nurse practitioners, other advanced practice nurses, and physicians have the knowledge and expertise to help a woman make decisions about contraception that will satisfy her personal, social, cultural, and interpersonal needs.

Assessment for the couple desiring contraception involves assessment of the woman's reproductive history (menstrual, obstetric, gynecologic, contraceptive), physical examination, and sometimes current laboratory tests. The nurse must determine the woman's knowledge about reproduction, contraception, and STIs and her sexual partner's commitment to any particular method. Fig. 5-6 illustrates contraceptive counseling. The nurse obtains information about the frequency of coitus, number of sexual partners (present and past), and any objections that she or her partner might have about specific birth control methods. In addition, the nurse must determine a woman's willingness to touch her genitals. Religious and cultural factors may influence a couple's choice regarding a particular contraceptive method. The couple may believe in certain reproductive myths. For example, 30% of all adolescent pregnancies were in women who engaged in unprotected intercourse because of the perception that they could not get pregnant. Unbiased patient

COMMUNITY FOCUS

Education for Contraceptive Use

Nurses provide discharge planning after childbirth; they commonly staff family planning clinics and provide contraceptive information to those patients and others in the community. Education concerning contraceptive use in the postpartum period is a common component of discharge planning in many countries, with wide variation among health care delivery systems. Education at this time assumes women's receptiveness to information about contraception and that education or receptiveness to such information could be less at a later period. However, clinical trials have not demonstrated that education in the immediate postpartum period is effective. When assessing effectiveness of contraceptive education, attendance at family planning clinics, cessation of breastfeeding, knowledge about contraception, unplanned pregnancies, and satisfaction with care are factors that should be included. The content, timing, and organization of contraceptive education offered in the postpartum period and throughout the couple's lifetime need to be addressed.

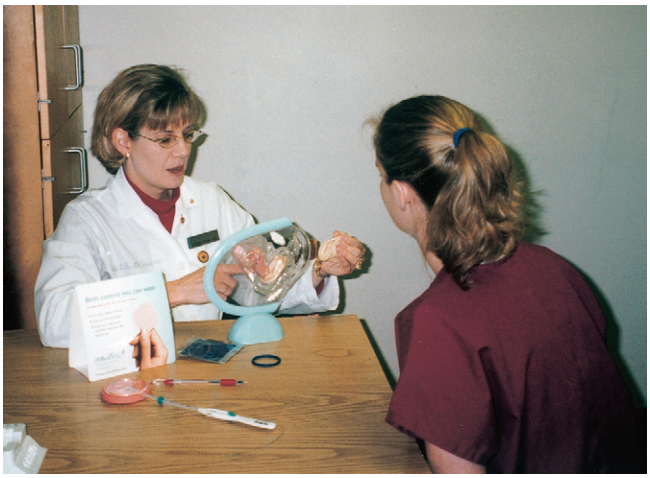

FIG 5-6 Nurse counseling woman about contraceptive methods. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

BOX 5-8 FACTORS AFFECTING CONTRACEPTIVE METHOD EFFECTIVENESS

- Frequency of intercourse
- Motivation to prevent pregnancy
- Understanding of how to use the method
- Adherence to the method
- Provision of short- or long-term protection
- Likelihood of pregnancy for the individual woman
- Consistent use of the method

teaching is fundamental to initiating and maintaining any form of contraception. The nurse counters myths with facts, clarifies misinformation, and fills in gaps in knowledge. The ideal contraceptive should be safe, easily available, economical, acceptable, simple to use, and promptly reversible. Although no method may ever achieve all of these objectives, significant advances in the development of new contraceptive technologies have occurred over the past 30 years.

Contraceptive failure rate refers to the percentage of contraceptive users expected to have an unplanned pregnancy during the first year even when they use a method consistently and correctly. Contraceptive effectiveness varies from couple to couple and depends on both the properties of the method and the characteristics of the user (Box 5-8). Effectiveness of a method can be expressed as theoretic (i.e., how effective the method is with perfect use) and typical (i.e., how effective the method is with typical use). Failure rates decrease over time, either because a user gains experience with and uses a method more appropriately or because the less effective users stop using the method. Safety of a method may be affected by a woman's medical history (e.g., thromboembolic problems and contraceptive methods containing estrogen). Nevertheless, in most instances pregnancy would be more dangerous to the woman with medical problems than a particular contraceptive method. In addition, many contraceptive methods have health promotion effects. Barrier methods such as the male condom offer some protection from acquiring STIs, and oral contraceptives lower the incidence of ovarian and endometrial cancer.

Following assessment and analysis, the couple determines possible contraceptive methods that are appropriate for their unique situation. Factors to consider when determining a contraceptive method are effectiveness, convenience, affordability, duration of action of method, reversibility of method, time of return to fertility, effects on uterine bleeding patterns, side effects, adverse events, health promotion effects of methods, effect of method on transmission of STIs, and medical contraindications for use.

The most effective reversible contraceptive methods at preventing pregnancy are the long–acting, reversible contraceptive (LARC) methods (e.g., contraceptive implants, intrauterine contraception). With these methods theoretic and typical pregnancy rates are the same because the method requires no user intervention after correct insertion. Effective methods include those that prevent pregnancy through exogenous hormones (estrogen and/or progestins) such as contraceptive injections, oral contraceptive pills, contraceptive patches, and vaginal rings. Each of these methods involves user interventions; thus typical-use pregnancy rates are higher than pregnancy rates with perfect use. The least effective contraceptive methods include the barrier methods and natural family planning. Examples include condoms, diaphragms, cervical caps, spermicides, withdrawal, and periodic abstinence during perceived ovulation.

CRITICAL THINKING CASE STUDY

Contraception for Adolescents

Maria is a 16-year-old Hispanic female who comes to the family planning clinic seeking contraception. She has recently become sexually active and tells the nurse that she is concerned that her mother will find out. She also has many questions about the type of contraception to use. She seeks the nurse's advice to help in her decision making.

1. Evidence—Is there sufficient evidence to draw conclusions about what advice to give Maria?
2. Assumptions—What assumptions can be made about contraception for adolescents:
   a. Types of contraception
   b. Legal issues
   c. Implications of culture on choice
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Effectiveness rates for these methods vary from user to user, depending on correct application of the method and consistency of use.

Expected outcomes related to contraceptive counseling are that the couple will verbalize understanding about appropriate contraceptive methods, state they are satisfied with the method chosen, use the method correctly and consistently, experience no adverse sequelae as a result of the chosen contraceptive method, and prevent unplanned pregnancy. The nurse assists with obtaining appropriate informed consent concerning contraception or sterilization, provides appropriate education to the couple, and documents the couple's understanding of the contraceptive method chosen. Evaluation involves achievement of patient-centered outcomes when the couple engage in effective use of the chosen contraceptive device, experience no adverse sequelae, and achieve pregnancy only when they desire to do so.

Methods of Contraception

The following discussion of contraceptive methods provides the nurse with information needed for patient teaching. After implementing the appropriate teaching for contraceptive use, the nurse supervises return demonstrations and practice to assess patient understanding (see Critical Thinking Case Study). The couple is given written instructions, telephone numbers, and/or email contact information for questions. If the woman has difficulty understanding written instructions, she and her partner, if available, are offered graphic material, a telephone number to call as necessary, and an opportunity to return for further instruction.

Coitus Interruptus

Coitus interruptus (withdrawal) involves the male partner withdrawing his penis from the woman's vagina before he ejaculates. Although coitus interruptus has been criticized as being an ineffective method of contraception, it is a good choice for couples who do not have another contraceptive available. Effectiveness is similar to barrier methods and depends on the man's ability to withdraw his penis before ejaculation. The percentage of women who experience an unintended pregnancy within the first year of typical use (failure rate) of withdrawal is about 27% (Kowal, 2011). Coitus interruptus does not protect against STIs or human immunodeficiency virus (HIV) infection.

Fertility Awareness Methods

Fertility awareness methods (FAMs) of contraception depend on identifying the beginning and end of the fertile period of the menstrual cycle. When women who want to use FAMs are educated about the menstrual cycle, three phases are identified:

1. Infertile phase: Before ovulation
2. Fertile phase: About 5 to 7 days around the middle of the cycle, including several days before and during ovulation and the day after ovulation
3. Infertile phase: After ovulation

Although ovulation can be unpredictable in many women, teaching the woman about how she can directly observe her fertility patterns is an empowering tool. In addition, knowledge about the signs and symptoms of ovulation can be very helpful when the couple desires pregnancy. There are nearly a dozen categories of FAMs. To prevent pregnancy each one uses a combination of charts, records, calculations, tools, observations, and either abstinence (natural family planning [NFP]) or barrier methods of birth control during the fertile period of the menstrual cycle. The charts and calculations associated with these methods can also be used to increase the likelihood of detecting the optimal timing of intercourse to achieve conception.

Advantages of these methods include low-to-no cost, absence of chemicals and hormones, and lack of alteration in the menstrual flow pattern. Disadvantages of FAMs include adherence needed for strict record keeping, unintentional interference from external influences that may alter the woman's core body temperature and vaginal secretions, decreased effectiveness in women with irregular cycles (particularly adolescents who have not established regular patterns of ovulation), decreased spontaneity of coitus, and the necessity of attending possibly time-consuming training sessions by qualified instructors. The typical failure rate for most FAMs is 24% during the first year of use (Trussell and Guthrie, 2011). FAMs do not protect against STIs or HIV infection.

FAMs involve several techniques to identify high risk, fertile days. The following discussion includes the most common techniques.

Natural Family Planning (Periodic Abstinence). **Natural family planning (NFP),** or periodic abstinence, provides contraception by using methods that rely on avoiding intercourse during fertile days. NFP methods are the only methods of contraception acceptable to the Roman Catholic Church. Signs and symptoms of fertility awareness most commonly used with abstinence are menstrual bleeding, cervical mucus, and basal body temperature. Development and marketing of ovulation predictor kits have also been very helpful for couples who choose NFP. Several application products have been developed for smart phones, which make FAM record tracking convenient and portable.

The human ovum can be fertilized no later than 16 to 24 hours after ovulation. Motile sperm have been recovered from the uterus and oviducts as long as 7 days after coitus. However, their ability to fertilize the ovum probably lasts no longer than 24 hours. Pregnancy is unlikely to occur if a couple abstains from intercourse for 4 days before and 3 or 4 days after ovulation (fertile period). Unprotected intercourse on the other days of the cycle (safe period) should not result in pregnancy. Nevertheless the exact time of ovulation cannot be predicted accurately, and couples may find it difficult to abstain from sexual intercourse for several days before and after ovulation. Women with irregular menstrual periods have the greatest risk of failure with this form of contraception.

Calendar Rhythm Method. Practice of the calendar rhythm method is based on the number of days in each cycle, counting from the first day of the menstrual cycle (first day of menstrual vaginal bleeding). The fertile period is determined after accurately recording the lengths of menstrual cycles for 6 months. The beginning of the fertile period is estimated by subtracting 18 days from the length of the shortest cycle. The end of the fertile period is determined by subtracting 11 days from the length of the longest cycle. If the shortest cycle is 24 days and the longest is 30 days, application of the formula to calculate the fertile period is as follows:

Shortest cycle, 24 – 18 = day 6

Longest cycle, 30 – 11 = day 19

To avoid conception the couple would abstain during the fertile period, days 6 through 19.

If the woman has very regular cycles of 28 days each, the formula indicates the fertile days to be as follows:

Shortest cycle, 28 – 18 = day 10

Longest cycle, 38 – 11 = day 17

To avoid conception the couple would abstain from days 10 through 17 because ovulation occurs on day 14 ± 2 days. A major drawback of the calendar method is that the couple is attempting to predict future events with past data. The unpredictability of the menstrual cycle is also not taken into consideration. The calendar rhythm method is most useful as an adjunct to the basal body temperature or cervical mucus method.

Standard Days Method. The standard days method (SDM) is essentially a modified form of the calendar rhythm method that has a "fixed" number of days of fertility for each cycle (i.e., days 8 to 19). A CycleBeads necklace (i.e., a color-coded string of beads) can be purchased as a concrete tool to track fertility (Fig. 5-7) or as a smart phone application. Day 1 of the menstrual flow is counted as the first day to begin counting. Women who use this device are taught to avoid unprotected intercourse on days 8 to 19 (white beads on CycleBeads necklace). Although this method is useful to women whose cycles are 26 to 32 days long, it is unreliable for those who have longer or shorter cycles (CycleBeads, 2012).

FIG 5-7 CycleBeads. *Red bead* marks the first day of the menstrual cycle. *White beads* mark days that are likely to be fertile days; therefore unprotected intercourse should be avoided. *Brown beads* are days when pregnancy is unlikely and unprotected intercourse is permitted. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

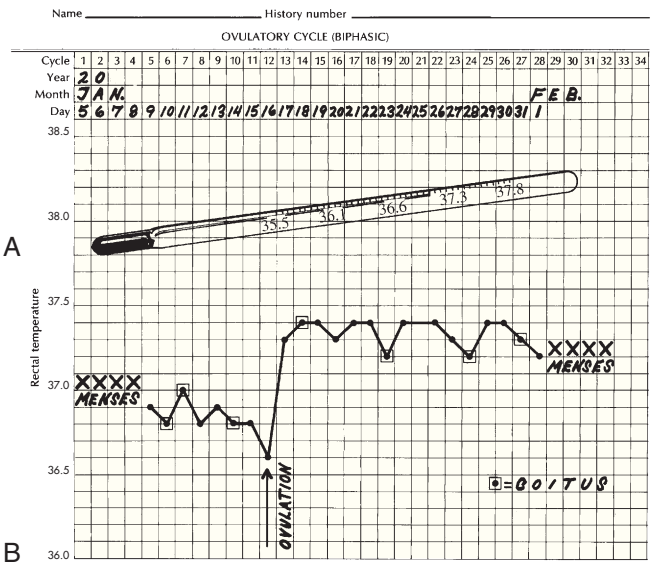

FIG 5-8 **A,** Special thermometer for recording basal body temperature, marked in tenths to enable person to read more easily. **B,** Basal temperature record shows decrease and sharp increase at time of ovulation. Biphasic curve indicates ovulatory cycle. A digital thermometer may also be used.

Basal Body Temperature Method. The basal body temperature (BBT) is the lowest body temperature of a healthy person, taken immediately after waking and before getting out of bed. The BBT usually varies from 36.2° to 36.3° C during menses and for approximately 5 to 7 days afterward (Fig. 5-8).

About the time of ovulation a slight drop in temperature (approximately 0.5° C) may occur in some women, but others may have no decrease at all. After ovulation, in concert with the increasing progesterone levels of the early luteal phase of the cycle, the BBT increases slightly (approximately 0.4° to 0.8° C). The temperature remains on an elevated plateau until 2 to 4 days before menstruation. Then BBT decreases to the low levels recorded during the previous cycle unless pregnancy has occurred. In pregnant women the temperature remains elevated. If ovulation fails to occur, the pattern of lower body temperature continues throughout the cycle.

To use this method the fertile period is defined as the day of first temperature drop, or first elevation, through 3 consecutive days of elevated temperature. Abstinence begins the first day of menstrual bleeding and lasts through 3 consecutive days of sustained temperature rise (at least 0.2° C). The decrease and subsequent increase in temperature are referred to as the thermal shift. When the temperatures of the entire month are recorded on a graph, the pattern described is more apparent. It is more difficult to perceive day-to-day variations without the entire picture (see Guidelines box). Either a glass mercury thermometer or a digital thermometer may be used for BBT, but the thermometer must measure the temperature within one tenth of a degree. The glass mercury thermometer needs no batteries but is fragile and can break. A digital thermometer requires batteries but may have a history recall function and an audible beep when the temperature assessment is finished. Digital thermometers that monitor temperature throughout the day combined with an accelerometer to monitor movement have been cleared for use by the Food and Drug Administration (FDA). These devices can be wirelessly uploaded to a computer through a companion device. Their use in FAM needs further research.

GUIDELINES

Basal Body Temperature

- Discuss basal body temperature (BBT) with the woman.
- Show the woman a diagram depicting the phases of the menstrual cycle.
- Discuss the hormones in the woman's body that are responsible for her menstrual cycle and ovulation. Leave time for questions.
- Show the woman a sample BBT graph (see Fig. 5-8) and the biphasic line seen in ovulatory cycles.
- Show the woman the BBT thermometer and how it is calibrated.
- Provide a demonstration.
- Encourage the woman to demonstrate taking and reading the thermometer and graphing the temperature while the nurse watches.
- Encourage the woman to start a log to keep track of any other activity that might interfere with her true BBT.

Infection, fatigue, less than 3 hours of sleep per night, awakening late, and anxiety may cause temperature fluctuations and alter the expected pattern. If a new BBT thermometer is purchased, this fact is noted on the chart because the readings may vary slightly. Jet lag, alcohol taken the evening before, or sleeping in a heated waterbed must also be noted on the chart because each affects the BBT. Therefore the BBT alone is not a reliable method of predicting ovulation.

Cervical Mucus Ovulation-Detection Method. The cervical mucus ovulation-detection method (i.e., Billings method or Creighton model ovulation method) requires that the woman recognize and interpret the cyclic changes in the amount and consistency of cervical mucus that characterize her own unique pattern of changes at the time of ovulation. Cervical mucus changes before and during ovulation to facilitate and promote the viability and motility of sperm. Without adequate cervical mucus, coitus does not result in conception. This method requires that a woman check the quantity and character of mucus on the vulva or introitus with her fingers or tissue paper each day for several months. This way she can learn how her cervical mucus responds to ovulation during her menstrual cycles. To ensure an accurate assessment of changes, the cervical mucus should be free from semen, contraceptive gels or foams, and blood or discharge from vaginal infections for at least one full cycle. Other factors that create difficulty in identifying mucus changes include douches and vaginal deodorants, being in the sexually aroused state (which thins the mucus), and taking medications such as antihistamines (which dry the mucus). Intercourse is considered safe without restriction beginning the fourth day after the last day of wet, clear, slippery mucus, which would indicate that ovulation has occurred 2 to 3 days previously.

Some women find this method unacceptable if they are uncomfortable touching their genitals. Whether or not a woman wants to use this method for contraception, it is to her advantage to learn to recognize mucus characteristics at ovulation (see Guidelines box). Self-evaluation of cervical mucus can be highly accurate and useful diagnostically for any of the following purposes:

- To alert the couple to the reestablishment of ovulation while breastfeeding and after discontinuation of oral contraception
- To note anovulatory cycles at any time and at the beginning of menopause
- To help couples plan a pregnancy

GUIDELINES

Cervical Mucus Characteristics

Setting the Stage

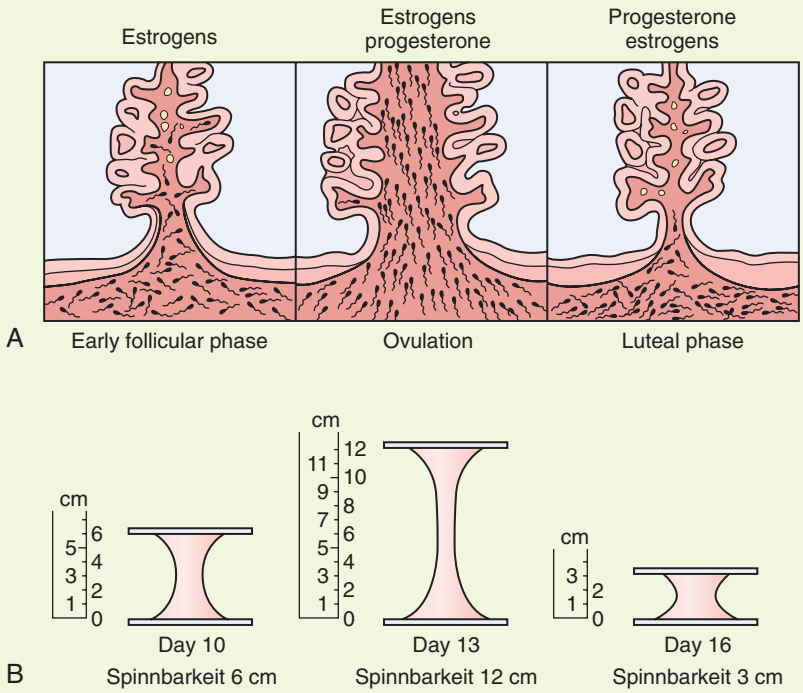
- Show charts of the menstrual cycle along with changes in the cervical mucus.
- Have the woman practice assessing mucus using raw egg white.
- Supply her with a basal body temperature (BBT) log and graph if she does not already have one.
- Explain that the assessment of cervical mucus characteristics is best when mucus is not mixed with semen, contraceptive jellies or foams, or discharge from infections.

Content Related to Cervical Mucus

- Explain to the woman (or couple) how cervical mucus changes throughout the menstrual cycle.
- Right before ovulation the watery, thin, clear mucus becomes more abundant and thick. It feels like a lubricant and can be stretched approximately 5 cm between the thumb and forefinger; this is called *spinnbarkeit*. This characteristic indicates the period of maximum fertility. Sperm deposited in this type of mucus can survive until ovulation occurs.

Assessment Technique

- Stress that good hand washing is imperative to begin and end all self-assessment.
- Start observation from last day of menstrual flow.
- Assess cervical mucus several times a day for several cycles. Mucus can be obtained from vaginal introitus; there is no need to reach into vagina to cervix.
- Record findings on the same record on which her BBT is entered.



Symptothermal Method. The symptothermal method combines the BBT and cervical mucus methods with awareness of secondary phase–related symptoms of menstrual cycle. The woman gains fertility awareness as she learns the psychologic and physiologic symptoms that mark the phases of her cycle. Secondary symptoms include increased libido, midcycle spotting, mittelschmerz (cramplike pain before ovulation), pelvic fullness or tenderness, and vulvar fullness.

The woman is taught to palpate her cervix to assess for changes indicating ovulation: the cervical os dilates slightly, the cervix softens and rises in the vagina, and cervical mucus is copious and slippery. The woman notes days on which coitus, changes in routine, illness, and other changes that might affect BBT have occurred (Fig. 5-9). Calendar calculations and cervical mucus changes are used to estimate the onset of the fertile period; changes in cervical mucus or the BBT are used to estimate the end of the fertile period.

TwoDay Method of Family Planning. Based on monitoring and the recording of cervical secretions, an algorithm for identifying the fertile window has been developed by the Institute for Reproductive Health at Georgetown University (Institute for Reproductive Health Georgetown University, 2012; Jennings and Burke, 2011). The TwoDay algorithm appears to be simpler to teach, learn, and use than other natural methods. Results suggest that the algorithm can be an effective alternative for low-literacy populations or for programs that find current NFP methods too time consuming or otherwise not feasible to incorporate within their services. Two questions are posed. Each day the woman is to ask herself, (1) "Did I note secretions today?" and (2) "Did I note secretions yesterday?" If the answer to either question is yes, she should avoid coitus or use a backup

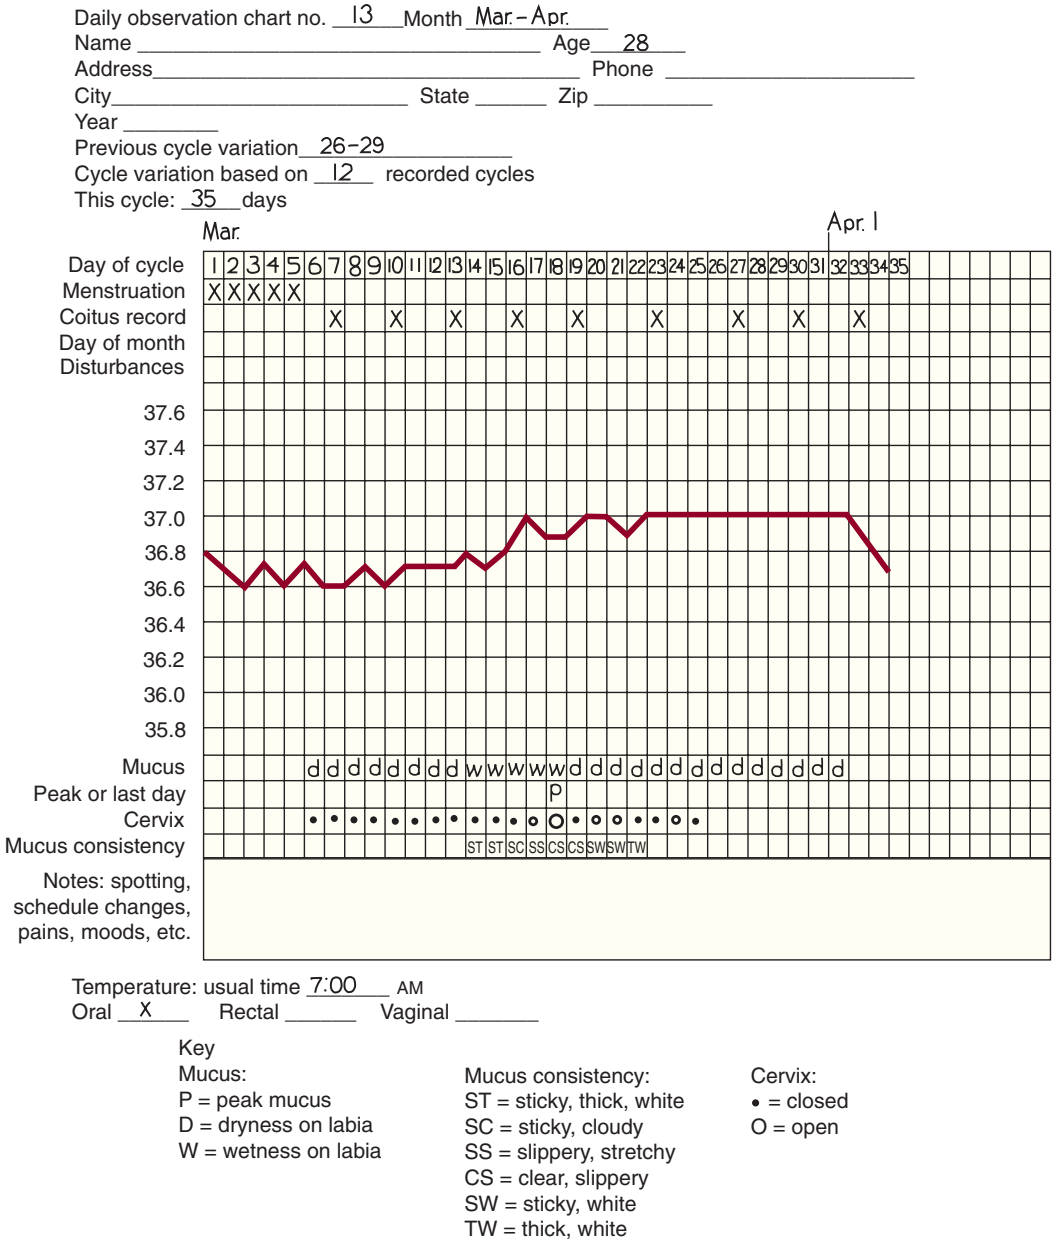


FIG 5-9 Example of completed symptothermal chart.

method of birth control. If the answer to both questions is no, her probability of getting pregnant is low. Further studies are needed to determine the efficacy of the TwoDay algorithm in avoiding pregnancy and to assess its acceptability to users and providers.

Home Predictor Test Kits for Ovulation. Although the methods previously discussed are characteristic of ovulation, they do not prove that ovulation actually occurred or indicate the exact timing. The urine predictor test for ovulation is a major addition to the NFP and fertility-awareness methods to help women who want to plan the time of their pregnancies and for those who are trying to conceive (Fig. 5-10). The urine predictor test for ovulation detects the sudden surge of LH that occurs approximately 12 to 24 hours before ovulation. Unlike BBT, this test is not affected by illness, emotions, or physical activity. For home use a test kit contains sufficient material for several days' testing during each cycle. A positive response indicating an LH surge is noted by a color change that is easy to interpret. Directions for use of urine predictor test kits vary with the manufacturer.

The Marquette Model. The Marquette Model (MM) is a natural family planning method that was developed through the Marquette University College of Nursing Institute for Natural Family Planning (Fehring, Schneider, and Barron, 2008). The MM uses cervical monitoring along with the ClearPlan Easy Fertility Monitor. The ClearPlan monitor is a handheld device that uses test strips to measure urinary metabolites of estrogen and LH. The monitor provides the user with "low," "high," and "peak" fertility readings. The MM incorporates the use of the monitor as an aid to learning NFP and fertility awareness.

FIG 5-10 Examples of ovulation predictor tests. (Courtesy Shannon Perry, Phoenix, AZ.)

FIG 5-11 Spermicides. (Courtesy Marjorie Pyle, RNC, Life Circle, Costa Mesa, CA.)

Research continues on the efficacy of available home test kits and devices for the prevention of pregnancy (Jennings and Burke, 2011).

Breastfeeding: Lactational Amenorrhea Method. Lactational amenorrhea method (LAM) can be a highly effective, *temporary* method of birth control. LAM is more popular in underdeveloped countries and traditional societies in which breastfeeding is used to prolong birth intervals. The method has seen limited use in the United States because most American women do not establish breastfeeding patterns that provide maximum protection against pregnancy (Kennedy and Trussell, 2011a).

When the infant suckles at the mother's breast, a surge of prolactin is released. Prolactin inhibits estrogen production and suppresses ovulation and the return of menses. LAM works best if the mother is exclusively breastfeeding, if she has not had a menstrual flow since birth, and if the infant is under 6 months of age. Effectiveness is enhanced by frequent feedings at intervals of less than 4 hours during the day and no more than 6 hours during the night, long duration of each feeding, and no bottle supplementation. The woman should be counseled that disruption of the breastfeeding pattern or formula supplementation can increase the risk of pregnancy. The typical failure rate is 2% (Kennedy and Trussell, 2011b).

Barrier Methods

Barrier contraceptives have gained in popularity not only as a contraceptive method but also as protection against the spread of STIs such as human papilloma virus and herpes simplex virus (HSV). Some male condoms and female vaginal methods provide a physical barrier to several STIs, and some male condoms provide protection against HIV. Spermicides serve as chemical barriers against semen and inhibit the ability of sperm to fertilize the ovum.

The nurse should remember that any user of a barrier method of contraception must also be aware of emergency contraception (EC) options in case there is a failure of the method. An example of a barrier method failure would be if a condom broke during intercourse. In this instance EC would be indicated to prevent unplanned pregnancy.

Spermicides. **Spermicides** such as nonoxynol-9 (N-9) work by reducing the mobility of the sperm. The chemicals attack the sperm flagella and body, thereby preventing the sperm from reaching the cervical os. N-9, the most commonly used spermicidal chemical in the United States, is a surfactant that destroys the sperm cell membrane. Results from data analyses now suggest that frequent use (more than 2 times a day) of N-9 or the use of N-9 as a lubricant during anal intercourse may increase the transmission of HIV and can cause lesions (Trussell and Guthrie, 2011). There is no evidence that the addition of spermicides to male condoms decreases the risk of subsequent pregnancy. Women with high risk behaviors that increase their likelihood of contracting HIV and other STIs are advised to avoid the use of spermicidal products containing N-9, including lubricated condoms, diaphragms, and cervical caps to which N-9 is added.

Intravaginal spermicides are marketed and sold without prescriptions as aerosol foams, tablets, suppositories, creams, films, and gels (Fig. 5-11). Preloaded, single-dose applicators small enough to be carried in a small purse are available. Effectiveness of spermicides depends on consistent and accurate use. Not more than 1 hour before sexual intercourse, the spermicide should be inserted high into the vagina so it makes contact with the cervix. Spermicide must be reapplied for each additional act of intercourse, even if a barrier method is used. Studies have shown varying effectiveness rates for spermicidal use alone. Typical failure rate in the first year of spermicidal use alone is 29% (Trussell and Guthrie, 2011). Some female barrier methods (e.g., diaphragm, cervical caps) offer more effective protection against pregnancy with the addition of spermicides.

Condoms. The male condom is a thin, stretchable sheath that covers the penis before genital, oral, or anal contact and is removed when the penis is withdrawn from the partner's orifice after ejaculation. Condoms are made of latex rubber, which provides a barrier to sperm and STIs (including HIV); polyurethane (strong, thin plastic); or natural membranes (animal tissue). In addition to providing a physical barrier for sperm, nonspermicidal latex condoms also provide a barrier for STIs (particularly gonorrhea, chlamydia, and trichomonas) and HIV transmission. Condoms lubricated with N-9 are not recommended for preventing STIs or HIV and do not increase protection against pregnancy. Latex condoms break down with oil-based lubricants (e.g., petroleum jelly and suntan oil) and should be used only with water-based or silicone lubricants. Because of the growing number of people with latex allergies, condom manufacturers have begun using polyurethane, which is thinner and stronger than latex.

BOX 5-9 MALE CONDOMS

Mechanism of Action

Sheath is applied over the erect penis before insertion or loss of preejaculatory drops of semen. Used correctly, condoms prevent sperm from entering the cervix. Spermicide-coated condoms cause ejaculated sperm to be immobilized rapidly, thus increasing contraceptive effectiveness.

Failure Rate

- Typical users, 18%
- Correct and consistent users, 2%

Advantages

- Safe
- No side effects
- Readily available
- Premalignant changes in cervix can be prevented or ameliorated in women whose partners use condoms
- Method of male nonsurgical contraception

Disadvantages

- Lovemaking must be interrupted to apply sheath.
- Sensation may be altered.
- If used improperly, spillage of sperm can result in pregnancy.
- Condoms occasionally may tear during intercourse.

Sexually Transmitted Infection Protection

If a condom is used throughout the act of intercourse and there is no unprotected contact with female genitals, a latex rubber condom, which is impermeable to viruses, can act as a protective measure against sexually transmitted infections.

Nursing Considerations

Teach man to do the following:

- Use a new condom (check expiration date) for each act of sexual intercourse or other acts between partners that involve contact with the penis.
- Place the condom after the penis is erect and before intimate contact.
- Place the condom on the head of the penis (A) and unroll it all the way to the base (B).
- Leave an empty space at the tip (A); remove any air remaining in the tip by gently pressing air out toward the base of the penis.
- If a lubricant is desired, use water-based products such as K-Y lubricating jelly. Do not use petroleum-based products because they can cause the condom to break.
- After ejaculation carefully withdraw the still-erect penis from the vagina, holding onto the condom rim; remove and discard the condom.
- Store unused condoms in a cool, dry place.
- Do not use condoms that are sticky, brittle, or obviously damaged.

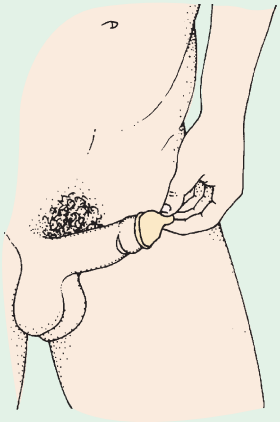

Fig. A

Fig. B

! NURSING ALERT

All patients should be questioned about the potential for latex allergy. Latex condom use is contraindicated for patients with latex sensitivity.

Although polyurethane condoms are as effective for STI prevention as latex condoms, they are more likely to slip or lose contour when compared to latex condoms. Therefore with perfect use latex condoms offer better protection against pregnancy. Polyurethane condoms do offer pregnancy protection equivalent to that of most barrier products. A small percentage of condoms are made from lamb cecum (natural skin). Natural skin condoms do not provide the same protection against STIs and HIV infection as latex condoms. Natural skin condoms contain small pores that could allow passage of viruses such as hepatitis B, HSV, and HIV and are not generally recommended.

A functional difference in condom shape is the presence or absence of a sperm reservoir tip. To enhance vaginal stimulation, some condoms are contoured and rippled or have ribbed or roughened surfaces. Thinner construction increases heat transmission and sensitivity; a variety of colors increases condom acceptability and attractiveness. A wet jelly or dry powder lubricates some condoms. Typical failure rate for the first year of use of the male condom is 18%. Effective condom use is a skill that must be taught.

! NURSING ALERT

It is a false assumption that everyone knows how to use condoms. To prevent unintended pregnancy and the spread of STIs, it is essential for condoms be used correctly. Proper instruction in use must be provided. The sheath is applied over the erect penis before insertion and before the loss of preejaculatory drops of semen (see Box 5-9). All types of condoms must be discarded after each single use. Condoms are available without prescription from a variety of sources, including vending machines.

Box 5-9 summarizes advantages and disadvantages of male condoms.

The female condom is a vaginal sheath made of nitrile, a nonlatex, synthetic rubber and has flexible rings at both ends (Fig. 5-12, *A*). The closed end of the pouch is inserted into the vagina and anchored around the cervix; the open ring covers the labia. A woman

whose partner will not wear a male condom can use this device as a protective mechanical barrier. Rewetting drops or oil- or water-based lubricants can be used to help decrease the distracting noise that is produced while penile thrusting occurs. The female condom is available in one size, is intended for single use only, and is sold over the counter. Male condoms should not be used concurrently because the friction from both sheaths can increase the likelihood of either or both tearing (Female Health Company, 2012). Typical failure rate in the first year of female condom use is 21% (Trussell and Guthrie, 2011).

Diaphragm. The contraceptive **diaphragm** is a shallow, dome-shaped, latex or silicone device with a flexible rim that covers the cervix. The diaphragm is a mechanical barrier to the meeting of sperm with the ovum. By holding spermicide in place against the cervix for the 6 hours it takes to destroy the sperm, the diaphragm also provides a chemical barrier to pregnancy. Diaphragms are available in a wide range of diameters (50 to 95 mm) and differ in the inner construction of the circular rim. The types of rims are coil spring, arcing spring, and wide-seal rim. The diaphragm should be the largest size the woman can wear without being aware of its presence. Typical failure rate of the diaphragm combined with spermicide is 12% in the first year of use (Trussell and Guthrie, 2011).

Nursing Considerations. The woman using a diaphragm needs an annual gynecologic examination to assess its fit (Fritz and Speroff, 2011a). The device may need to be refitted after a 20% weight loss or gain, term birth, or second-trimester miscarriage and after any abdominal or pelvic surgery. Because various types of diaphragms are on the market, the nurse uses the package insert when teaching the woman how to use and care for the diaphragm (see Home Care box).

Disadvantages of diaphragm use include the reluctance of some women to insert and remove it. Although it can be inserted up to 6 hours before intercourse, a cold diaphragm and a cold gel temporarily reduce vaginal response to sexual stimulation if insertion occurs immediately before intercourse. Some women or couples object to the messiness of the spermicide. These annoyances associated with diaphragm use, along with failure to insert the device once foreplay has begun, are the most common reasons for failures of this method. Side effects may include irritation of tissues related to contact with spermicides.

The diaphragm is not a good option for women with poor vaginal muscle tone or recurrent urinary tract infections. For proper placement the diaphragm must rest behind the pubic symphysis and completely cover the cervix. To decrease the chance of exerting urethral pressure, the woman should be reminded to empty her bladder before diaphragm insertion and immediately after intercourse. Diaphragms are contraindicated for women with pelvic relaxation (uterine prolapse) or a large cystocele. Women with a latex allergy should not use latex diaphragms.

Although reported in very small numbers, **toxic shock syndrome (TSS)** can occur in association with the use of the contraceptive diaphragm and cervical caps. The nurse should instruct the woman about ways to reduce her risk for TSS. These measures include prompt removal 6 to 8 hours after intercourse, not using the diaphragm or cervical caps during menses, and learning and watching for danger signs of TSS.

! NURSING ALERT

The nurse should alert the woman who uses a diaphragm or cervical cap as a contraceptive method for signs of TSS. The most common signs include a sunburn type of rash, diarrhea, dizziness, faintness, weakness, sore throat, aching muscles and joints, sudden high fever, and vomiting.

Cervical Cap. The FemCap is the only type of cervical cap available in the United States (see Fig. 5-12, *B*). It comes in three sizes and is made of silicone rubber. The cap fits snugly around the base of the cervix close to the junction of the cervix and vaginal fornices. It is recommended that the cap remain in place no less than 6 hours and no more than 48 hours at a time. It is left in place at least 6 hours after the last act of intercourse. The seal provides a physical barrier to sperm; spermicide inside the cap adds a chemical barrier.

HOME CARE

Use and Care of the Diaphragm

Positions for Insertion of Diaphragm

Squatting

- Squatting is the most commonly used position, and most women find it satisfactory.

Leg-Up Method

- Another position is to raise the left foot (if right hand is used for insertion) on a low stool and, while in a bending position, insert the diaphragm.

Chair Method

- Another practical method for diaphragm insertion is to sit far forward on the edge of a chair.

Reclining

- You may prefer to insert the diaphragm while in a semireclining position in bed.

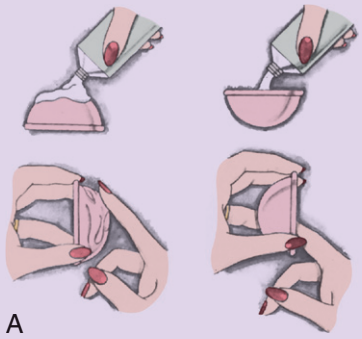
Inspection of Diaphragm

Your diaphragm must be inspected carefully before each use. The best way to do this is:

- Hold the diaphragm up to a light source. Carefully stretch it at the area of the rim, on all sides, to make sure that there are no holes. Remember, it is possible to puncture the diaphragm with sharp fingernails.
- Another way to check for pinholes is to carefully fill the diaphragm with water. If there is any problem, it will be seen immediately.
- If your diaphragm is puckered, especially near the rim, this could mean thin spots.
- The diaphragm should not be used if you see any of these; consult your health care provider.

Preparation of Diaphragm

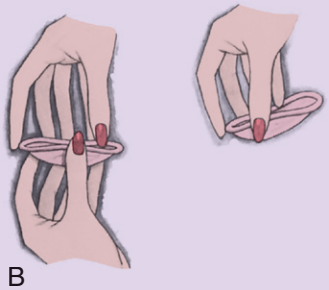
- Rinse off cornstarch. Your diaphragm must always be used with a spermicidal lubricant to be effective. Pregnancy cannot be prevented effectively by the diaphragm alone.
- Always empty your bladder before inserting the diaphragm. Place about 2 tsp of contraceptive jelly or contraceptive cream on the side of the diaphragm that will rest against the cervix (or whichever way you have been instructed). Spread it around to coat the surface and the rim. This aids in insertion and offers a more complete seal. Many women also spread some jelly or cream on the other side of the diaphragm (Fig. A).



A

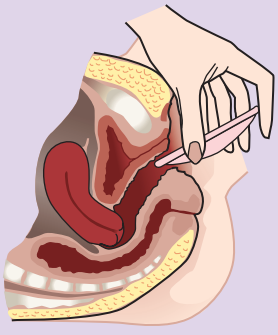
Insertion of Diaphragm

- The diaphragm can be inserted as long as 6 hours before intercourse. Hold it between your thumb and fingers. The dome can be either up or down, as directed by your health care provider. Place your index finger on the outer rim of the compressed diaphragm (Fig. B).



B

- Use the fingers of the other hand to spread the labia (lips of the vagina). This will aid in guiding the diaphragm into place.
- Insert the diaphragm into the vagina. Direct it inward and downward as far as it will go to the space behind and below the cervix (Fig. C).

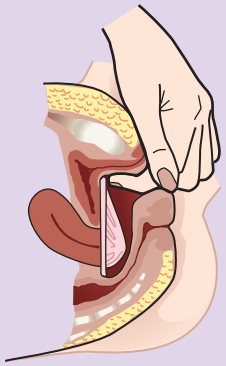


C

HOME CARE

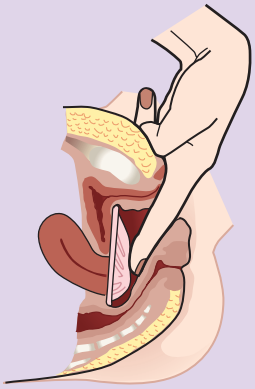
Use and Care of the Diaphragm—cont'd

- Tuck the front of the rim of the diaphragm behind the pubic bone so the rubber hugs the front wall of the vagina (Fig. D).



D

- Feel for your cervix through the diaphragm to be certain that it is placed properly and covered securely by the rubber dome (Fig. E).



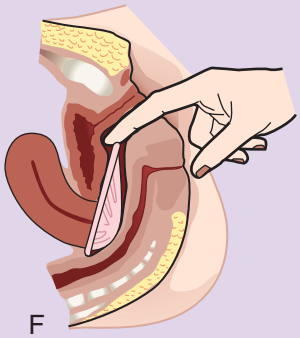
E

General Information

- Regardless of the time of the month, you must use your diaphragm every time intercourse takes place. It must be left in place for at least 6 hours after the last intercourse. If you remove it before the 6-hour period, your chance of becoming pregnant could be greatly increased. If you have repeated acts of intercourse, you must add more spermicide for each act.

Removal of Diaphragm

- The only proper way to remove the diaphragm is to insert your forefinger up and over the top side of the diaphragm and slightly to the side.
- Next turn the palm of your hand downward and backward, hooking the forefinger firmly on top of the inside of the upper rim of the diaphragm, breaking the suction.
- Pull the diaphragm down and out. This avoids the possibility of tearing it with the fingernails. You should not remove it by trying to catch the rim from below the dome (Fig. F).



F

Care of Diaphragm

- When using a vaginal diaphragm, avoid using oil-based products such as certain body lubricants, mineral oil, baby oil, vaginal lubricants, or vaginitis preparations. These products can weaken the rubber.
- A little care means longer wear for your diaphragm. After each use wash it in warm water and mild soap. Do not use detergent soaps, cold-cream soaps, deodorant soaps, and soaps containing oil products because they can weaken the rubber.
- After washing dry the diaphragm thoroughly. All water and moisture should be removed with a towel. Dust the diaphragm with cornstarch. Scented talc, body powder, baby powder, and the like should not be used because they can weaken the rubber.
- To clean the introducer (if one is used), wash with mild soap and warm water, rinse, and dry thoroughly.
- Place the diaphragm back in the plastic case for storage. Do not store it near a radiator or heat source or exposed to light for an extended period.

The extended period of wear may be an added convenience for women.

Instructions for the actual insertion and use of the cervical cap closely resemble the instructions for use of the contraceptive diaphragm. Some of the differences are that the cervical cap can be inserted hours before sexual intercourse without a later need for additional spermicide, the cervical cap requires less spermicide than the diaphragm when initially inserted, and no additional spermicide is required for repeated acts of intercourse. Effectiveness of the first-generation FemCap has been found to be less than that of the diaphragm (Fritz and Speroff, 2011a).

Nursing Considerations. The angle of the uterus, the vaginal muscle tone, and the shape of the cervix may interfere with the ease of fitting and use of the cervical cap. Correct fitting requires time, effort, and skill of both the woman and the clinician, although the FemCap may be easier to fit than previous types of cervical caps.

Because of the potential risk of TSS associated with the use of the cervical cap, another form of birth control is recommended for use during menstrual bleeding and up to at least 6 weeks after birth. The cap should be refitted after any gynecologic surgery or birth and after major weight losses or gains. Otherwise the size should be checked at least once a year.

Women who are not good candidates for wearing the cervical cap include those with abnormal Papanicolaou (Pap) test results, those who cannot be fitted properly with the existing cap sizes or

who find the insertion and removal of the device too difficult, those with a history of TSS or with vaginal or cervical infections, and those who experience allergic responses to the cap or to spermicide.

Contraceptive Sponge. The vaginal sponge is a small, round, polyurethane sponge that contains N-9 spermicide (see Fig. 5-12, *C*). It is designed to fit over the cervix (one size fits all). The side that is placed next to the cervix is concave for better fit. The opposite side has a woven polyester loop to be used for removal of the sponge.

The sponge must be moistened with water before it is inserted into the vagina to cover the cervix. It provides protection for up to 24 hours and for repeated instances of sexual intercourse. It should be left in place for at least 6 hours after the last act of intercourse. Wearing it longer than 24 to 30 hours may put the woman at risk for TSS. Typical failure rate of the vaginal sponge is greater than that of the diaphragm (Fritz and Speroff, 2011a).

Hormonal Methods

Many different hormonal contraception therapies using different delivery methods are available in the United States today. General classes are described in Table 5-3. Because of the wide variety of preparations available, the woman and nurse must read the package insert for information about specific products prescribed. Formulations include combined estrogen-progestin steroidal medications or progestational agents. The formulations are administered orally, transdermally, vaginally, by implantation, or by injection.

Combined Estrogen-Progestin Contraceptives

Oral Contraceptives. The normal menstrual cycle is maintained through hormonal feedback mechanisms. FSH and LH are secreted in response to fluctuating levels of ovarian estrogen and progesterone. Regular ingestion of combined oral contraceptive pills (COCs) suppresses the action of the hypothalamus and anterior pituitary, leading to insufficient secretion of FSH and LH; therefore follicles do not mature, and ovulation is inhibited.

Other contraceptive effects are induced by the combined steroids. Maturation of the endometrium is altered, making the uterine lining a less favorable site for implantation. COCs also have a direct effect on the endometrium; thus from 1 to 4 days after the last COC is taken the endometrium sloughs and bleeds as a result of hormone withdrawal. The withdrawal bleeding is usually less profuse than that of normal menstruation and may last only 2 to 3 days. Some women have no bleeding at all. The cervical mucus remains thick from the effect of the progestin. Cervical mucus under the effect of progesterone does not provide as suitable an environment for sperm penetration as does the thin, watery mucus that the healthy reproductive woman produces before and during ovulation.

Monophasic pills provide fixed dosages of estrogen and progestin. They alter the amount of progestin and sometimes estrogen within each cycle. These preparations reduce the total dosage of hormones in a single cycle without sacrificing contraceptive efficacy. To maintain adequate hormone levels for contraception and enhance compliance, COCs should be taken at the same time each day. Taken exactly as directed, COCs prevent ovulation, and pregnancy cannot occur. The overall theoretic effectiveness rate of COCs is almost 100%.

Because taking the pill does not relate directly to the sexual act, COC acceptability may be increased. Improvement in sexual response may occur once the possibility of pregnancy is not an issue. For many women it is convenient to know when to expect the next menstrual flow.

Contraindications for COC use include a history of thromboembolic disorders, cerebrovascular or coronary artery disease, breast cancer, estrogen-dependent tumors, pregnancy, impaired liver function, liver tumor, lactation less than 6 weeks postpartum, smoking if older than 35 years of age, migraine with aura, surgery with prolonged immobilization or any surgery on the legs, hypertension (160/100), and diabetes mellitus (of more than 20 years' duration) with vascular disease.

The effectiveness of **oral contraceptives** is decreased when the following medications are taken simultaneously:

- Anticonvulsants such as barbiturates, oxcarbazepine, phenytoin, phenobarbital, carbamazepine, primidone, and topiramate
- Systemic antifungals such as griseofulvin
- Antituberculosis drugs such as rifampicin and rifabutin
- Anti-HIV protease inhibitors such as nelfinavir and amprenavir

After discontinuing oral contraception fertility usually returns quickly, but fertility rates may be slightly lower the first 3 to 12 months after discontinuation.

Nursing Considerations. Many different preparations of oral hormonal contraceptives are available. Because of these wide variations in pills, each woman must be clear about the unique dosage regimen for the preparation prescribed for her and follow directions on the package insert. Directions for care after missing one or two tablets also vary. Fig. 5-13 illustrates a standard approach to missed pills. A simpler recommendation is to implement EC after two missed pills, regardless of dose. Signs of potential complications associated with the use of oral contraceptives must be reviewed with the woman, as noted in Box 5-10. Oral contraceptives do not protect a woman against STIs. Male condoms used in combination with COCs provide protection against STIs, and this combination gives excellent protection against unplanned pregnancy.

Transdermal Contraceptive System. The contraceptive patch delivers continuous levels of progesterone and ethynyl estradiol. The patch can be applied to the lower abdomen, upper outer arm, buttock, or upper torso (except the breasts). Application is on the

TABLE 5-3 HORMONAL CONTRACEPTION

COMPOSITION	ROUTE OF ADMINISTRATION	DURATION OF EFFECT
Combination estrogen and progestin (synthetic estrogens and progestins in varying doses and formulations)	Oral	24 hours (extended cycle possible with daily pill for 12 weeks)
	Transdermal patch	7 days
	Vaginal ring insertion	3 weeks
Progestin only		
• Norethindrone, norgestrel	Oral	24 hours
• Medroxyprogesterone acetate	Intramuscular or subcutaneous injection	3 months
• Etonogestrel	Subdermal implant	Up to 3 years
• Levonorgestrel	Intrauterine device	1 year

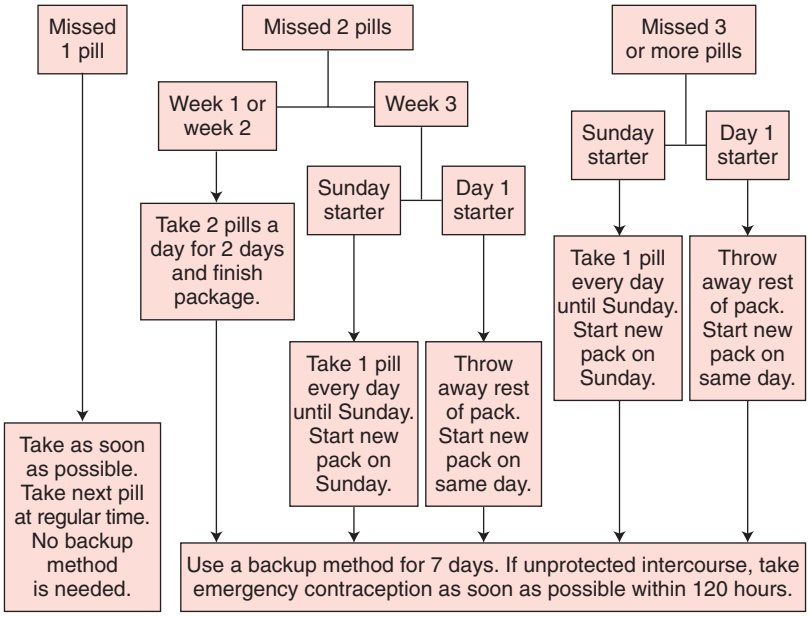


FIG 5-13 Flowchart for missed contraceptive pills. (Courtesy Patsy Huff, PharmD, Chapel Hill, NC.)

BOX 5-10 SIGNS OF POTENTIAL COMPLICATIONS: ORAL CONTRACEPTIVES

Before oral contraceptives are prescribed and periodically throughout hormone therapy, the woman is alerted to stop taking the pill and report immediately any of the following symptoms to the health care provider. The mnemonic ACHES helps in remembering this list:

- A—Abdominal pain: may indicate a problem with the liver or gallbladder
- C—Chest pain or shortness of breath: may indicate possible clot problem within lungs or heart
- H—Headaches (sudden or persistent): may be caused by cardiovascular accident or hypertension
- E—Eye problems: may indicate vascular accident or hypertension
- S—Severe leg pain: may indicate a thromboembolic process

same day once a week for 3 weeks but not at the same site, followed by a week without the patch. Withdrawal bleeding occurs during the "no patch" week. Mechanisms of action, contraindications, and side effects are similar to those of COCs. The typical failure rate during the first year of use is under 2% in women weighing less than 198 lbs.

Vaginal Contraceptive Ring. The **vaginal ring** (made of ethylene vinyl acetate co-polymer) delivers continuous levels of progesterone and ethynyl estradiol. Mechanisms of action, contraindications, and side effects are similar to those of COCs. One vaginal ring is worn for 3 weeks, followed by a week without the ring. Withdrawal bleeding occurs during the "no ring" week. The ring can be inserted by the woman and does not have to be fitted. Some wearers may experience vaginal discomfort, usually related to increased vaginal discharge; but other wearers report that the ring alleviates symptoms of vaginitis. Some couples say that the ring can be felt during intercourse. Although it is not recommended that the ring be removed for intercourse, contraceptive effectiveness would not decrease if it were replaced within 3 hours. The typical failure rate of the vaginal contraceptive ring is under 2% during the first year of use.

Progestin-Only Contraception. **Progestin**-only methods impair fertility by inhibiting ovulation, thickening and decreasing the amount of cervical mucus, thinning the endometrium, and altering cilia in the uterine tubes. Because progestin-only methods do not contain estrogen, they may be used in certain instances such as lactation, when estrogen would not be recommended.

Oral Progestins (Minipill). Progestin-only pills are less effective than COCs. Because minipills contain such a low dose of progestin, they must be taken at the same time every day. If the pill is taken more than 3 hours late (27 hours after the last pill), a backup contraceptive method must be initiated. Much of the contraceptive effectiveness of the minipill depends on progestin-induced changes in cervical mucus, and this effect lasts about 24 hours after oral ingestion of the pill. Users often complain of irregular vaginal bleeding. The failure rate for typical users of the minipill is approximately 8% during the first year of use. Effectiveness is increased if minipills are taken correctly. There are two instances in which the minipill is quite effective: in lactating women and women over 40. The reduced fecundity of lactation and the perimenopause period enhance the contraceptive effects of the minipill.

Injectable Progestins. Depot medroxyprogesterone acetate (DMPA; Depo-Provera) is given subcutaneously or intramuscularly in the deltoid or gluteus maximus muscle. It should be initiated during the first 5 days of the menstrual cycle and administered every 11 to 13 weeks.

! NURSING ALERT

When administering an injection of progestin (e.g., DMPA), the site should not be massaged after the injection because this action can hasten the absorption and shorten the period of effectiveness.

Advantages of DMPA include a contraceptive effectiveness comparable to that of combined oral contraceptives, long-lasting effects, requirement of injections only 4 times a year, and the unlikelihood of lactation being impaired. Side effects at the end of a year include decreased bone mineral density, weight gain, lipid changes, increased risk of venous thrombosis and thromboembolism, irregular vaginal spotting, decreased libido, and breast changes. Other disadvantages include no protection against STIs (including HIV). Return to fertility may be delayed as long as up to 18 months after discontinuing DMPA, with the median time being 10 months. Typical failure rate is 3% in the first year of use.

! NURSING ALERT

Women who use DMPA may lose significant bone mineral density with increasing duration of use. It is unknown if this effect is reversible. It is unknown if use of DMPA during adolescence or early adulthood, a critical period of bone accretion, will reduce peak bone mass and increase the risk of osteoporotic fracture in later life. Women who receive DMPA should be counseled about calcium intake and exercise.

Implantable Progestins. Contraceptive implants consist of one or more nonbiodegradable flexible tubes or rods that are inserted under the skin of a woman's arm. These implants contain a progestin hormone and are effective for contraception for at least 3 years. They must be removed at the end of the recommended time. The FDA has approved two devices for use in the United States, a two-rod subdermal levonorgestrel implant (Jadelle) and a single-rod etonogestrel implant (Implanon, Nexplanon). Jadelle is unavailable in the United States (Raymond, 2011).

Insertion and removal of the single-rod etonogestrel capsule are minor surgical procedures involving a local anesthetic, a small incision, and no sutures. The capsule is placed subdermally in the inner aspect of the nondominant upper arm. The progestin prevents some, but not all, ovulatory cycles and thickens cervical mucus. Other advantages of the single-rod implant are that it provides long-term continuous contraception that is not related to frequency of coitus and is quickly reversible. The single-rod implant can be inserted immediately after the birth in breastfeeding women without affecting lactation. Irregular menstrual bleeding is the most common side effect. Less common side effects include headaches, nervousness, nausea, skin changes, and vertigo. The implant does not protect against STIs. As in other hormonal contraception methods, condoms should be used for protection against STIs. Typical failure rates for the first year of use are 0.05% (Trussell and Guthrie, 2011).

Emergency Contraception

EC offers protection against pregnancy after intercourse occurs in instances such as broken condoms, sexual assault, dislodged cervical cap, disruption of use of any other method, or any other case of unprotected intercourse. Methods that are available in the United States that could provide postcoital contraception include:

- Ella (Ulipristal): single 30-mg pill containing an antiprogestin
- Plan B One-Step: single progestin-only pill containing 1.5 mg levonorgestrel
- Next Choice: two levonorgestrel 0.75-mg tablets taken orally 12 hours apart or both together
- Combined oral: estrogen-progestin contraceptive pills (e.g., 100-mcg ethinyl estradiol plus 0.5 mg levonorgestrel); two doses given 12 hours apart (Yuzpe regimen)
- Copper intrauterine device (IUD) insertion within 120 hours of intercourse

Plan B One-Step and Next Choice are approved by the FDA for over-the-counter sale to women ages 17 and older with proof of age. Adolescents 16 years and under require a prescription. Ella is available only with a prescription. States vary in the ability of pharmacists to dispense EC, and some states have implemented refusal legislation (Guttmacher Institute, 2012b).

In general, for the most effectiveness, EC should be taken by a woman as soon as possible but within 72 hours of unprotected intercourse or a birth control mishap (e.g., broken condom, dislodged ring or cervical cap, missed oral contraceptive pills, late for injection) to prevent unintended pregnancy (Fritz and Speroff, 2011a). Research has shown a moderate amount of effectiveness between 72 and 120 hours but no data are available for effectiveness after 120 hours (Trussell and Schwartz, 2011).

If taken before ovulation, EC prevents ovulation by inhibiting follicular development. If taken after ovulation occurs, there is little effect on ovarian hormone production or the endometrium. To minimize the side effect of nausea that occurs with high doses of estrogen and progestin (Yuzpe regimen), the woman can be advised to take an over-the-counter antiemetic 1 hour before each dose. Nausea is not as common with the Plan B (One-Step, Next Choice) regimen. Women with contraindications for estrogen use should use progestin-only EC. No medical contraindications for EC exist, except pregnancy and undiagnosed abnormal vaginal bleeding (Trussell and Schwarz, 2011).If the woman does not begin menstruation within 21 days after taking the pills, she should be evaluated for pregnancy (Trussell and Schwarz, 2011). EC is ineffective if the woman is pregnant since the pills do not disturb an implanted pregnancy. Risk of pregnancy is reduced by as much as 75% and 89% if the woman takes EC pills (Trussell and Schwarz, 2011).

! NURSING ALERT

EC will not protect the woman against pregnancy if she engages in unprotected intercourse in the days or weeks that follow treatment. Because ingestion of EC pills may delay ovulation, caution the woman that she needs to establish a reliable form of birth control to prevent unintended pregnancy (Trussell and Schwarz, 2011). Information about EC method options and access to providers is available on the Internet at www.NOT-2-LATE.com or by calling 888-NOT-2-LATE.

IUDs containing copper (see later discussion) provide another EC option. The IUD should be inserted within 8 days of unprotected intercourse (Trussell and Schwarz, 2011). This method is suggested only for women who wish to have the benefit of long-term contraception. The risk of pregnancy is reduced by as much as 99% with emergency insertion of the copper-releasing IUD.

Contraceptive counseling should be provided to all women requesting EC, including a discussion of modification of risky sexual behaviors to prevent STIs and unwanted pregnancy.

Intrauterine Devices

An **intrauterine device (IUD)** is a small T-shaped device with bendable arms for insertion through the cervix into the uterine

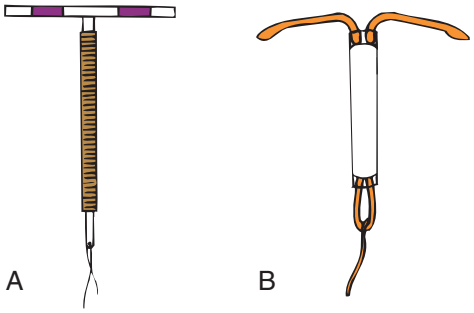

FIG 5-14 Intrauterine devices. **A,** Copper T380A. **B,** Levonorgestrel-releasing intrauterine device.

cavity. Two strings hang from the base of the stem through the cervix and protrude into the vagina for the woman to feel for assurance that the device has not been dislodged (Fig. 5-14). There are two FDA-approved IUDs. The Copper T380A (Paragard) IUD is made of radiopaque polyethylene and fine solid copper and is approved for 10 years of use. The copper primarily serves as a spermicide and inflames the endometrium, preventing fertilization. Sometimes women experience an increase in bleeding and cramping within the first year after insertion, but nonsteroidal antiinflammatory drugs (NSAIDs) can provide pain relief. The typical failure rate in the first year of use of the copper IUD is 0.8% (Dean and Schwarz, 2011).

The levonorgestrel intrauterine system (IUS) (Mirena) releases levonorgestrel from its vertical reservoir. Effective for up to 5 years, it impairs sperm motility, irritates the lining of the uterus, and has some anovulatory effects. Uterine cramping and uterine bleeding are usually decreased with this device, although irregular spotting is common in the first few months following insertion. The typical failure rate in the first year of use is 0.2% (Dean and Schwarz, 2011).

IUDs offer constant contraception without the need to remember to take pills each day or engage in other manipulation before or between coital acts. If pregnancy can be excluded, either device (the Copper T380A or the levonorgestrel intrauterine system) can be placed at any time during the menstrual cycle. These devices may be inserted immediately after childbirth or following a first-trimester abortion. The contraceptive effects are reversible. When pregnancy is desired, the health care provider removes the device.

Disadvantages of IUD use include increased risk of pelvic inflammatory disease within the first 20 days after insertion, especially if infection is present at the time of insertion. There is also a slight risk of uterine perforation. Neither the Copper T380A nor the levonorgestrel intrauterine system offers protection against STIs or HIV. The Copper T380A is more likely to be associated with regular menses that may have heavier flow. Women who have the levonorgestrel intrauterine system are more likely to experience scant, irregular episodes of vaginal bleeding or amenorrhea.

Nursing Considerations. The woman should be taught to check for the presence of the IUD thread after menstruation to rule out expulsion of the device. If pregnancy occurs with the IUD in place, the IUD should be removed immediately in the first trimester if the strings are visible. Later in pregnancy ultrasound examination should be used to localize the IUD and rule out placenta previa. Retention of the IUD during pregnancy increases the risk of septic miscarriage and ectopic pregnancy. Some women allergic to copper develop a rash, necessitating removal of the copper-bearing IUD. Signs of potential complications of intrauterine contraception are listed in Box 5-11.

BOX 5-11 SIGNS OF POTENTIAL COMPLICATIONS: INTRAUTERINE DEVICES

Signs of potential complications related to intrauterine devices can be remembered using the *pains* mnemonic:

- P Period late, abnormal spotting or bleeding
- A Abdominal pain, pain with intercourse
- I Infection exposure, abnormal vaginal discharge
- N Not feeling well, fever, or chills
- S String missing: shorter or longer

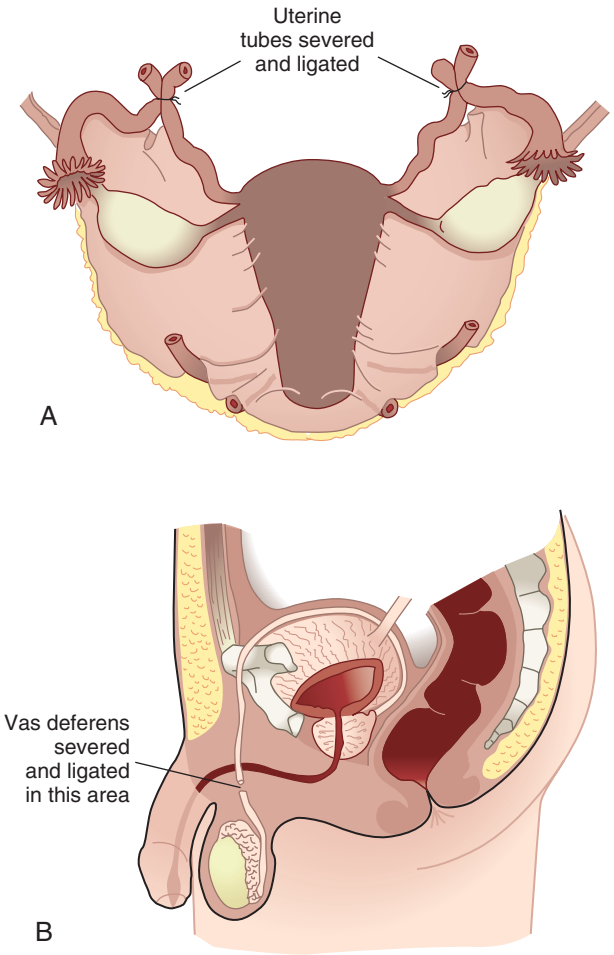

FIG 5-15 Sterilization. **A,** Uterine tubes ligated and severed (tubal ligation). **B,** Sperm duct ligated and severed (vasectomy).

Sterilization

Sterilization refers to surgical procedures intended to render the person infertile. Most procedures involve the occlusion of the passageways for the ova and sperm (Fig. 5-15). For the woman the oviducts (uterine tubes) are occluded; for the man the sperm ducts (vas deferens) are occluded. Only surgical removal of the

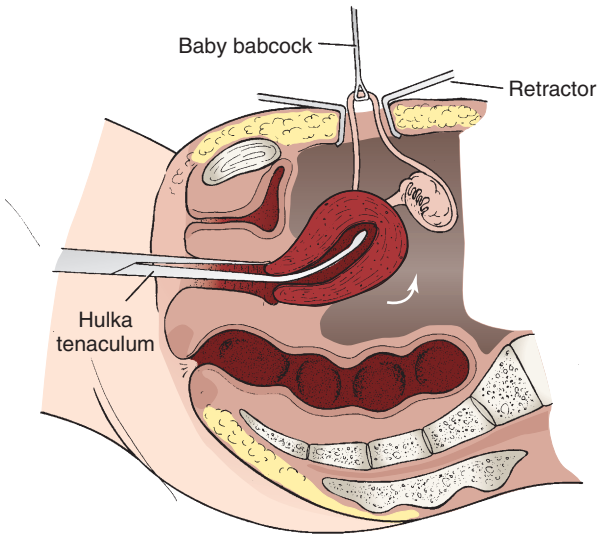

FIG 5-16 Use of minilaparotomy to gain access to uterine tubes for occlusion procedures. Tenaculum is used to lift uterus upward *(arrow)* toward incision.

PATIENT TEACHING

What To Expect After Tubal Ligation

- You should expect no change in hormones and their influence.
- Your menstrual period will be about the same as before the sterilization.
- You may feel pain at ovulation.
- The ovum disintegrates within the abdominal cavity.
- It is highly unlikely that you will become pregnant.
- You should not have a change in sexual functioning; you may enjoy sexual relations more because you will not be concerned about becoming pregnant.
- Sterilization offers no protection against sexually transmitted infections. Therefore you may need to use condoms.

ovaries (oophorectomy) or uterus (hysterectomy) or both results in absolute **sterility** for the woman. All other sterilization procedures have a small but definite failure rate (i.e., pregnancy may result).

Female Sterilization. Female sterilization (bilateral **tubal ligation**) may be done immediately after giving birth (within 24 to 48 hours), concomitantly with abortion, or as an interval procedure (during any phase of the menstrual cycle). Half of all female sterilization procedures are performed immediately after a pregnancy. Sterilization procedures can be done safely on an outpatient basis. Failure rate for methods of female sterilization vary by the method and the woman's age, but the average is 0.5% (Roncari and Hou, 2011).

Tubal Occlusion. A laparoscopic approach or a minilaparotomy may be used for tubal ligation (Fig. 5-16), tubal electrocoagulation, or the application of bands or clips. Electrocoagulation and ligation are considered to be permanent methods. Use of the bands or clips has the theoretic advantage of possible removal and return of tubal patency (see Patient Teaching box).

Tubal Reconstruction. Restoration of tubal continuity (reanastomosis) and function is technically feasible except after laparoscopic tubal electrocoagulation. Sterilization reversal is costly, difficult (requiring microsurgery), and uncertain. The success rate varies with the extent of tubal destruction and removal. The risk of ectopic pregnancy after tubal reanastomosis is increased by 2% to 12.5%.

Laws and Regulations. All states have strict regulations for informed consent. Many states permit voluntary sterilization of any mature, rational woman without reference to her marital or pregnancy status. Although the partner's consent is not required by law, the woman is encouraged to discuss the situation with her partner, and health care providers may request the partner's consent. Sterilization of minors or mentally incompetent individuals is restricted by most states and often requires the approval of a board of eugenicists or other court-appointed individuals.

LEGAL TIP: Sterilization

If federal funds are used for sterilization, the person must be at least 21 years of age. Informed consent must include an explanation of the risks, benefits, and alternatives; a statement that describes sterilization as a permanent, irreversible method of birth control; and a statement that mandates a 30-day waiting period between giving consent and the sterilization. Informed consent must be in the person's native language, or an interpreter must be provided to read the consent form to the person.

Male Sterilization. **Vasectomy** is the sealing, tying, or cutting of a man's vas deferens so the sperm cannot travel from the testes to the penis. Vasectomy is the easiest and most commonly used operation for male sterilization. The surgery can be performed with local anesthesia on an outpatient basis. Pain, bleeding, infection, and other postsurgical complications are considered to be possible disadvantages to the surgical procedure.

Two methods are used for scrotal entry: conventional and no-scalpel vasectomy. The surgeon identifies and immobilizes the vas deferens through the scrotum. Then the vas is ligated or cauterized (see Fig. 5-15, *B*). Surgeons vary in their techniques to occlude the vas deferens: ligation with sutures, division, cautery, application of clips, excision of a segment of the vas, fascial interposition, or some combination of these methods.

Vasectomy has no effect on potency (ability to achieve and maintain erection) or volume of ejaculate. Endocrine production of testosterone continues so secondary sex characteristics are not affected. Sperm production continues, but sperm are unable to leave the epididymis and are lysed by the immune system. Vasectomy does not change the man's transmission of the HIV virus if he is infected. He will need to be instructed to engage in a number of ejaculations until there are no viable sperm remaining above the area of the surgery. Until this occurs, as documented by semen analysis, the couple should use back-up contraception.

Complications after bilateral vasectomy are uncommon and usually not serious. They include bleeding (usually external), suture reaction, and reaction to the anesthetic agent. Men occasionally develop a hematoma, infection, or epididymitis. Less common are painful granulomas from accumulation of sperm. The failure rate for male sterilization is 0.15% (Roncari and Hou, 2011).

Tubal Reconstruction. Microsurgery to reanastomose (restore tubal continuity) the sperm ducts can be accomplished successfully (i.e., sperm in the ejaculate) in more than 90% of cases; however, the fertility rate following reanastomosis is only about 50%. The rate of success decreases as the time since the procedure was initially performed increases. The vasectomy may result in permanent changes in the testes that leave men unable to father children. The changes are those ordinarily seen only in the elderly (e.g., interstitial fibrosis [scar tissue between the seminiferous tubules]). In addition some men develop antibodies against their own sperm (autoimmunization).

Nursing Considerations. The nurse plays an important role in helping people make decisions so all requirements for informed consent are met. The nurse also provides information about alternatives to sterilization such as contraception.

Information must be given about what is entailed in the various procedures, how much discomfort or pain can be expected, and what type of care is needed. Many individuals fear sterilization procedures because of imagined effects on sexual functioning. They need reassurance concerning the hormonal and psychologic basis of sexual functioning. The fact that uterine tube occlusion or vasectomy has no biologic sequelae in terms of sexual adequacy needs to be communicated and reinforced.

Preoperative care includes health assessment, which includes a psychologic assessment, physical examination, and laboratory tests. The nurse confirms that the individual understands printed instructions. Ambivalence and extreme fear of the procedure should be reported to the physician.

Postoperative care depends on the procedure performed (e.g., laparoscopy, laparotomy for tubal occlusion, or vasectomy). General care includes recovery after anesthesia, vital signs, fluid-electrolyte balance (intake and output, laboratory values), prevention of or early identification and treatment of infection or hemorrhage, control of discomfort, and assessment of emotional response to the procedure and recovery.

Discharge planning depends on the type of procedure performed. In general the patient is given written instructions about observing for and reporting symptoms and signs of complications, the type of recovery to be expected, and the date and time for a follow-up appointment.

ABORTION

Induced abortion is the purposeful interruption of a pregnancy before 20 weeks of gestation. (Spontaneous abortion or miscarriage is discussed in Chapter 12.) If the abortion is performed at the woman's request, the term **elective abortion** is usually used; if performed for reasons of maternal or fetal health or disease, the term **therapeutic abortion** applies. Many factors contribute to a woman's decision to have an abortion. Indications include (1) preservation of the life or health of the mother, (2) genetic disorders of the fetus, (3) rape or incest, and (4) the pregnant woman's request. The control of birth, dealing as it does with human sexuality and the question of life and death, is one of the most emotional components of health care. It has been the most controversial social issue in the last half of the twentieth century and continues to be so today. Regulations exist to protect the mother from the complications of abortion.

Abortion is regulated in most countries, including the United States. Before 1970 legal abortion was not widely available in the United States. However, in January 1973 the U.S. Supreme Court set aside previous antiabortion laws and legalized it. This decision established a trimester approach to abortion.

Following the U.S. Supreme Court ruling in 1973 in the case of Roe versus Wade, the decision of first-trimester abortion was deemed to be between the pregnant woman and her health care provider, and state laws determining abortion to be illegal were struck down. During the second trimester abortion is left to the discretion of the individual states to regulate procedures as long as these regulations are reasonably related to the woman's health. In the third trimester abortions may be limited or even prohibited by state regulation unless the restriction interferes with the life or health of the pregnant woman (*Roe v. Wade*, 1973). Hospitals maintained by Roman Catholics and some of those maintained by strict fundamentalists forbid abortion (and often sterilization) despite legal challenges.

Currently 39 states legislate that abortion be performed by a licensed physician. Nurse practitioners can perform abortions (if the practice is within their scope of practice) in the states of California, Montana, Vermont, New Hampshire, and Rhode Island. Congress has legislated that Medicaid funds can only be used to pay for abortion when a woman's life is endangered. States vary on the financing of abortions, with 17 states using their own funds to pay for them, depending on the circumstances surrounding the procedure. States also vary regarding parental notification and/or consent regarding abortion, with 37 states providing legislation for some type of parental involvement in the abortion of a pregnant daughter who is a minor. Individual health care providers may refuse to participate in abortion in 46 states (Guttmacher Institute, 2012a).

In 2008 in the United States there were approximately 6.5 million pregnancies, and approximately 19% of these pregnancies ended in termination (Sedgh, Singh, Shah, et al., 2012). The number of abortions in the United States has decreased from 1.31 million in 2000 to 1.21 million in 2008 (Guttmacher Institute, 2012a). Most terminations were performed in women who were unmarried (84%). Non-Hispanic Caucasian women comprised 36% of those who experienced elective abortion. Non-Hispanic African-American women comprised 30% of those who experienced elective abortions, Hispanic women accounted for 25% of elective abortions, and women of other races accounted for 9% of abortions (Guttmacher Institute, 2012a). Most abortions occur in women who already have children, and abortion rates tend to be higher in women whose income is below the poverty level.

The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, 2009) supports a nurse's right to choose whether to participate in abortion procedures in keeping with her or his "personal, moral, ethical, or religious beliefs." AWHONN also advocates that "nurses have a professional obligation to inform their employers, at the time of employment, of any attitudes and beliefs that may interfere with essential job functions."

Rates of biologic complications after abortions such as ectopic pregnancy, infection, or hemorrhage tend to be low if the woman aborts during the first trimester. Psychologic sequelae of induced abortion are uncommon and may be related to circumstances and support systems surrounding the pregnant woman such as the attitudes reflected by friends, family, and health care workers. The woman facing an abortion is pregnant and exhibits the emotional responses shared by all pregnant women, including the possibility of depression.

Nurses and other health care providers often struggle with the same values and moral convictions as those of the pregnant woman.

BOX 5-12 SELECTED NURSING DIAGNOSES FOR WOMEN HAVING ELECTIVE ABORTION

- Decisional conflict related to
  - Value system
- Fear related to
  - Abortion procedure
  - Potential complications
  - Implications for future pregnancies
  - What others might think
- Grieving related to
  - Distress at loss or feelings of guilt
- Risk for infection related to
  - Effects of the procedure
  - Lack of understanding of preoperative and postoperative self-care
- Acute pain related to
  - Effects of the procedure or postoperative events

The conflicts and doubts of the nurse can be readily communicated to women who are already anxious. Regardless of personal views on abortion, nurses who provide care to women seeking abortion have an ethical responsibility to counsel women about their options and make appropriate referrals.

LEGAL TIP: Institutional Policies for Nurses' Rights and Responsibilities Related to Abortion

Nurses' rights and responsibilities related to caring for abortion patients should be protected through policies that describe how the institution accommodates the nurse's ethical or moral beliefs and what the nurse should do to avoid patient abandonment in such situations. Nurses should know what policies are in place in their institutions and encourage such policies to be written.

CARE MANAGEMENT

A thorough assessment is conducted through history, physical examination, and laboratory tests. The length of pregnancy and the condition of the woman must be determined to select the appropriate type of abortion procedure. An ultrasound examination should be performed before a second-trimester abortion is done. If the woman is Rh-negative, she is a candidate for prophylaxis against Rh isoimmunization. She should receive Rh_o(D) immune globulin within 72 hours after the abortion if she is D-negative and if Coombs' test results are negative (if the woman is unsensitized or isoimmunization has not developed).

The woman's understanding of alternatives, the types of abortions, and expected recovery is assessed. Misinformation and gaps in knowledge are identified and corrected. The record is reviewed for the signed informed consent, and the woman's understanding is verified. General preoperative, operative, and postoperative assessments are performed.

Analysis of data leads to identification of the appropriate nursing diagnoses for the woman undergoing elective abortion. Potential nursing diagnoses are listed in Box 5-12. Counseling about abortion includes helping the woman identify how she perceives the pregnancy, providing information about the choices available (i.e., having an abortion or carrying the pregnancy to term and then either keeping the infant or placing the baby for adoption), and informing about the types of abortion procedures (see Critical Thinking Case Study).

CRITICAL THINKING CASE STUDY

Termination of Pregnancy

Angelica is a 19-year-old single woman whose contraceptive failed. She is 6 weeks' pregnant and is seeking termination of the pregnancy. She has many questions for the nurse in the family planning clinic: Which procedure is most likely to be chosen at this gestation? What are the risks associated with the procedure? Should her boyfriend be involved in the decision to terminate the pregnancy?

1. Evidence—Is there sufficient evidence to draw conclusions about what information the nurse should provide Angelica?
2. Assumptions—What assumptions can be made about Angelica's reaction to termination of the pregnancy?
   a. Psychologic/emotional reaction and sequelae
   b. Physical response
   c. Future childbearing
   d. Relationship with her boyfriend
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

First-Trimester Abortion

Methods for performing early elective abortion (less than 9 weeks of gestation) include surgical (aspiration) and medical methods (mifepristone with prostaglandin and methotrexate with misoprostol). About 90% of abortions in the United States are performed during the first trimester, with more than 60% performed by 8 weeks after the last menstrual period (Paul and Stein, 2011).

Surgical (Aspiration) Abortion

Aspiration (vacuum or suction curettage) is the most common procedure in the first trimester. Aspiration abortion is usually performed under local anesthesia in a physician's office, a clinic, or a hospital. The ideal time for performing this procedure is 8 to 12 weeks after the last menstrual period. The suction procedure for performing an early elective abortion usually requires less than 5 minutes.

A bimanual examination is done before the procedure to assess uterine size and position. A speculum is inserted, and the cervix is anesthetized with a local anesthetic agent. The cervix is dilated if necessary, and a cannula connected to suction is inserted into the uterine cavity. The products of conception are evacuated from the uterus.

During the procedure the woman is kept informed about what to expect next (e.g., menstrual-like cramping and sounds of the suction machine). The nurse assesses the woman's vital signs. The aspirated uterine contents must be inspected carefully to ascertain whether all fetal parts and adequate placental tissue have been evacuated. After the abortion the woman rests on the table until she is ready to stand. She remains in the recovery area or waiting room for 1 to 3 hours for detection of excessive cramping or bleeding; then she is discharged.

Bleeding after the operation is normally about the equivalent of a heavy menstrual period, and cramps are rarely severe. Excessive

vaginal bleeding and infection such as endometritis or salpingitis are the most common complications of induced abortion. Retained products of conception are the primary cause of vaginal bleeding. Evacuation of the uterus, uterine massage, and administration of oxytocin or methylergonovine (Methergine) may be necessary to decrease vaginal bleeding (Paul and Stein, 2011). Prophylactic antibiotics to decrease the risk of infection are commonly prescribed. Generally postabortion pain can be relieved with NSAIDs such as ibuprofen.

Nursing Interventions. Instructions following a surgical abortion differ among health care providers (e.g., tampons should not be used for at least 3 days or should be avoided for up to 3 weeks, and resumption of sexual intercourse may be permitted within 1 week or discouraged for 2 weeks). The woman may shower daily. Instruction is given to watch for excessive bleeding and other signs of complications and to avoid douches of any type. The woman can expect her menstrual period to resume 4 to 6 weeks after the day of the procedure. The nurse offers information about the birth control method the woman prefers if contraceptive counseling has not been done during the counseling interview that usually precedes the decision to have an abortion. The woman must be strongly encouraged to return for her follow-up visit so complications can be detected and an acceptable contraceptive method prescribed. A pregnancy test may also be performed to determine if the pregnancy has been terminated successfully.

SAFETY ALERT

The woman who has an induced abortion should be given clear instructions to return immediately to the health care facility or emergency department for any of the following symptoms:

- Fever greater than 38° C (100.4° F)
- Chills
- Bleeding greater than two saturated pads in 2 hours or heavy bleeding lasting a few days
- Foul-smelling vaginal discharge
- Severe abdominal pain, cramping, or backache
- Abdominal tenderness (when pressure applied)

Source: Paul M, Stein T: Abortion. In Hatcher RA, Trussell J, Nelson AL, editors: *Contraceptive technology*, ed 20, Atlanta 2011, Ardent Media.

Medical Abortion

Early abortion using medication rather than surgery has been popular in Canada and Europe for more than 15 years, but medical abortion is a relatively new procedure in the United States. Medical abortions are available for use in the United States for up to 9 weeks after the last menstrual period. Methotrexate, misoprostol, and mifepristone are the drugs used in the current regimens to induce early abortion. About 17% of all reported abortion procedures in 2008 were medical procedures (Guttmacher Institute, 2012a).

Methotrexate is a cytotoxic drug that causes early abortion by blocking folic acid in fetal cells so they cannot divide. Misoprostol (Cytotec) is a prostaglandin analog that acts directly on the cervix to soften and dilate and on the uterine muscle to stimulate contractions. Mifepristone, formerly known as RU 486, was approved by the FDA in 2000. It works by binding to progesterone receptors and blocking the action of progesterone, which is necessary for maintaining pregnancy (Paul and Stein, 2011).

Methotrexate and Misoprostol. Methotrexate can be given intramuscularly or orally (usually mixed with orange juice). Vaginal placement of misoprostol follows in 3 to 7 days. Women commonly have nausea, vomiting, and cramping after the misoprostol insertion. The woman returns for a follow-up visit to confirm the abortion is complete. If abortion does not occur, misoprostol is repeated, or **vacuum aspiration** is performed to remove the products of conception (Paul and Stein, 2011).

Mifepristone and Misoprostol. Mifepristone can be taken up to 7 weeks after the last menstrual period. The FDA-approved regimen is that the woman takes 600 mg of mifepristone orally; 48 hours later she returns to the office and takes 400 mcg of misoprostol orally (unless abortion has already occurred and been confirmed). Two weeks after the administration of mifepristone, the woman must return to the office for a clinical examination or ultrasound to confirm that the pregnancy has been terminated. In 1% to 5% of cases the drugs do not work, and surgical abortion (aspiration) is needed (Paul and Stein, 2011).

With any medical abortion regimen, the woman usually experiences bleeding and cramping. Side effects of the medications include nausea, vomiting, diarrhea, headache, dizziness, fever, and chills. These are attributed to misoprostol and usually subside in a few hours after administration (Paul and Stein, 2011).

Second-Trimester Abortion

Because the great majority of induced abortions in the United States occur in the first trimester, only about 10% are performed in the second trimester. Second-trimester abortion is associated with more complications and costs than first-trimester abortions. Dilation and evacuation (D&E) accounts for almost all procedures performed in the United States. In general medical administration of second-trimester abortions involves the same drugs (misoprostol and mifepristone) used in medical termination of pregnancy during the first trimester. The D&E procedure is generally preferred by patients because it is less expensive and better tolerated than medical abortion during the second trimester (Fritz and Speroff, 2011b).

Dilation and Evacuation

D&E can be performed at any point up to 20 weeks of gestation, although it is more often performed between 13 and 16 weeks (Paul and Stein, 2011). The cervix requires more dilation because the products of conception are larger. Often laminaria are inserted several hours or several days before the procedure, or misoprostol can be applied to the cervix to soften the tissue. The procedure is similar to that of vaginal aspiration, except that a larger cannula is used and other instruments may be needed to remove the fetus and placenta. Nursing care includes monitoring vital signs, providing emotional support, administering analgesics, and postoperative monitoring. Disadvantages of D&E include possible long-term harmful effects on the cervix.

Nursing Considerations

The woman considering an abortion will need help to explore the meaning of the various alternatives for elective abortion and consequences to herself and her significant others. It is often difficult for a woman to express her true feelings (e.g., what abortion means to her now and in the future and what support or regret her friends and peers may demonstrate). A calm, matter-of-fact approach on the part of the nurse can be helpful. Clarifying, restating, and reflecting statements; open-ended questions; and feedback are

communication techniques that can be used to maintain a realistic focus on the situation and bring the woman's problems into the open. If family or friends cannot be involved, scheduling time for nursing personnel to give the necessary support is an essential component of the care plan.

Information about alternatives to abortion such as referral to adoption agencies or support services if the woman chooses to keep her baby is provided. If a decision is made to have an abortion, the woman must be assured of continued support. Information about what is entailed in various procedures, how much discomfort or pain can be expected, and what type of care is needed must be given. A discussion of the various feelings, including depression, guilt, regret, and relief, that the woman might experience after the abortion is needed. Information about community resources for postabortion counseling may be needed.

After the abortion studies have indicated that most women report relief, but some have temporary distress or mixed emotions. Evidence of long-term depression after elective abortion has been inconclusive. Guilt and anxiety may occur more with young women, women with poor social support, multiparous women, and women with a history of psychiatric illness. Women having second-trimester abortions may have more emotional distress than women having abortions in the first trimester. Because symptoms can vary among women who have had abortions, nurses must assess women for grief reactions and facilitate the grieving process through active listening and nonjudgmental support and care.

KEY POINTS

- Infertility is the inability to conceive and carry a fetus to term gestation at a time the couple has chosen to do so.
- Infertility increases in women older than 35 years of age.
- In the United States about 40% of infertility is related to female causes, 40% is related to male causes, and 20% of infertility causes are unexplained.
- Common etiologic factors associated with infertility include decreased sperm production, ovulation disorders, tubal occlusion, and endometriosis.
- Reproductive alternatives for family building include IVF-ET, GIFT, ZIFT, oocyte donation, embryo donation, TDI, surrogate motherhood, and adoption.
- A variety of contraceptive methods with various effectiveness rates, advantages, and disadvantages are available.
- Women and their partners should choose the contraceptive method(s) best suited to them.
- Effective contraceptives are available through both prescription and nonprescription sources.
- Proper use of latex condoms provides protection against STIs.
- Tubal ligations and vasectomies are permanent sterilization methods used by increasing numbers of women and men.
- Emergency contraception pills should be taken as soon as possible after unprotected intercourse but no later than 120 hours.
- Induced abortion performed in the first trimester is safer and less complex than an abortion performed in the second trimester.
- The most common complications of induced abortion include infection, retained products of conception, and excessive vaginal bleeding.

CHAPTER

6

Genetics, Conception, and Fetal Development

Shannon E. Perry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Explain the key concepts of basic human genetics.
- Explore how recent advances in genetics have changed the field of health care.
- Discuss key findings and the ethical, legal, and social implications of the Human Genome Project.
- Describe expanded roles for nurses in genetics and genetic counseling.
- Identify genetic disorders commonly tested for in maternity and newborn nursing.
- Discuss the current status of gene therapy.
- Summarize the process of fertilization.
- Describe the development, structure, and functions of the placenta.
- Describe the composition and functions of the amniotic fluid.
- Identify three organs or tissues arising from each of the three primary germ layers.
- Summarize the significant changes in growth and development of the embryo and fetus.
- Identify the potential effects of teratogens during vulnerable periods of embryonic and fetal development.

This chapter presents a brief discussion of genetics and the role of the nurse in genetics. It also provides an overview of the process of fertilization and of the development of the normal embryo and fetus.

GENETICS

Recent advances in molecular biology and genomics have revolutionized the field of health care by providing the tools needed to determine the hereditary component of many diseases as well as improve our ability to predict susceptibility to disease, onset and progression of disease, and response to medications (Guttmacher, McGuire, Ponder, et al., 2010). This increase in genetic knowledge has resulted in a gradual shift from genetics to genomics. Genetics is the study of individual genes and their effect on relatively rare single-gene disorders, whereas genomics is the study of all the genes in the human genome together, including their interactions with each other, the environment, and the influence of other psychosocial factors and cultural factors. Genes are basic physical units of inheritance that are passed from parents to offspring and contain the information needed to specify traits. The genome is the entire set of genetic instructions found in each cell. For these and other definitions of genetic terms, visit the *Talking Glossary of Genetic Terms* (www.genome.gov/Glossary).

Genetic services are rapidly becoming an integral part of routine health care as a result of:

- Growing public interest in personalized genomic information (information about much or all of a person's genome)
- Increasing development of practice guidelines
- Mounting commercial pressures
- Ever-increasing opportunities for individuals, families, and communities to participate in the direction and design of their genomic health care (Guttmacher, McGuire, Ponder, et al., 2010)

Moreover, many individuals and families have participated in direct-to-consumer genetic testing (testing marketed directly to consumers through television, print advertisements, and websites for companies such as DNA Direct [www.dnadirect.com/web], 23 and Me [www.23andme.com], and DeCODEme [www.decodeme.com]). Although much of the information provided by direct-to-consumer testing companies is recreational (e.g., ancestry information, information about type of ear wax, bitter taste perception), some of it is health related and could be interpreted as diagnosis (Evans and Green, 2009). Because of this, direct-to-consumer testing that is provided without the involvement of competent health care professionals may be not only unhelpful but even harmful (Guttmacher, McGuire, Ponder, et al., 2010; McGuire and Burke, 2010).

Genetic disorders affect people of all ages, from all socioeconomic levels, and from all racial and ethnic backgrounds. Genetic disorders affect not only individuals but also families, communities, and society. Advances in genetic testing and genetically based treatments have altered the care provided to affected individuals. Improvements in diagnostic capability have resulted in earlier diagnosis and enabled individuals who previously would have died in childhood to survive into adulthood. However, for most genetic conditions, therapeutic or preventive measures do not exist or are very limited. Consequently, the most useful means of reducing the incidence of these disorders is by preventing their transmission. It is standard practice to assess all pregnant women for heritable disorders to identify potential problems.

Nursing Expertise in Genetics and Genomics

Genetic disorders span every clinical practice specialty and site, including schools, clinics, offices, hospitals, mental health agencies, and community health settings. Because the potential impact on families and the community is significant, genetic information, technology, and testing must be incorporated into health care services. Genetics must be integrated into nursing education and practice.

Expanded roles for nurses with expertise in genetics and genomics are developing in many areas of maternity and women's health nursing. These areas include but are not limited to:

- Preconception counseling and testing
- Neonatal genetic screening and testing
- Palliative care for infants with life-threatening genetic conditions and their families
- The identification and care of individuals with genetic conditions and their families
- The care of women with genetic conditions who require specialized care during pregnancy, such as women with congenital heart disease, cystic fibrosis, and factor V Leiden.

Essential Competencies in Genetics and Genomics for All Nurses

Nearly 50 organizations, including the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN) and the National Association of Neonatal Nurses (NANN), have endorsed the *Essentials of Genetic and Genomic Nursing: Competencies, Curricula Guidelines, and Outcome Indicators* (ed 2) (Consensus Panel on Genetic/Genomic Nursing Competencies, 2009). The competencies in the document reflect the minimum amount of genetic and genomic competency expected of all nurses. The competencies are not intended to replace or recreate current standards of practice. The document is available at www.genome.gov/Pages/Careers/HealthProfessionalEducation/geneticscompetency.pdf. Some of the competencies most relevant to nurses in maternity nursing include:

- Constructs a pedigree from collected family history information using standardized symbols and terminology
- Develops a plan of care that incorporates genetic and genomic assessment information
- Provides patients with credible, accurate, appropriate, and current genetic and genomic information, resources, services, and/or technologies that facilitate decision making
- Recognizes when one's own attitudes and values related to genetic and genomic science may affect care provided to patients
- Facilitates referrals for specialized genetic and genomic services for patients as needed
- Evaluates impact and effectiveness of genetic and genomic technology, information, interventions, and treatments on patients' outcome

Human Genome Project and Implications for Clinical Practice

The Human Genome Project was a publicly funded international effort coordinated by the National Institutes of Health (NIH) and the U.S. Department of Energy (www.doegenomes.org). When the Human Genome Project was initiated in 1990, the ultimate goal of the project was to map the **human genome** (the complete set of genetic instructions in the nucleus of each human cell) by 2005. Considering that the human genome consists of approximately 3 billion base pairs of DNA, many people regarded this as an impossible task. However, by 2003 a substantially complete version of the human genome was announced.

Two key findings from the Human Genome Project were that (1) all human beings are 99.9% identical at the DNA level and (2) there are approximately 20,500 genes in the human genome. The finding that human beings are 99.9% identical at the DNA level should help discourage the use of science as a justification for drawing precise racial boundaries around certain groups of people. Originally scientists had estimated that there were 50,000 to 140,000 genes in the human genome.

A more recent effort by the National Human Genome Research Institute (NHGRI) called the **Enc**yclopedia of **D**NA **E**lements, or ENCODE, was organized to identify the genome's functional elements. By 2012 researchers "linked more than 80% of the human genome sequence to a specific biological function and mapped more than 4 million regulatory regions where proteins specifically interact with the DNA" (ENCODE, 2012). This made clearer the active genome in which genes are turned on and off by proteins using sites that may be at a great distance from the genes. Identification of regulatory regions will help explain different functions of different types of cells (www.genome.gov/pfv.cfm?pageID=27549810).

Importance of Family History

Completion of the Human Genome Project and the resultant identification of the inherited causes for many diseases have created a renewed interest in family history. Although it is easy to be impressed by the 1900 genetic tests currently available, family history will most likely continue to be the single most cost-effective piece of genetic information. A complete three-generation family history that includes ethnicity information concerning both sides of the family is the best genetic "test" applicable to preconception care. When nurses and other clinicians conduct a family history, they can gain not only valuable information about the structure of the family and diseases that affect various individuals in the family but also a rich understanding of family relationships, social context, occupations, lifestyle, and health habits. The process of collecting this information often facilitates the development of a relationship between the patient/family and the clinician. In 2004 the United States Department of Health and Human Services (USDHHS) launched the Family History Initiative by designating Thanksgiving Day as National Family History Day. The U.S. Surgeon General encouraged families to use their family gatherings as a time to talk about and collect important family health history. A number of family history tools are available free of charge online. One of the most widely used is the *My Family Health Portrait* (https://familyhistory.hhs.gov). Another family health history tool—*Does it run in the family?*—was developed by the Genetic Alliance (www.doesitruninthefamily.org).

Gene Identification and Testing

Initial efforts to sequence and analyze the human genome have proven invaluable in the identification of genes involved in disease and in the development of genetic tests. Hundreds of genes involved in diseases such as breast cancer, colorectal cancer, Alzheimer's disease, and cystic fibrosis (CF) have been identified. The number of commercially available genetic tests continues to increase and can be found on GeneTests, a publicly funded genetics information resource for clinicians (www.ncbi.nlm.nih.gov/sites/GeneTests/).

Genetic testing involves the analysis of human DNA, ribonucleic acid (RNA), **chromosomes** (threadlike packages of genes and other DNA in the nucleus of a cell), or proteins to detect abnormalities related to an inherited condition. Genetic tests can be used to examine directly the DNA and RNA that make up a gene (direct or molecular testing), look at markers that are coinherited with a gene that causes a genetic condition (linkage analysis), examine the protein products of genes (biochemical testing), or examine chromosomes (cytogenetic testing).

Most of the genetic tests now being offered in clinical practice are tests for single-gene disorders in patients with clinical symptoms or who have a family history of a genetic disease. Some of these genetic tests are prenatal tests or tests used to identify the genetic status of a pregnancy at risk for a genetic condition. Current prenatal testing options include:

- Maternal serum screening (a blood test used to see if a pregnant woman is at increased risk for carrying a fetus with a neural tube defect or chromosomal abnormalities such as Down syndrome, trisomy 18, and trisomy 13)
- Fetal ultrasound or sonogram (an imaging technique using high-frequency sound waves to produce images of the fetus inside the uterus)
- Invasive procedures (amniocentesis and chorionic villus sampling)

(See Chapter 10 for discussion of these tests.) Other tests are carrier screening tests used to identify individuals who have a gene mutation for a genetic condition but do not show symptoms of the condition because it is an autosomal recessive condition (e.g., CF, sickle cell disease, Tay-Sachs disease).

Another type of genetic testing is predictive testing, which is used to clarify the genetic status of asymptomatic family members. The two types of predictive testing are presymptomatic and predispositional. Mutation analysis for Huntington's disease (HD), a neurodegenerative disorder, is an example of presymptomatic testing. If the gene mutation for HD is present, symptoms of HD are certain to appear if the individual lives long enough. Testing for a BRCA1 gene mutation to determine breast cancer susceptibility is an example of predispositional testing. Predispositional testing differs from presymptomatic testing in that a positive result (indicating that a BRCA1 mutation is present) does not indicate a 100% risk for developing the condition (breast cancer).

In addition to using genetic tests for single-gene disorders in patients with clinical symptoms or with a family history of a genetic disease, genetic tests are being used for population-based screening. For example, newborn screening for phenylketonuria (PKU) and other inborn errors of metabolism (IEMs) has been going on in the United States and many other countries for decades (Guttmacher, McGuire, Ponder, et al., 2010). Initially, state-mandated newborn screening in the United States was concerned with only a few conditions. With the advent of tandem mass spectrometry, the number of conditions tested for during newborn screening grew rapidly. Currently, most states use blood spots collected from newborns to test for at least 30 different metabolic and genetic diseases. The conditions most commonly tested for are PKU, congenital hypothyroidism, galactosemia, and sickle cell disease and other hemoglobinopathies. A complete list of conditions tested for in each state is available on the National Newborn Screening and Genetics Resource website (genes-r-us.uthscsa.edu).

Genetic tests are also used to determine paternity, identify victims of war and other tragedies, and profile criminals (www.genetests.org).

Pharmacogenomics

One of most promising clinical applications of the Human Genome Project has been pharmacogenomic testing (the use of genetic information to individualize drug therapy). Associations between genetic variation and drug effect have been observed for a number of commonly used drugs. One of these drugs is warfarin, an anticoagulant commonly used to reduce the risk for thromboembolic events in patients with a history of deep vein thrombosis, pulmonary embolism, myocardial infarction, or atrial fibrillation (Meckley, Gudgeon, Anderson, et al., 2010). There is mounting evidence that genotype-guided warfarin dosing may not only help reduce the serious adverse drug reactions commonly associated with warfarin but also increase dosing accuracy, shorten the time to dose stabilization, and help identify individuals who may require more frequent monitoring.

Gene Therapy

The aim of gene therapy is to correct defective genes that are responsible for disease development. Generally, gene therapy involves inserting a healthy copy of the defective gene into the **somatic cells** (any cell of the body except sperm and egg cells) of the affected individual. Although the early optimism about gene therapy was probably never fully justified, gene therapy has now moved from preclinical to clinical studies for many diseases. These diseases range from hemophilia and other single-gene disorders to complex disorders such as cancer, HIV, and cardiovascular disorders. Major challenges to gene therapy include determining how to target the right gene to the right location in the right cells, expressing the transferred gene at the right time, and minimizing adverse reactions.

Ethical, Legal, and Social Implications

Because of widespread concern about misuse of the information gained through genetics research, 5% of the Human Genome Project budget was designated for the study of the ethical, legal, and social implications (ELSI) of human genome research. Two large ELSI programs were created to identify, analyze, and address the ELSIs of human genome research at the same time that the basic science issues were being studied. During the past decade, issues of high priority for these programs have been:

- Privacy and fairness in the use and interpretation of genetic information
- Clinical integration of new genetics technologies
- Issues surrounding genetics research, such as possible discrimination and stigmatization
- Education for professionals and the general public about genetics, genetics health care, and ELSI of human genome research

Both ELSI programs have excellent websites that include much educational information, as well as links to other informative sites (www.genome.gov/10001618; www.ornl.gov/sci/techresources/Human_Genome/elsi/elsi.shtml).

The major risk associated with genetic testing concerns what happens with the information gained through testing—it may result

in increased anxiety and altered family relationships; it may be difficult to keep confidential; and it may result in discrimination and stigmatization. More important, there is a large gap between the ability to test for a genetic condition and the ability to treat that same condition. Informed consent is difficult to ensure when some of the outcomes, benefits, and risks of genetic testing remain unknown.

Factors Influencing the Decision to Undergo Genetic Testing

The decision to undergo genetic testing is seldom autonomous and based solely on the needs and preferences of the individual being tested. Instead, it is often a decision based on feelings of responsibility and commitment to others. For example, a woman who is receiving treatment for breast cancer may undergo BRCA1/BRCA2 mutation testing not because she wants to find out if she carries a BRCA1 or BRCA2 mutation but, instead, because her two unaffected sisters have asked her to be tested and she feels a sense of responsibility and commitment to them. A female airline pilot with a family history of HD, who has no desire to find out if she has the gene mutation associated with HD, may undergo mutation analysis for HD because she feels she has an obligation to her family, her employer, and the people who fly with her.

Decisions about genetic testing are shaped and, in many instances, constrained by factors such as social norms where care is received and socioeconomic status. Most pregnant women in the United States now have at least one ultrasound examination, many undergo some type of **multiple-marker screening,** and a growing number undergo other types of prenatal testing. The range of prenatal testing options available to a pregnant woman and her family may vary significantly, based on where the pregnant woman receives prenatal care and her socioeconomic status. Certain types of prenatal testing may not be available in smaller communities and rural settings (e.g., chorionic villus sampling and fluorescent in situ hybridization [FISH] analysis). In addition, certain types of genetic testing may not be offered in conservative medical communities (e.g., preimplantation diagnosis). Some types of genetic testing are expensive and typically not covered by health insurance. Because of this, these tests may be available only to a relatively small number of individuals and families—those who can afford to pay for them.

Cultural and ethnic differences also have a significant impact on decisions about genetic testing. When prenatal diagnosis was first introduced, the principal constituency was a self-selected group of Caucasian, well-informed, middle- to upper-class women. Today the widespread use of genetic testing has introduced prenatal testing to new groups of women, women who had not previously considered genetics services. The fact that many of the women currently undergoing prenatal testing may not share mainstream U.S. views about the role of medicine and prenatal care, the meaning of disability, or how to respond to scientific risks and uncertainties further amplifies the complexity of ethical issues associated with prenatal testing.

Clinical Genetics

Genetic Transmission

Human development is a complicated process that depends on the systematic unraveling of instructions found in the genetic material of the egg and the sperm. Development from conception to birth of a normal, healthy baby occurs without incident in most cases; occasionally, however, some anomaly in the genetic code of the embryo creates a birth defect or disorder.

Genes and Chromosomes

The hereditary material carried in the nucleus of each of the somatic cells determines an individual's characteristics. This material, called *DNA* (deoxyribonucleic acid), forms threadlike strands known as *chromosomes.* Each chromosome is composed of many smaller segments of DNA referred to as *genes.* Genes or combinations of genes contain coded information that determines an individual's unique characteristics. The code is found in the specific linear order of the molecules that combine to form the strands of DNA. Genes control both the types of proteins that are made and the rate at which they are produced. Genes never act in isolation; they always interact with other genes and the environment.

All normal human somatic cells contain 46 chromosomes arranged as 23 pairs of homologous (matched) chromosomes; one chromosome of each pair is inherited from each parent. There are 22 pairs of *autosomes,* which control most traits in the body, and one pair of **sex chromosomes.** The larger female chromosome is called the *X;* the smaller male chromosome is the *Y.* Whereas the Y chromosome is primarily concerned with sex determination, the X chromosome contains genes that are involved in much more than sex determination. Generally, the presence of a Y chromosome causes an embryo to develop as a male; in the absence of a Y chromosome, the individual develops as a female. Thus in a normal female, the homologous pair of sex chromosomes are XX, and in a normal male, the homologous pair are XY.

Homologous chromosomes (except the X and Y chromosomes in males) have the same number and arrangement of genes. In other words, if one chromosome has a gene for hair color, its partner chromosome also will have a gene for hair color and these hair-color genes will have the same loci or be located in the same place on the two chromosomes. Although both genes code for hair color, they may not code for the same hair color. Genes at corresponding loci on homologous chromosomes that code for different forms or variations of the same trait are called **alleles.** An individual having two copies of the same allele for a given trait is said to be **homozygous** for that trait. With two different alleles, the person is **heterozygous** for the trait.

The term **genotype** typically is used to refer to the genetic makeup of an individual when discussing a specific gene pair, but at times, genotype is used to refer to an individual's entire genetic makeup or all the genes that the individual can pass on to future generations. **Phenotype** refers to the observable expression of an individual's genotype, such as physical features, a biochemical or molecular trait, and even a psychologic trait. A trait or disorder is considered *dominant* if it is expressed or phenotypically apparent when only one copy of the gene is present. It is considered *recessive* if it is expressed only when two copies of the alleles associated with the trait are present.

As more is learned about genetics and genomics, the concepts of dominance and recessivity have become more complex, especially in X-linked disorders. For example, traits considered to be recessive may be expressed even when only one copy of a gene located on the X chromosome is present. This occurs frequently in males because males have only one X chromosome; thus they have only one copy of the genes located on the X chromosome. Whichever gene is present on the one X chromosome determines which trait is expressed. Females, conversely, have two X chromosomes, so they have two copies of the genes located on the X chromosome. However, in any female somatic cell, only one X chromosome is functioning (otherwise there would be inequality in gene dosage between males and females). This process, known as *X-inactivation* or the *Lyon hypothesis,* is generally a random occurrence. That is, there is a 50-50

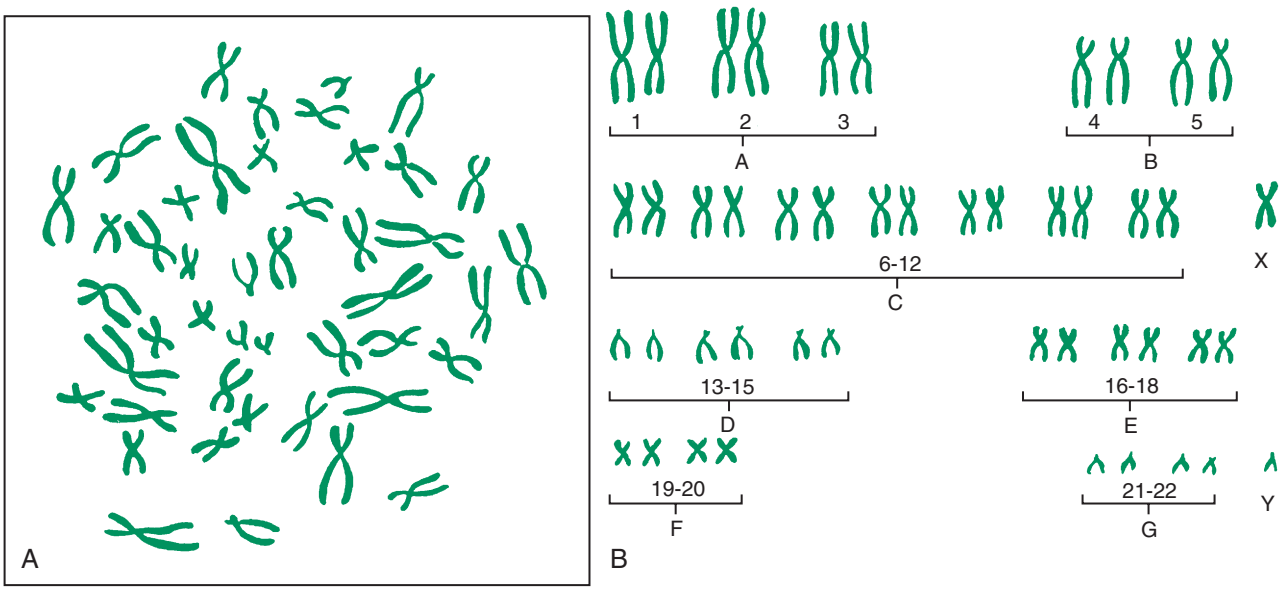

FIG 6-1 Chromosomes during cell division. **A,** Example of photomicrograph. **B,** Chromosomes arranged in karyotype; female and male sex-determining chromosomes.

chance as to whether the maternal X or the paternal X is inactivated. Occasionally the percentage of cells that have the X with an abnormal or mutant gene is very high. This helps explain why hemophilia, an X-linked recessive disorder, can clinically manifest itself in a female known to be a heterozygous carrier (a female who has only one copy of the gene mutation). It also helps explain why traditional methods of carrier detection are less effective for X-linked recessive disorders; the possible range for enzyme activity values can vary greatly, depending on which X chromosome is inactivated.

Chromosomal Abnormalities

Chromosomal abnormalities are a major cause of reproductive loss, congenital problems, and gynecologic disorders. The incidence of abnormalities is approximately 0.6% in newborns, 6% in stillbirths, and 60% in spontaneous abortions (Martin, 2008). Errors resulting in chromosomal abnormalities can occur in **mitosis** (cell division occurring in somatic cells that results in two identical daughter cells containing a diploid number of chromosomes) or **meiosis** (division of a sex cell into two and four haploid cells). These errors can occur in either the autosomes or the sex chromosomes. Even without the presence of obvious structural malformations, small deviations in chromosomes can cause problems in fetal development.

The pictorial analysis of the number, form, and size of an individual's chromosomes is known as a **karyotype.** Cells from any nucleated, replicating body tissue (not red blood cells, nerves, or muscles) can be used. The most commonly used tissues are white blood cells and fetal cells in amniotic fluid. The cells are grown in a culture and arrested when they are in metaphase (during metaphase, the chromosomes are condensed and visible with a light microscope), and then the cells are dropped onto a slide. This breaks the cell membranes and spreads the chromosomes, making them easier to visualize. Next, the cells are stained with special stains (e.g., Giemsa stain) that create striping or "banding" patterns. These patterns aid in the analysis because they are consistent from person to person. Once the chromosome spreads are photographed or scanned by a computer, they are cut out and arranged in a specific numeric order according to their length and shape. The chromosomes are numbered from largest to smallest, 1 to 22, and the sex chromosomes are designated by the letter *X* or *Y.* Each chromosome is divided into two "arms" designated by *p* (short arm) and *q* (long arm). A female karyotype is designated as 46,XX and a male karyotype is designated as 46,XY. Fig. 6-1 illustrates the chromosomes in a body cell and a karyotype.

Autosomal Abnormalities

Autosomal abnormalities involve differences in the number or structure of autosome chromosomes (pairs 1 through 22). They result from unequal distribution of the genetic material during **gamete** (egg and sperm) formation.

Abnormalities of Chromosome Number. A **euploid cell** is a cell with the correct or normal number of chromosomes within the cell. Because most gametes are **haploid** (1N, 23 chromosomes) and most somatic cells are **diploid** (2N, 46 chromosomes), they are both considered euploid cells. Deviations from the correct number of chromosomes per cell can be one of two types: (1) **polyploidy,** in which the deviation is an exact multiple of the haploid number of chromosomes or one chromosome set (23 chromosomes); or (2) **aneuploidy,** in which the numeric deviation is not an exact multiple of the haploid set. A triploid (3N) cell is an example of a polyploidy. It has 69 chromosomes. A tetraploid (4N) cell, also an example of a polyploidy, has 92 chromosomes.

Aneuploidy is the most commonly identified chromosome abnormality in humans and the leading genetic cause of intellectual disability. A **monosomy** is the product of the union between a normal gamete and a gamete that is missing a chromosome. Monosomic individuals have only 45 chromosomes in each of their cells. The product of the union of a normal gamete with a gamete containing an extra chromosome is a **trisomy.** The most common autosomal aneuploid conditions involve trisomies. Trisomic individuals have 47 chromosomes in most or all of their cells.

The vast majority of trisomies occur during **oogenesis** (the process by which a premeiotic female germ cell divides into a mature egg); the incidence of these types of chromosomal errors increases exponentially with advancing maternal age. Although variation

exists among trisomies with regard to the parent and stage of origin of the extra chromosome, most trisomies are maternal meiosis I (MI) errors. This means that most trisomies are caused by nondisjunction during the first meiotic division. The first meiotic division involves the segregation of homologous or similar chromosomes. One pair of chromosomes fails to separate. One resulting cell contains both chromosomes, and the other contains none. The fact that most trisomies are maternal MI errors is not that surprising, because maternal MI occurs over a long time span. It is initiated in precursor cells during fetal development, but it is not completed until the time those cells undergo ovulation after menarche.

The most common trisomy abnormality is Down syndrome (DS). Approximately one in every 691 newborns has DS; there are over 400,000 individuals with DS living in the United States (www.ndss.org). Ninety-five percent of individuals with DS have trisomy 21 (nondisjunction) or an extra chromosome 21 (47,XX+21, female with DS; or 47,XY+21, male with DS). Another type of DS, translocation, occurs when extra chromosome 21 material is present in every cell of the individual but it is attached to another chromosome. In the third type of DS, mosaicism, extra chromosome 21 material is found in some but not all of the cells.

Although the risk for having a child with DS increases with maternal age (incidence is approximately 1 in 1200 for a 25-year-old woman; 1 in 350 for a 35-year-old woman; and 1 in 30 for a 45-year-old woman), children with Down syndrome can be born to mothers of any age (www.ndss.org). Eighty percent of children with Down syndrome are born to mothers younger than 35 years. The risk for a mother having a second child with Down syndrome is about 1% when the cause of the Down syndrome is trisomy 21.

Other autosomal trisomies that maternity nurses might see are trisomy 18 (Edwards syndrome) and trisomy 13 (Patau syndrome). Trisomy 18 is more common than trisomy 13; it occurs in about 1 of 3000 live births versus 1 of 10,000 live births for trisomy 13. Infants with trisomy 18 and trisomy 13 usually have severe to profound intellectual disabilities. Although both conditions have a poor prognosis, with the vast majority of affected infants dying before they reach their first birthday, a growing number of infants with these trisomies are living longer and a small number are actually living into their 40s and 50s.

Nondisjunction can also occur during mitosis. If this occurs early in development, when cell lines are forming, the individual has a mixture of cells, some with a normal number of chromosomes and others either missing a chromosome or containing an extra chromosome. This condition is known as *mosaicism.* The most common form of mosaicism in autosomes is mosaic Down syndrome.

Abnormalities of Chromosome Structure. Structural abnormalities can occur in any chromosome. Types of structural abnormalities include translocation, duplication, deletion, microdeletion, and inversion. **Translocation** results when there is an exchange of chromosomal material between two chromosomes. Exposure to certain drugs, viruses, and radiation can cause translocations, but often they arise for no apparent reason.

The two major types of translocation are reciprocal and robertsonian. Reciprocal translocations are the most common. In a reciprocal translocation, either the parts of the two chromosomes are exchanged equally (balanced translocation) or a part of a chromosome is transferred to a different chromosome, creating an unbalanced translocation because there is extra chromosomal material—extra of one chromosome but correct amount or deficient amount of the other chromosome. In a balanced translocation, the individual is phenotypically normal because there is no extra chromosome material; it is just rearranged. In an unbalanced translocation, the individual will be both genotypically and phenotypically abnormal.

In a robertsonian translocation, the short arms (p arms) of two different acrocentric chromosomes (chromosomes with very short p arms) break, leaving sticky ends that then cause the two long arms (q arms) to stick together. This forms a new, large chromosome that is made of the two long arms. The individual with a balanced robertsonian translocation has 45 chromosomes. Because the short arm of acrocentric chromosomes contains genes for ribosomal RNA and these genes are represented elsewhere, the individual usually does not show any symptoms. The individual may produce an unbalanced gamete (sperm or egg with too many or two few genes). This can lead to reproductive difficulties such as miscarriages or birth defects.

In duplication, there is an extra chromosomal segment within the same homologous or another nonhomologous chromosome. Clinical findings are highly variable and depend on which of the chromosomal segments are involved.

Deletions result in the loss of chromosomal material and partial monosomy for the chromosome involved. Microdeletions are deletions too small to be detected by standard cytogenetic techniques. Whenever a portion of a chromosome is deleted from one chromosome and added to another, the gamete produced may have either extra copies of genes or too few copies. The clinical effects produced may be mild or severe depending on the amount of genetic material involved. Two of the more common conditions are the deletion of the short arm of chromosome 5 (cri du chat syndrome) and the deletion of the long arm of chromosome 18.

Inversions are deviations in which a portion of the chromosome has been rearranged in reverse order. Few birth defects have been attributed to the presence of inversions, but it is suspected that inversions may be responsible for problems with infertility and miscarriages. More than 40% of inversions involve chromosome 9.

Sex Chromosome Abnormalities

Several sex chromosome abnormalities are caused by nondisjunction during gametogenesis in either parent. The most common deviation in females is *Turner syndrome,* or monosomy X (45,X). The affected female exhibits juvenile external genitalia with undeveloped ovaries. She is short in stature and often has webbing of the neck, a low hairline in the back, low-set ears, and lymphedema of her hands and feet. Intelligence may be impaired. Most affected embryos miscarry spontaneously. In most cases of Turner syndrome, it is the paternal X or Y that is lost.

The most common deviation in males is *Klinefelter syndrome,* or trisomy XXY. The affected male has poorly developed secondary sexual characteristics and small testes. He is infertile, usually tall, and effeminate and may be slow to learn (www.genetic.org). Males who have mosaic Klinefelter syndrome may be fertile.

Patterns of Genetic Transmission

Heritable characteristics are those that can be passed on to offspring. The patterns by which genetic material is transmitted to the next generation are affected by the number of genes involved in the expression of the trait. Many phenotypic characteristics result from two or more genes on different chromosomes acting together (referred to as *multifactorial inheritance*); others are controlled by a single gene *(unifactorial inheritance*). Specialists in genetics (e.g., geneticists, genetic counselors, and nurses with advanced expertise in genetics) predict the probability of the presence of an abnormal gene from the known occurrence of the trait in the individual's family and the known patterns by which the trait is inherited.

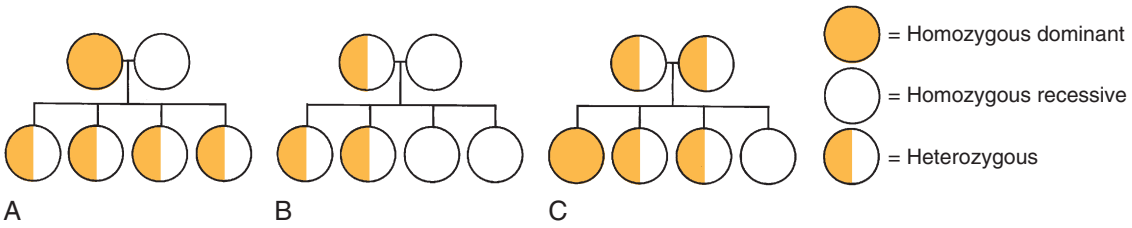

FIG 6-2 Possible offspring in three types of matings. **A,** Homozygous-dominant parent and homozygous-recessive parent. Children: all heterozygous, displaying dominant trait. **B,** Heterozygous parent and homozygous-recessive parent. Children: 50% heterozygous, displaying dominant trait; 50% homozygous, displaying recessive trait. **C,** Both parents heterozygous. Children: 25% homozygous, displaying dominant trait; 25% homozygous, displaying recessive trait; 50% heterozygous, displaying dominant trait.

Multifactorial Inheritance

Most common congenital malformations result from multifactorial inheritance, a combination of genetic and environmental factors. Examples are cleft lip, cleft palate, congenital heart disease, neural tube defects, and pyloric stenosis. Each malformation can range from mild to severe, depending on the number of genes for the defect present or the amount of environmental influence. A neural tube defect may range from spina bifida (a bony defect in the lumbar region of the vertebrae with little or no neurologic impairment) to anencephaly (absence of brain development, which is always fatal). Some malformations occur more often in one sex. For example, pyloric stenosis and cleft lip are more common in males, and cleft palate is more common in females.

Unifactorial Inheritance

If a single gene controls a particular trait or disorder, its pattern of inheritance is referred to as *unifactorial mendelian* or *single-gene inheritance.* The number of single-gene disorders far exceeds the number of chromosomal abnormalities. Potential patterns of inheritance for single-gene disorders include autosomal dominant, autosomal recessive, and X-linked dominant and recessive modes of inheritance (Fig. 6-2).

Autosomal Dominant Inheritance. Autosomal dominant inheritance disorders are those in which only one copy of a variant allele is needed for phenotypic expression. The variant allele may be a result of a **mutation**—a spontaneous and permanent change in the normal gene structure in which case the disorder occurs for the first time in the family. Usually an affected individual comes from multiple generations having the disorder. An affected parent who is heterozygous for the trait has a 50% chance of passing the variant allele to each offspring (see Fig. 6-2, *B* and *C*). There is a vertical pattern of inheritance (i.e., there is no skipping of generations; if an individual has an autosomal dominant disorder such as HD, so must one of his or her parents). Males and females are equally affected.

Autosomal dominant disorders are not always expressed with the same severity of symptoms. For example, a woman who has an autosomal dominant disorder may show few symptoms and may not become aware of her diagnosis until after she gives birth to a severely affected child. Predicting whether an offspring will have a minor or severe abnormality is not possible. Examples of autosomal dominant disorders are HD, Marfan syndrome, neurofibromatosis, myotonic dystrophy, Stickler syndrome, Treacher Collins syndrome, and achondroplasia (dwarfism).

Autosomal Recessive Inheritance. Autosomal recessive inheritance disorders are those in which both genes of a pair associated with the disorder must be abnormal for the disorder to be expressed. Heterozygous individuals have only one variant allele and are unaffected clinically because their normal gene overshadows the variant allele. They are known as *carriers* of the recessive trait. Because these recessive traits are inherited by generations of the same family, an increased incidence of the disorder occurs in consanguineous matings (closely related parents). For the trait to be expressed, two carriers must each contribute a variant allele to the offspring (see Fig. 6-2, *C*). The chance of the trait occurring in each child is 25%. A clinically normal offspring may be a carrier of the gene. Autosomal recessive disorders have a horizontal pattern of inheritance rather than the vertical pattern seen with autosomal dominant disorders. That is, autosomal recessive disorders are usually observed in one or more siblings but not in earlier generations. Males and females are equally affected. Most inborn errors of metabolism (IEMs), such as phenylketonuria, galactosemia, maple syrup urine disease, Tay-Sachs disease, sickle cell anemia, and cystic fibrosis, are autosomal recessive inherited disorders.

Inborn Errors of Metabolism. More than 350 *inborn errors of metabolism* have been recognized (Jorde, Carey, and Bamshad, 2010). Individually, IEMs are relatively rare, but collectively, they are common (1 in 5000 live births). Most IEMs are inherited in an autosomal recessive pattern. IEMs occur when a gene mutation reduces the efficiency of encoded enzymes to a level at which normal metabolism cannot occur. Defective enzyme action interrupts the normal series of chemical reactions from the affected point onward. The result may be an accumulation of a damaging product, such as phenylalanine in PKU, or the absence of a necessary product, such as the lack of melanin in albinism caused by lack of tyrosinase. Diagnostic and carrier testing is available for a growing number of IEMs. In addition, many states in the United States have started screening for specific IEMs as part of their expanded newborn screening programs using tandem mass spectrometry. However, many of the deaths caused by IEMs are the result of enzyme variants not currently screened for in many of the newborn screening programs (Jorde, Carey, and Bamshad, 2010). (See discussion of IEMs in Chapter 25.)

X-Linked Dominant Inheritance. X-linked dominant inheritance disorders occur in males and heterozygous females, but because of X inactivation, affected females are usually less severely affected than affected males and they are more likely to transmit the variant allele to their offspring. Heterozygous females (females who have one wild-type allele and one variant allele) have a 50% chance of transmitting the variant allele to each offspring. The variant allele is often lethal in affected males since, unlike affected females, they have no

normal gene (wild-type allele). Mating of an affected male and an unaffected female is uncommon as a result of the tendency for the variant allele to be lethal in affected males. Relatively few X-linked dominant disorders have been identified. Two examples are vitamin D–resistant rickets and Rett syndrome.

X-Linked Recessive Inheritance. Abnormal genes for X-linked recessive inheritance disorders are carried on the X chromosome. Females may be heterozygous or homozygous for traits carried on the X chromosome because they have two X chromosomes. Males are hemizygous because they have only one X chromosome, which carries genes with no alleles on the Y chromosome. Therefore X-linked recessive disorders are most commonly manifested in the male with the abnormal gene on his single X chromosome. Hemophilia, color blindness, and Duchenne muscular dystrophy are X-linked recessive disorders.

The male with an X-linked recessive disorder receives the disease-associated allele from his carrier mother on her affected X chromosome. Female carriers (those heterozygous for the trait) have a 50% probability of transmitting the disease-associated allele to each offspring. An affected male can pass the disease-associated allele to his daughters but not to his sons. The daughters will be carriers of the trait if they receive a normal gene on the X chromosome from their mother. They will be affected only if they receive a disease-associated allele on the X chromosome from both their mother and their father.

GENETIC COUNSELING

It is standard practice in obstetrics to determine whether a heritable disorder exists in a couple or in anyone in either of their families. The goal of screening is to detect or define risk for disease in low risk populations and identify those for whom diagnostic testing may be appropriate. A nurse can obtain a genetics history using a questionnaire or checklist such as the one in Fig. 6-3.

Genetic counseling is a professional service that provides genetics information, education, and support to individuals and families with ongoing or potential genetic health concerns. It is typically provided by a team of genetics specialists that includes clinical geneticists (physicians), medical geneticists with a PhD, genetics fellows, genetics counselors, and, in a growing number of cases, advanced practice genetics nurse specialists. Cytogeneticists, biochemical geneticists, and molecular geneticists support the clinical genetics team by providing laboratory expertise that helps with the diagnosis and management of individuals and families affected by genetic conditions.

Genetic counseling occurs in regional genetics centers, major medical centers, outreach or satellite genetics clinics, public health clinics, some community hospitals, and now that genetics has entered the mainstream of health care, in a wide variety of other settings. These include but are not limited to managed health care organizations, commercial facilities, and private practices. A number of specialized groups provide genetics education and counseling for individuals and families affected by specific genetic disorders, such as DS, CF, diabetes, muscular dystrophy, HD, and cancer. Genetic counseling also is offered over the Internet.

Individuals and families seek out or are referred for genetic counseling for a wide variety of reasons and at all stages of their lives. Some seek preconception or prenatal information; others are referred after the birth of a child with a birth defect or a suspected genetic condition; still others seek information because they have a family history of a genetic condition. Regardless of the setting or the individual's and family's stage of life, genetic counseling should be offered and available to all individuals and families who have questions about genetics and their health. However, there is a shortage of appropriately trained genetics professionals who can provide genetic counseling. This means that many individuals and families will not be offered genetic counseling when they undergo genetic testing. Moreover, some of the genetics education and counseling that is provided will be inadequate (see Community Focus box).

COMMUNITY FOCUS

Resources for Genetic Disorders

- Select a hereditary disorder such as cystic fibrosis, muscular dystrophy, hemophilia, Tay-Sachs disease, or sickle cell anemia. Visit the website of the national organization. Locate accredited care centers that are in your community. Do the centers offer preconception counseling?
- Visit the Genetic Alliance website at www.geneticalliance.org. Select a disorder and go to the disease information search link. Review the patient information sections about clinical description, insurance issues, research, and treatment.
- Share your findings with your classmates in a clinical conference.

Existing genetics resources include:

- Centers for Disease Control and Prevention (www.cdc.gov/genetics/activities/ogdp.htm)
- Genetic Alliance (www.geneticalliance.org/)
- National Coalition for Health Professional Education in Genetics (www.nchpeg.org/)
- Genetics Education Program for Nurses at Cincinnati Children's Hospital Medical Center (www.cincinnatichildrens.org/ed/clinical/gpnf/default.htm)
- NHGRI Education (www.genome.gov/Education/)
- National Center for Biotechnology Information (www.ncbi.nlm.nih.gov/)
- Other websites, such as www.hsl.unc.edu/Services/Guides/focusonclingen.cfm

Some of these resources may be in health care professionals' own communities, but others are regional, national, and international resources.

Estimation of Risk

Most families with a history of genetic disease want an answer to the following question: What is the chance that our future children will have this disease? Because the answer to this question may have profound implications for individual family members and the family as a whole, health care professionals must be able to answer this question as accurately as they can in a timely manner. In some cases, estimation of risk is rather straightforward; in other cases, it is complicated.

If a couple has not yet had children but they are known to be at risk for having children with a genetic disease, they will be given an occurrence risk. Once the mating of a couple has produced one or more children with a genetic disease, the couple will be given a recurrence risk. Both occurrence and recurrence risks are determined by the mode of inheritance for the genetic disease in question. For genetic diseases caused by a factor that segregates during cell division (genes and chromosomes), risk can be estimated with a high degree of accuracy by application of mendelian principles.

In an autosomal dominant disorder, both the occurrence and recurrence risk is 50%, or one in two, that a subsequent offspring will be affected when one parent is affected and the other is not. The

Risk Factors for Genetic Disorders

Answer the following questions about risk factors. If you answer "yes" to any of them, you may be at increased risk for having a baby with a genetic disorder.

_____Will you be age 35 years or older when your baby is due?

_____Will the baby's father be age 50 years or older when your baby is due?

_____If you or the baby's father are of Mediterranean or Asian descent, do either of you or does anyone in your families have thalassemia?

_____Is there a family history of neural tube defects?

_____Have you or the baby's father ever had a child with a neural tube defect?

_____Is there a family history of congenital heart defects?

_____Is there a family history of Down syndrome?

_____Have you or the baby's father ever had a child with Down syndrome?

_____If you or the baby's father are of Eastern European Jewish, French Canadian, or Cajun descent, is there a family history of Tay-Sachs disease?

_____If you or your partner are of Eastern European Jewish descent, is there a family history of Canavan disease or any other genetic disorders?

_____If you or your partner are African-American, is there a family history of sickle cell disease or sickle cell trait?

_____Is there a family history of hemophilia?

_____Is there a family history of muscular dystrophy?

_____Is there a family history of cystic fibrosis?

_____Is there a family history of Huntington's disease?

_____Does anyone in your family or the family of the baby's father have cystic fibrosis?

_____Is anyone in your family or the family of the baby's father's mentally retarded?

_____If so, was that person tested for fragile X syndrome?

_____Do you, the baby's father, anyone in your families, or any of your children have any other genetic diseases, chromosomal disorders, or birth defects?

_____Do you have a metabolic disorder such as diabetes or phenylketonuria?

_____Do you have a history of pregnancy issues (miscarriage or stillbirth)?

FIG 6-3 Questionnaire for identifying couples having increased risk for offspring with genetic disorders. (Courtesy American College of Obstetricians and Gynecologists: *Your pregnancy and childbirth month to month,* ed 5, Washington, DC, 2010, Author.)

recurrence risk for autosomal recessive disorders is 25%, or one in four, if both parents are carriers (they each have one recessive disease gene and one normal gene). Occasionally an individual homozygous for a recessive disease gene mates with an individual who is a carrier of the same recessive gene. In this case, the recurrence risk is 50%, or one in two. If two individuals affected by an autosomal recessive disorder mate, all of their children will be affected. For X-linked disorders, recurrence risk is related to the sex of the child. Translocation chromosomes have a high risk for recurrence.

A number of autosomal disorders display fairly complex patterns of inheritance, making estimation of risk somewhat difficult. For example, if a child is born with a genetic disease and there has been no history of the disease in the family, the disease may have been caused by a new mutation (this is more likely if the disease in question is an autosomal dominant disorder, such as achondroplasia). If the child's genetic disease has been caused by a new mutation, the recurrence risk for the parents' subsequent children is low (1% to 2%), but it is not as low as that for the general population. Offspring of the affected child may have a substantially elevated occurrence risk.

The risk for recurrence for multifactorial conditions can be estimated empirically. An empiric risk is based not on genetics theory but, rather, on experience and observation of the disorder in other families. Recurrence risks are determined by applying the frequency of a similar disorder in other families to the case under consideration.

An important concept to be emphasized to individuals and families during a genetic counseling session is that *each pregnancy is an independent event.* For example, in monogenic disorders in which the risk factor is one in four that the child will be affected, the risk remains the same no matter how many affected children are already in the family. Families may maintain the erroneous assumption that the presence of one affected child ensures that the next three will be free of the disorder. However, "chance has no memory." The risk is one in four for each pregnancy. Conversely, in a family with a child who has a disorder with multifactorial causes, the risk increases with each subsequent child born with the disorder.

Interpretation of Risk

The guiding principle for genetics counselors has traditionally been nondirectiveness. According to the principle of nondirectiveness, the individual who is providing genetic counseling respects the right of the individual or family being counseled to make autonomous decisions. Counselors using a nondirective approach avoid making recommendations, and they try to communicate genetics information in an unbiased manner. The first step in providing nondirective counseling is becoming aware of one's own values and beliefs. Another important step is recognizing how one's values and beliefs can influence or interfere with the communication of genetics information.

If the individual who is providing genetic counseling has difficulty being nonjudgmental and objective, he or she may either intentionally or unintentionally influence the decision-making process. Individuals and families also may pressure the counselor to make decisions for them with questions such as "What would you do if you were me?" Families and individuals need education, guidance, and support throughout the counseling process. They should be given the facts and possible consequences as well as all of the assistance they need in problem solving, but the final decision regarding a course of action must be their own.

Multiple Roles for Nurses in Genetics

Nurses play many roles in genetics. Some nurses play a key role in the identification of families in need of genetic counseling, and they collaborate with other health care professionals to make referrals to specialists in genetics. Other nurses take a more active role in genetic counseling.

Probably the most important of all nursing functions is to provide emotional support during all aspects of the counseling process. Feelings that are generated under the real or imagined threat posed by a genetic disorder are as varied as the people being counseled. Responses may include a variety of stress reactions, such as apathy, denial, anger, hostility, fear, embarrassment, grief, and loss of self-esteem. Guilt and self-blame are universal reactions. Many look on the disorder as a stigma, especially if the disorder is visible to others. Old wives' tales, superstitions, and long-held misconceptions may influence a family's reaction to a genetic disorder.

Nurses are ideally positioned to help individuals and families maximize the benefits of the genetics revolution, but first, nurses need (1) a working knowledge of human genetics, (2) an awareness of recent advances in genetics and genomics, and (3) an understanding of the potential effects of genomic discoveries on individual and family well-being. More research is needed concerning the family experience of genetic testing. Nurses must understand why individuals and families decide to undergo or to forgo genetic testing. Nurses also need to be aware of how individuals and families define and manage ethical, legal, and social issues that emerge during the genetic testing experience.

CONCEPTION

Cell Division

Cells are reproduced by two different methods: mitosis and meiosis. In mitosis, the body cells replicate to yield two cells with the same genetic makeup as the parent cell. First the cell makes a copy of its DNA, and then it divides. Each daughter cell receives one copy of the genetic material. Mitotic division facilitates growth and development or cell replacement.

Meiosis, the process by which germ cells divide and decrease their chromosomal number by half, produces gametes (eggs and sperm). Each homologous pair of chromosomes contains one chromosome received from the mother and one from the father; thus meiosis results in cells that contain one of each of the 23 pairs of chromosomes. Because these germ cells contain 23 single chromosomes, half of the genetic material of a normal somatic cell, they are called *haploid.* This halving of the genetic material is accomplished by replicating the DNA once and then dividing twice. When the female gamete (egg or ovum) and the male gamete (spermatozoon) unite to form the zygote, the diploid number of human chromosomes (46, or 23 pairs) is restored.

The process of DNA replication and cell division in meiosis allows different alleles (genes on corresponding loci that code for variations of the same trait) for genes to be distributed at random by each parent and then rearranged on the paired chromosomes. The chromosomes then separate and proceed to different gametes. Because the two parents have genotypes derived from four different grandparents, many combinations of genes on each chromosome are possible. This random mixing of alleles accounts for the variation of traits seen in the offspring of the same two parents.

Gametogenesis

Oogenesis, the process of egg (ovum) formation, begins during fetal life of the female. All the cells that may undergo meiosis in a woman's lifetime are contained in her ovaries at birth. The majority of the estimated 2 million primary oocytes (the cells that undergo the first meiotic division) degenerate spontaneously. Only 400 to 500 ova will mature during the approximately 35 years of a woman's reproductive life. The primary oocytes begin the first meiotic division (i.e., they replicate their DNA) during fetal life, but they remain suspended at this stage until puberty (Fig. 6-4, *A*). Then, usually monthly, one primary oocyte matures and completes the first meiotic division, yielding two unequal cells: the secondary oocyte and a small polar body. Both contain 22 autosomes and one X sex chromosome.

At ovulation the second meiotic division begins. However, the ovum does not complete the second meiotic division unless fertilization occurs. At fertilization, when the sperm is united with the mature ovum, a second polar body and the **zygote** (the united egg and sperm) are produced (see Fig. 6-4, *C*). The three polar bodies degenerate.

When a male reaches puberty, his testes begin the process of **spermatogenesis.** The cells that undergo meiosis in the male are called *spermatocytes.* The primary spermatocyte, which undergoes the first meiotic division, contains the diploid number of chromosomes. The cell has already copied its DNA before division, so four alleles for each gene are present. The cell is still considered diploid because the copies are bound together (i.e., one allele plus its copy on each chromosome).

During the first meiotic division, two haploid secondary spermatocytes are formed. Each secondary spermatocyte contains 22

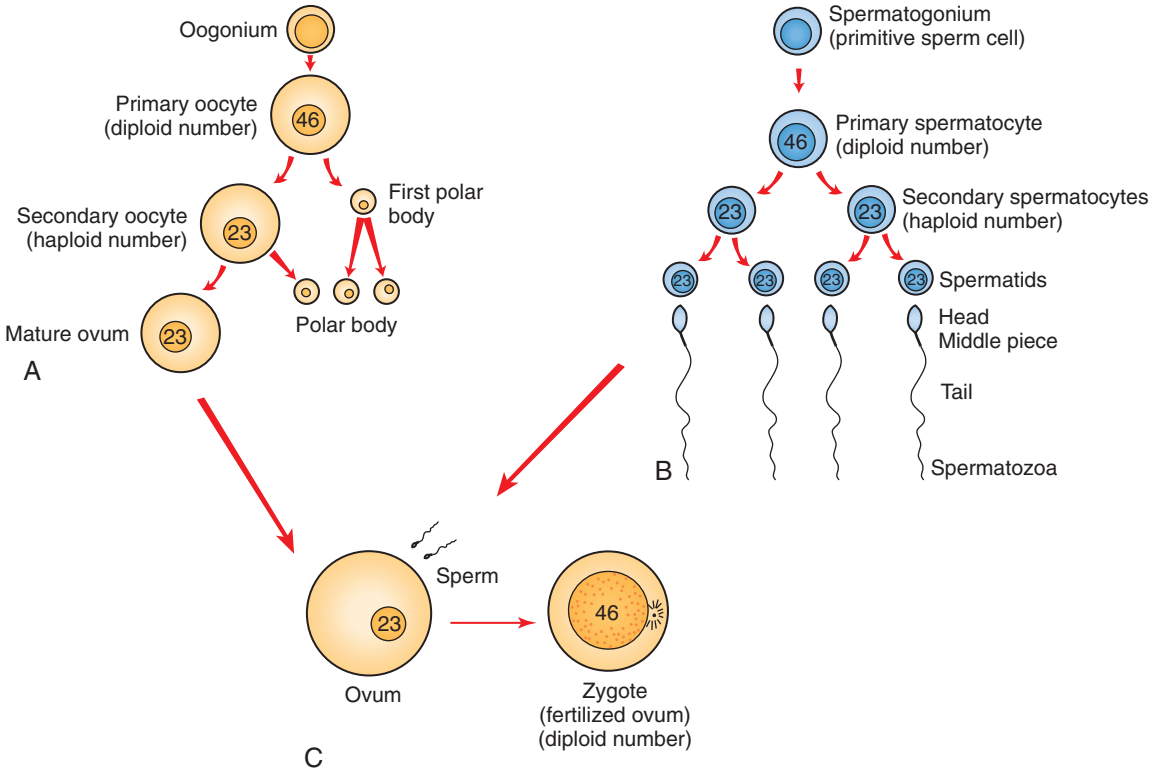

FIG 6-4 Gametogenesis and fertilization. **A,** Oogenesis. Gametogenesis in the female produces one mature ovum and three polar bodies. Note relative difference in overall size between ovum and sperm. **B,** Spermatogenesis. Gametogenesis in the male produces four mature gametes, the sperm. **C,** Fertilization results in the single-cell zygote and restoration of the diploid number of chromosomes.

autosomes and one sex chromosome; one contains the X chromosome (plus its copy) and the other, the Y chromosome (plus its copy). During the second meiotic division, the male produces two gametes with an X chromosome and two gametes with a Y chromosome, all of which will develop into viable sperm (see Fig. 6-4, *B*).

Conception

Conception, defined as the union of a single egg and sperm, marks the beginning of a pregnancy. Conception occurs not as an isolated event but as part of a sequential process. This sequential process includes gamete (egg and sperm) formation, ovulation (release of the egg), union of the gametes (which results in an embryo), and implantation in the uterus.

Ovum

Meiosis occurs in the female in the ovarian follicles and produces an egg, or ovum. Each month one ovum matures with a host of surrounding supportive cells. At ovulation the ovum is released from the ruptured ovarian follicle. High estrogen levels increase the motility of the uterine tubes so that their cilia can capture the ovum and propel it through the tube toward the uterine cavity. An ovum cannot move by itself.

Two protective layers surround the ovum (Fig. 6-5). The inner layer is a thick, acellular layer called the *zona pellucida.* The outer layer, called the *corona radiata,* is composed of elongated cells.

Ova are considered fertile for about 24 hours after ovulation. If unfertilized by a sperm, the ovum degenerates and is resorbed.

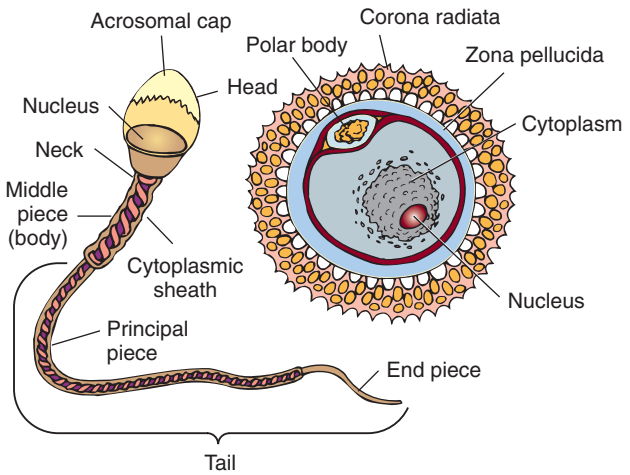

FIG 6-5 Ovum and sperm.

Sperm

Ejaculation during sexual intercourse normally propels about a teaspoon of semen containing as many as 200 to 500 million sperm into the vagina. The sperm swim by means of the flagellar movement of their tails. Some sperm can reach the site of fertilization within 5 minutes, but average transit time is 4 to 6 hours. Sperm remain viable within the woman's reproductive system for an average of 2 to 3 days. Most sperm are lost in the vagina, within the

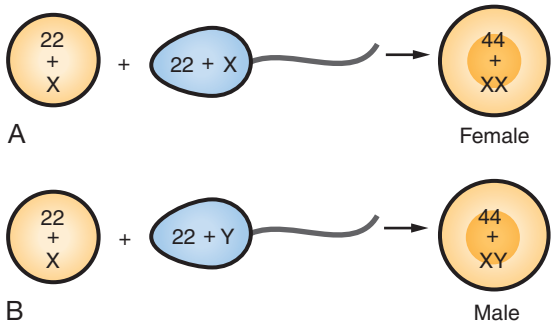

FIG 6-6 Fertilization. **A,** Ovum fertilized by X-bearing sperm to form female zygote. **B,** Ovum fertilized by Y-bearing sperm to form male zygote.

cervical mucus, or in the endometrium; or they enter the tube that contains no ovum.

As sperm travel through the female reproductive tract, enzymes are produced to aid in their capacitation. *Capacitation* is a physiologic change that removes the protective coating from the heads of the sperm. Small perforations then form in the acrosome (a cap on the sperm) and allow enzymes (e.g., hyaluronidase) to escape (see Fig. 6-5). These enzymes are necessary for the sperm to penetrate the protective layers of the ovum before fertilization.

Fertilization

Fertilization takes place in the ampulla (the outer third) of the uterine tube. When a sperm successfully penetrates the membrane surrounding the ovum, both sperm and ovum are enclosed within the membrane and the membrane becomes impenetrable to other sperm; this process is termed the zona reaction. The second meiotic division of the secondary oocyte is then completed, and the nucleus of the ovum becomes the female pronucleus. The head of the sperm enlarges to become the male pronucleus, and the tail degenerates. The nuclei fuse and the chromosomes combine, restoring the diploid number (46) (Fig. 6-6). Conception, the formation of the zygote (the first cell of the new individual), has been achieved.

Mitotic cellular replication, called *cleavage,* begins as the zygote travels the length of the uterine tube into the uterus. This voyage takes 3 to 4 days. Because the fertilized egg divides rapidly with no increase in size, successively smaller cells, called *blastomeres,* are formed with each division. A 16-cell morula, a solid ball of cells, is produced within 3 days and is still surrounded by the protective zona pellucida (Fig. 6-7, *A*). Further development occurs as the morula floats freely within the uterus. Fluid passes through the zona pellucida into the intercellular spaces between the blastomeres, separating them into two parts: the trophoblast (which gives rise to the placenta) and the embryoblast (which gives rise to the embryo). A cavity forms within the cell mass as the spaces come together, forming a structure called the *blastocyst cavity.* When the cavity becomes recognizable, the whole structure of the developing embryo is known as the *blastocyst.* Stem cells are derived from the inner cell mass of the blastocyst. The outer layer of cells surrounding the cavity is the trophoblast. The trophoblast differentiates into villous and extravillous trophoblast (Fig. 6-8).

Implantation

The zona pellucida degenerates, the trophoblast cells displace endometrial cells at the implantation site, and the blastocyst embeds in the endometrium, usually in the anterior or posterior fundal region. Between 6 and 10 days after conception, the trophoblast secretes

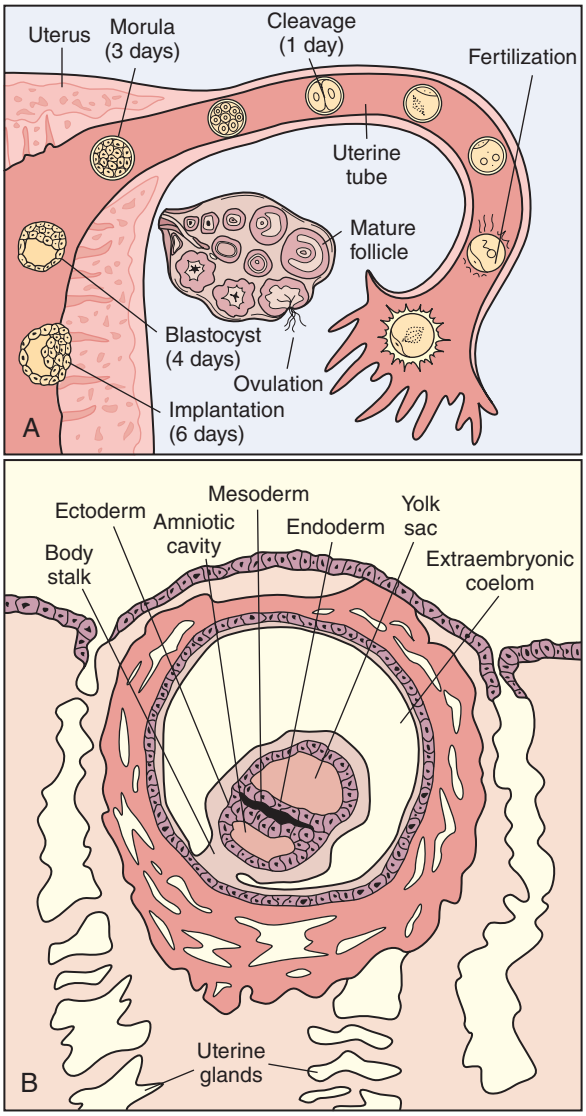

FIG 6-7 First weeks of human development. **A,** Follicular development in ovary, ovulation, fertilization, and transport of early embryo down uterine tube and into uterus, where implantation occurs. **B,** Blastocyst embedded in endometrium. Germ layers forming. (*A,* From Carlson BM: *Human embryology and developmental biology,* ed 5, St Louis, 2013, Mosby; *B,* Adapted from Langley LL, Telford IR, Christensen, JB: *Dynamic human anatomy and physiology,* ed 5, New York, 1980, McGraw-Hill.)

enzymes that enable it to burrow into the endometrium until the entire blastocyst is covered. This is known as *implantation.* Endometrial blood vessels erode, and some women have implantation bleeding (slight spotting and bleeding at the time of the first missed menstrual period). Chorionic villi, fingerlike projections, develop out of the trophoblast and extend into the blood-filled spaces of the endometrium. These villi are vascular processes that obtain oxygen and nutrients from the maternal bloodstream and dispose of carbon dioxide and waste products into the maternal blood.

After implantation, the endometrium is called the decidua. The portion directly under the blastocyst, where the chorionic villi tap into the maternal blood vessels, is the decidua basalis. The portion covering the blastocyst is the decidua capsularis, and the portion lining the rest of the uterus is the decidua vera (Fig. 6-9).

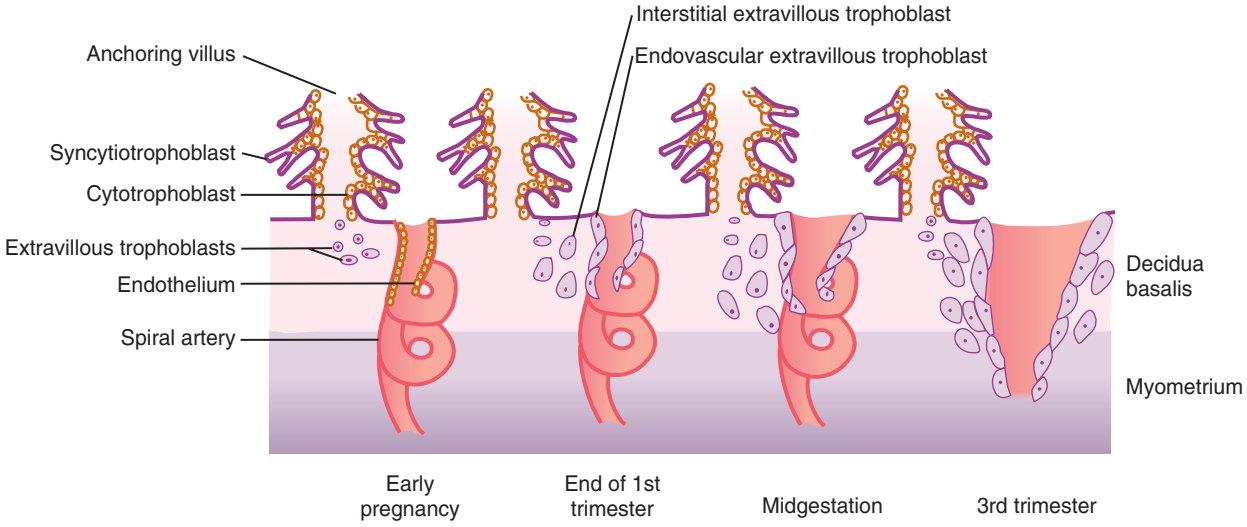

FIG 6-8 Extravillous trophoblasts are found outside the villus and can be subdivided into endovascular and interstitial categories. Endovascular trophoblasts invade and transform spiral arteries during pregnancy to create low-resistance blood flow that is characteristic of the placenta. Interstitial trophoblasts invade the decidua and surround spiral arteries. (From Cunningham F, Leveno K, Bloom S, et al: *Williams obstetrics*, ed 23, New York, 2010, McGraw-Hill.)

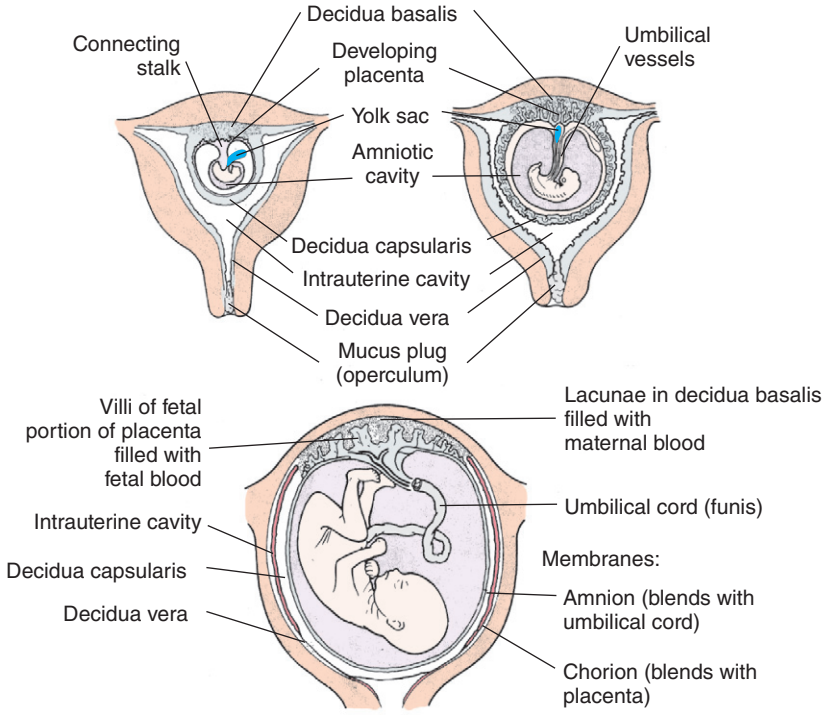

FIG 6-9 Development of fetal membranes. Note gradual obliteration of intrauterine cavity as decidua capsularis and decidua vera meet. Also note thinning of uterine wall. Chorionic and amnionic membranes are in apposition to each other but may be peeled apart.

THE EMBRYO AND FETUS

Pregnancy lasts approximately 10 lunar months, 9 calendar months, 40 weeks, or 280 days. Length of pregnancy is computed from the first day of the last menstrual period (LMP) until the day of birth. However, conception occurs approximately 2 weeks after the first day of the LMP. Thus the postconception age of the fetus is 2 weeks less, for a total of 266 days or 38 weeks. Postconception age is used in the discussion of fetal development.

Intrauterine development is divided into three stages: ovum or preembryonic, embryo, and fetus (see Fig. 6-19). The stage of the ovum lasts from conception until day 14. This period covers cellular replication, blastocyst formation, initial development of the embryonic membranes, and establishment of the primary germ layers.

Primary Germ Layers

During the third week after conception, the embryonic disk differentiates into three primary germ layers: the ectoderm, the mesoderm, and the endoderm (or entoderm) (see Fig. 6-7, *B*). All tissues and organs of the embryo develop from these three layers.

The ectoderm, the upper layer of the embryonic disk, gives rise to the epidermis, glands (anterior pituitary, cutaneous, and mammary), nails and hair, central and peripheral nervous systems, lens of the eyes, tooth enamel, and floor of the amniotic cavity.

The mesoderm, the middle layer, develops into the bones and teeth, muscles (skeletal, smooth, and cardiac), dermis and connective tissue, cardiovascular system and spleen, and urogenital system.

The endoderm, the lower layer, gives rise to the epithelium lining the respiratory tract and digestive tract, including the oropharynx, liver and pancreas, urethra, bladder, and vagina. The endoderm forms the roof of the yolk sac.

Development of the Embryo

The stage of the embryo lasts from day 15 until approximately 8 weeks after conception, when the embryo measures approximately 3 cm from crown to rump. The embryonic stage is the most critical time in the development of the organ systems and the main external features. Developing areas with rapid cell division are the most vulnerable to malformation caused by environmental teratogens (substances or exposure that causes abnormal development). At the end of the eighth week, all organ systems and external structures are present and the embryo is unmistakably human (see Fig. 6-19 and Visible Embryo, www.visembryo.com, for a pictorial view of normal and abnormal development).

Membranes

At the time of implantation, two fetal membranes that will surround the developing embryo begin to form. The chorion develops from the trophoblast and contains the chorionic villi on its surface. The villi burrow into the decidua basalis and increase in size and complexity as the vascular processes develop into the placenta. The chorion becomes the covering of the fetal side of the placenta. It contains the major umbilical blood vessels that branch out over the surface of the placenta. As the embryo grows, the decidua capsularis stretches. The chorionic villi on this side atrophy and degenerate, leaving a smooth chorionic membrane.

The inner cell membrane, the amnion, develops from the interior cells of the blastocyst. The cavity that develops between this inner cell mass and the outer layer of cells (trophoblast) is the amniotic cavity (see Fig. 6-7, *B*). As it grows larger, the amnion forms on the side opposite the developing blastocyst (see Fig. 6-7, *B*, and Fig. 6-9). The developing embryo draws the amnion around itself to form a fluid-filled sac. The amnion becomes the covering of the umbilical cord and covers the chorion on the fetal surface of the placenta. As the embryo grows larger, the amnion enlarges to accommodate the embryo/fetus and the surrounding amniotic fluid. The amnion eventually comes in contact with the chorion surrounding the fetus (see the Critical Thinking Case Study).

Amniotic Fluid

The amniotic cavity initially derives its fluid by diffusion from the maternal blood. Fluid secreted by the respiratory and gastrointestinal tracts of the fetus also enters the amniotic cavity (Moore, Persaud, and Torchia, 2013). The amount of fluid increases weekly, and 700 to 1000 mL of transparent liquid is normally present at term. The volume of amniotic fluid changes constantly. The fetus swallows fluid, and fluid flows into and out of the fetal lungs.

CRITICAL THINKING CASE STUDY

Ultrasound Dating of Pregnancy

Sandra believes she is 8 weeks pregnant, but her obstetrician believes she is closer to 12 weeks of gestation. Sandra has come to the clinic for an ultrasound examination for dating. She has many questions for the nurse: How can they tell what gestation she is? What would the fetus look like at this time if she is 8 weeks of gestation? If she is 12 weeks of gestation? What fetal structures would be apparent on ultrasound if she is 8 weeks pregnant? If she is 12 weeks pregnant? Would any structural anomalies be apparent at 8 weeks? At 12 weeks? Why is it important to date a pregnancy accurately?

What information should the nurse provide Sandra?

1. Evidence—Is there sufficient evidence to draw conclusions about what information the nurse should provide Sandra?
2. Assumptions—Describe an underlying assumption about the following factors:
   a. Sandra's motivation to learn about fetal development
   b. Sandra's understanding of fetal development
   c. Sandra's knowledge about ultrasound examinations
   d. Why dating the pregnancy is important
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Beginning in week 11, the fetus urinates into the fluid, increasing its volume.

Amniotic fluid serves many functions. It helps maintain a constant body temperature. It serves as a source of oral fluid and as a repository for waste and assists in maintenance of fluid and electrolyte homeostasis. It cushions the fetus from trauma by blunting and dispersing outside forces. It allows freedom of movement for musculoskeletal development. It acts as a barrier to infection and allows fetal lung development (Moore, Persaud, and Torchia, 2013). The fluid keeps the embryo from tangling with the membranes, facilitating symmetric growth. If the embryo does become tangled with the membranes, amputations of extremities or other deformities can occur from constricting amniotic bands.

The volume of amniotic fluid is an important factor in assessing fetal well-being. Having less than 300 mL of amniotic fluid **(oligohydramnios)** is associated with fetal renal abnormalities. Having more than 2 L of amniotic fluid **(hydramnios)** is associated with gastrointestinal and other malformations.

Amniotic fluid contains albumin, urea, uric acid, creatinine, lecithin, sphingomyelin, bilirubin, fructose, fat, leukocytes, proteins, epithelial cells, enzymes, and lanugo hair. Study of fetal cells in amniotic fluid through amniocentesis yields much information about the fetus. Genetic studies (karyotyping) provide knowledge about the sex and the number and structure of chromosomes. Other studies such as the lecithin/sphingomyelin (L/S) ratio determine the health or maturity of the fetus (see Chapter 10).

Yolk Sac

When the amniotic cavity and amnion are forming, another blastocyst cavity forms on the other side of the developing embryonic disk (see Fig. 6-7, *B*). This cavity becomes surrounded by a membrane, forming the yolk sac. The yolk sac aids in transferring maternal nutrients and oxygen, which have diffused through the chorion, to the embryo. Blood vessels form to aid transport. Blood cells and

plasma are manufactured in the yolk sac during the second and third weeks while uteroplacental circulation is being established and is forming primitive blood cells until hematopoietic activity begins. At the end of the third week, the primitive heart begins to beat and circulate the blood through the embryo, the connecting stalk, the chorion, and the yolk sac.

The folding in of the embryo during the fourth week results in incorporation of part of the yolk sac into the embryo's body as the primitive digestive system. Primordial germ cells arise in the yolk sac and move into the embryo. The shrinking remains of the yolk sac degenerate (see Fig. 6-7, *B*), and by the fifth or sixth week, the remnant has separated from the embryo.

Umbilical Cord

By day 14 after conception, the embryonic disk, the amniotic sac, and the yolk sac are attached to the chorionic villi by the connecting stalk. During the third week, the blood vessels develop to supply the embryo with maternal nutrients and oxygen. During the fifth week, the embryo has curved inward on itself from both ends, bringing the connecting stalk to the ventral side of the embryo. The connecting stalk becomes compressed from both sides by the amnion and forms the narrower umbilical cord (see Fig. 6-7). Two arteries carry blood from the embryo to the chorionic villi, and one vein returns blood to the embryo. Approximately 1% of umbilical cords contain only two vessels: one artery and one vein. This occurrence is sometimes associated with congenital malformations.

The cord rapidly increases in length. At term the cord is 2 cm in diameter and ranges from 30 to 90 cm in length (with an average of 55 cm. It twists spirally on itself and loops around the embryo/fetus. A true knot is rare, but false knots occur as folds or kinks in the cord and may jeopardize circulation to the fetus. Connective tissue called *Wharton's jelly* prevents compression of the blood vessels and ensures continued nourishment of the embryo/fetus. Compression can occur if the cord lies between the fetal head and the pelvis or is twisted around the fetal body. When the cord is wrapped around the fetal neck, it is called a **nuchal cord.**

Because the placenta develops from the chorionic villi, the umbilical cord is usually located centrally. A peripheral location is less common and is known as a *battledore placenta.* The blood vessels are arrayed out from the center to all parts of the placenta (Fig. 6-10).

Placenta

Structure

The placenta begins to form at implantation. During the third week after conception, the trophoblast cells of the chorionic villi continue to invade the decidua basalis. As the uterine capillaries are tapped, the endometrial spiral arteries fill with maternal blood. The chorionic villi grow into the spaces with two layers of cells: the outer syncytium and the inner cytotrophoblast. A third layer develops into anchoring septa, dividing the projecting decidua into separate areas called *cotyledons.* In each of the 15 to 20 cotyledons, the chorionic villi branch out and a complex system of fetal blood vessels forms. Each cotyledon is a functional unit. The whole structure is the placenta (see Fig. 6-10).

The maternal-placental-embryonic circulation is in place by day 17, when the embryonic heart starts beating. By the end of the third week, embryonic blood is circulating between the embryo and the chorionic villi. In the intervillous spaces, maternal blood supplies oxygen and nutrients to the embryonic capillaries in the villi (Fig. 6-11). Waste products and carbon dioxide diffuse into the maternal blood.

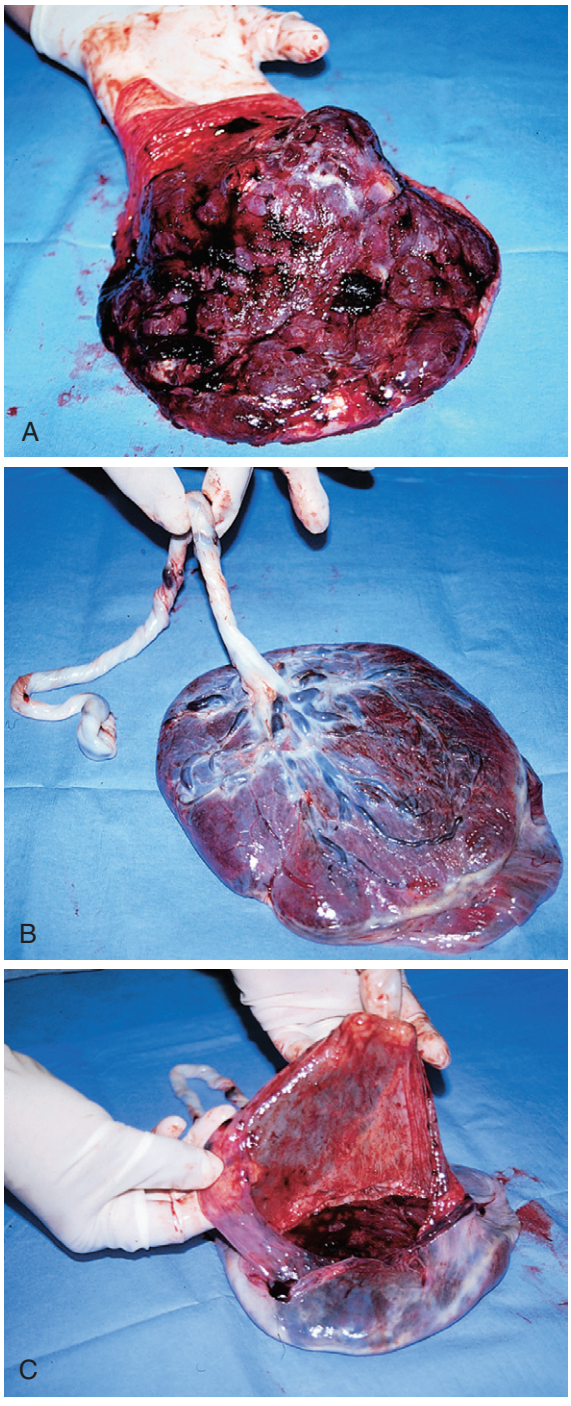

FIG 6-10 Term placenta. **A,** Maternal (or uterine) surface, showing cotyledons and grooves. **B,** Fetal (or amniotic) surface, showing blood vessels running under amnion and converging to form umbilical vessels at attachment of umbilical cord. **C,** Amnion and smooth chorion are arranged to show that they are (1) fused and (2) continuous with margins of placenta. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

The placenta functions as a means of metabolic exchange. Exchange is minimal at this time because the two cell layers of the villous membrane are too thick. Permeability increases as the cytotrophoblast thins and disappears; by the fifth month, only the single layer of syncytium is left between the maternal blood and the fetal

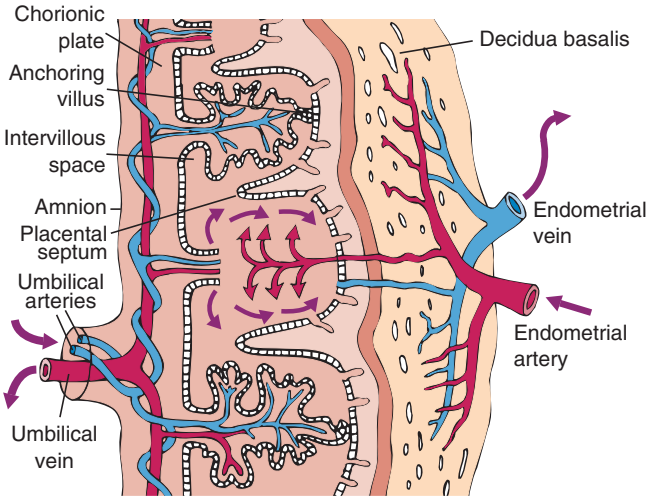

FIG 6-11 Schematic drawing of placenta illustrating how it supplies oxygen and nutrition to embryo and removes its waste products. Deoxygenated blood leaves fetus through the umbilical arteries and enters placenta, where it is oxygenated. Oxygenated blood leaves placenta through the umbilical vein, which enters the fetus via the umbilical cord.

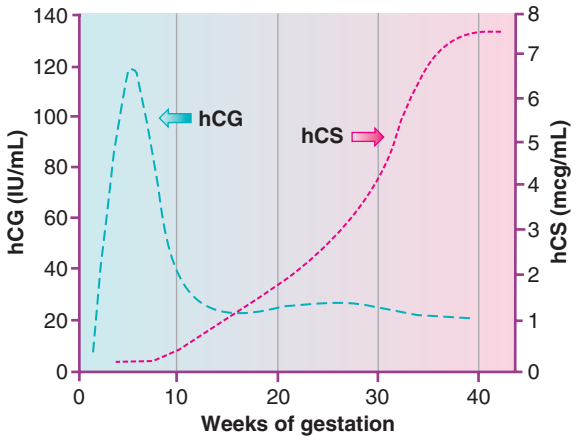

FIG 6-12 Distinct profile for the concentrations of human chorionic gonadotropin (hCG) and human chorionic somatomammotropin (hCS) in serum of women through normal pregnancy. *IU,* International units. (Adapted from Cunningham F, Leveno K, Bloom S, et al: *Williams obstetrics*, ed 23, New York, 2010, McGraw-Hill.)

capillaries. The syncytium is the functional layer of the placenta. By the eighth week, genetic testing may be done on a sample of chorionic villi obtained by aspiration biopsy; however, limb defects have been associated with chorionic villi sampling done before 10 weeks. The structure of the placenta is complete by the twelfth week. The placenta continues to grow wider until 20 weeks, when it covers about half of the uterine surface. It then continues to grow thicker. The branching villi continue to develop within the body of the placenta, increasing the functional surface area.

Functions

One of the early functions of the placenta is as an endocrine gland that produces four hormones necessary to maintain the pregnancy and support the embryo/fetus. The hormones are produced in the syncytium.

The protein hormone *human chorionic gonadotropin* (hCG) can be detected in the maternal serum by 8 to 10 days after conception, shortly after implantation. This hormone is the basis for pregnancy tests. The hCG preserves the function of the ovarian corpus luteum, ensuring a continued supply of estrogen and progesterone needed to maintain the pregnancy. Miscarriage occurs if the corpus luteum stops functioning before the placenta can produce sufficient estrogen and progesterone. The hCG reaches its maximum level at 50 to 70 days and then begins to decrease.

The other protein hormone produced by the placenta is *human chorionic somatomammotropin* (hCS) or *human placental lactogen* (hPL). This substance is similar to a growth hormone and stimulates maternal metabolism to supply needed nutrients for fetal growth. hCS increases the resistance to insulin, facilitates glucose transport across the placental membrane, and stimulates breast development to prepare for lactation (Fig. 6-12).

The placenta eventually produces more of the steroid hormone *progesterone* than the corpus luteum does during the first few months of pregnancy. Progesterone maintains the endometrium, decreases the contractility of the uterus, and stimulates maternal metabolism and development of breast alveoli.

By 7 weeks after fertilization, the placenta is producing most of the maternal estrogens, which are steroid hormones. The major estrogen secreted by the placenta is estriol, whereas the ovaries produce mostly estradiol. Estriol levels may be measured to determine placental functioning. Estrogen stimulates uterine growth and uteroplacental blood flow. It causes a proliferation of the breast glandular tissue and stimulates myometrial contractility. Placental estrogen production increases greatly toward the end of pregnancy. One theory for the cause of the onset of labor is the decrease in circulating levels of progesterone and the increased levels of estrogen (Fig. 6-13).

The metabolic functions of the placenta are respiration, nutrition, excretion, and storage. Oxygen diffuses from the maternal blood across the placental membrane into the fetal blood, and carbon dioxide diffuses in the opposite direction. In this way the placenta functions as lungs for the fetus.

Carbohydrates, proteins, calcium, and iron are stored in the placenta for ready access to meet fetal needs. Water, inorganic salts, carbohydrates, proteins, fats, and vitamins pass from the maternal blood supply across the placental membrane into the fetal blood, supplying nutrition. Water and most electrolytes with a molecular weight less than 500 readily diffuse through the membrane. Hydrostatic and osmotic pressures aid in the flow of water and some solutions. Facilitated and active transport assist in the transfer of glucose, amino acids, calcium, iron, and substances with higher molecular weights. Amino acids and calcium are transported against the concentration gradient between the maternal blood and fetal blood.

The fetal concentration of glucose is lower than the glucose level in the maternal blood because of its rapid metabolism by the fetus. This fetal requirement demands larger concentrations of glucose than simple diffusion can provide. Therefore maternal glucose moves into the fetal circulation by active transport.

Pinocytosis is a mechanism used for transferring large molecules, such as albumin and gamma globulins, across the placental membrane. This mechanism conveys the maternal immunoglobulins that provide early passive immunity to the fetus.

Metabolic waste products of the fetus cross the placental membrane from the fetal blood into the maternal blood. The maternal

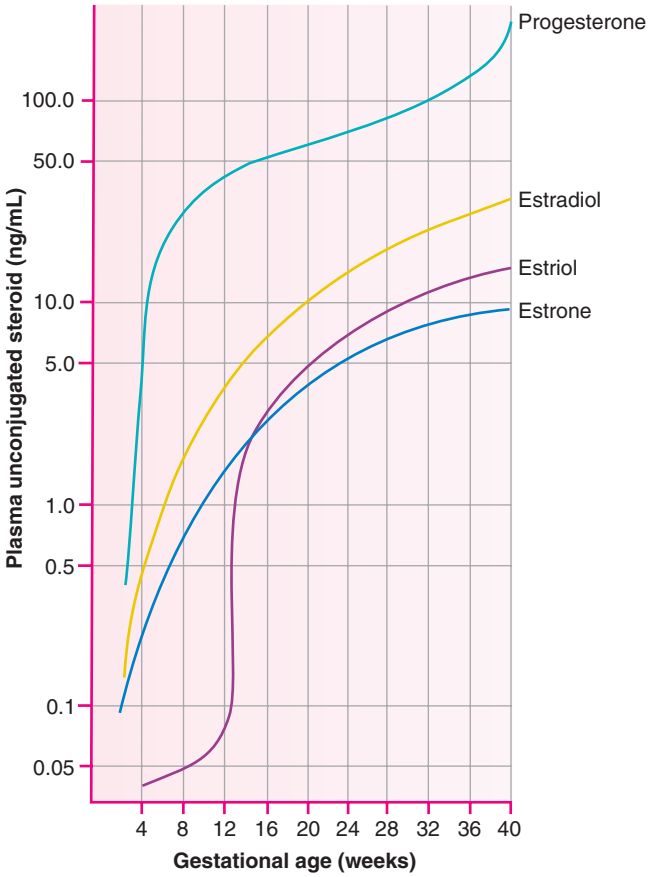

FIG 6-13 Plasma levels of progesterone, estradiol, estrone, and estriol in women during the course of gestation. (From Cunningham F, Leveno K, Bloom S, et al: *Williams obstetrics*, ed 23, New York, 2010, McGraw-Hill.)

kidneys then excrete them. Many viruses can cross the placental membrane and infect the fetus. Some bacteria and protozoa first infect the placenta and then infect the fetus. Drugs can also cross the placental membrane and may harm the fetus. Caffeine, alcohol, nicotine, carbon monoxide and other toxic substances in cigarette smoke, and prescription and recreational drugs (e.g., marijuana, cocaine) readily cross the placenta (Box 6-1).

Although no direct link exists between the fetal blood in the vessels of the chorionic villi and the maternal blood in the intervillous spaces, only one cell layer separates them. Breaks occasionally occur in the placental membrane. Fetal erythrocytes then leak into the maternal circulation, and the mother may develop antibodies to the fetal red blood cells. This is often the way the Rh-negative mother becomes sensitized to the erythrocytes of her Rh-positive fetus (see the discussion of isoimmunization in Chapter 19).

Although the placenta and fetus are analogous to living tissue transplants, they are not destroyed by the host mother (Mor and Abrahams, 2009). Either the placental hormones suppress the immunologic response, or the tissue evokes no response.

Placental function depends on the maternal blood pressure supplying the circulation. Maternal arterial blood, under pressure in the small uterine spiral arteries, spurts into the intervillous spaces (see Fig. 6-11). As long as rich arterial blood continues to be supplied, pressure is exerted on the blood already in the intervillous spaces, pushing it toward drainage by the low-pressure uterine veins. At

term gestation, 10% of the maternal cardiac output goes to the uterus.

If there is interference with the circulation to the placenta, the placenta cannot supply the embryo or fetus. Vasoconstriction, such as that caused by hypertension or cocaine use, diminishes uterine blood flow. Decreased maternal blood pressure or decreased cardiac output also diminishes uterine blood flow.

When a woman lies on her back with the pressure of the uterus compressing the vena cava, blood return to the right atrium is diminished (see Fig. 16-5) and the discussion of supine hypotension in Chapter 16. Excessive maternal exercise that diverts blood to the muscles away from the uterus compromises placental circulation. Optimum circulation is achieved when the woman is lying at rest on her side. Decreased uterine circulation may lead to intrauterine growth restriction of the fetus and infants who are small for gestational age.

Braxton Hicks contractions seem to enhance the movement of blood through the intervillous spaces, aiding placental circulation. However, prolonged contractions or intervals that are too short between contractions during labor can reduce the blood flow to the placenta.

Fetal Maturation

The stage of the fetus lasts from 9 weeks (when the fetus becomes recognizable as a human being) until the pregnancy ends. Changes during the fetal period are not as dramatic, because refinement of structure and function is taking place. The fetus is less vulnerable to teratogens except for those that affect central nervous system functioning.

Viability refers to the capability of the fetus to survive outside the uterus. With modern technology and advances in maternal and neonatal care, infants who are 22 to 25 weeks of gestation are now considered to be on the threshold of viability (Cunningham, Leveno, Bloom, et al., 2010). The limitations on survival outside the uterus when an infant is born at this early stage are based on central nervous system function and oxygenation capability of the lungs.

Fetal Circulatory System

The cardiovascular system is the first organ system to function in the developing human. Blood vessel and blood cell formation begins

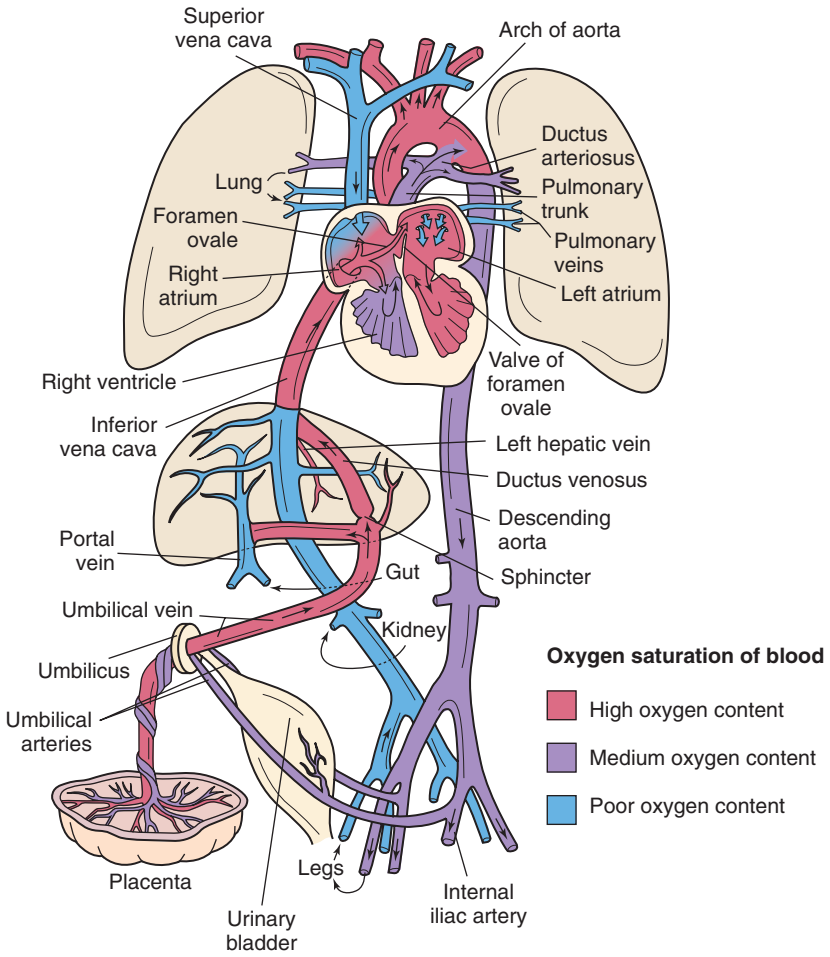

FIG 6-14 Schematic illustration of fetal circulation. The *colors* indicate the oxygen saturation of the blood, and the *arrows* show the course of the blood from the placenta to the heart. The organs are not drawn to scale. Observe that three shunts permit most of the blood to bypass the liver and lungs: (1) ductus venosus, (2) foramen ovale, and (3) ductus arteriosus. A small amount of highly oxygenated blood from the inferior vena cava remains in the right atrium and mixes with poorly oxygenated blood from the superior vena cava. This medium oxygenated blood then passes into the right ventricle. The poorly oxygenated blood returns to the placenta for oxygen and nutrients through the umbilical arteries. (From Moore KL, Persaud TVN, Torchia MG: *Before we are born: essentials of embryology and birth defects,* ed 8, Philadelphia, 2013, Saunders.)

in the third week and supplies the embryo with oxygen and nutrients from the mother. By the end of the third week, the tubular heart begins to beat and the primitive cardiovascular system links the embryo, connecting stalk, chorion, and yolk sac. During the fourth and fifth weeks, the heart develops into a four-chambered organ. By the end of the embryonic stage, the heart is developmentally complete.

The fetal lungs do not function for respiratory gas exchange, so a special circulatory pathway, the ductus arteriosus, bypasses the lungs. Oxygen-rich blood from the placenta flows rapidly through the umbilical vein into the fetal abdomen (Fig. 6-14). When the umbilical vein reaches the liver, it divides into two branches; one branch circulates some oxygenated blood through the liver. Most of the blood passes through the ductus venosus into the inferior vena cava. There it mixes with the deoxygenated blood from the fetal legs and abdomen on its way to the right atrium. Most of this blood passes straight through the right atrium and through the foramen ovale, an opening into the left atrium. There it mixes with the small amount of deoxygenated blood returning from the fetal lungs through the pulmonary veins.

The blood flows into the left ventricle and is squeezed out into the aorta, where the arteries supplying the heart, head, neck, and arms receive most of the oxygen-rich blood. This pattern of supplying the highest levels of oxygen and nutrients to the head, neck, and arms enhances the **cephalocaudal** (head-to-rump) development of the embryo/fetus.

Deoxygenated blood returning from the head and arms enters the right atrium through the superior vena cava. This blood is directed downward into the right ventricle, where it is squeezed into the pulmonary artery. A small amount of blood circulates through the resistant lung tissue, but the majority follows the path with less resistance through the ductus arteriosus into the aorta, distal to the point of exit of the arteries supplying the head and arms with oxygenated blood. The oxygen-poor blood flows through the abdominal aorta into the internal iliac arteries, where the umbilical arteries direct most of it back through the umbilical cord to the placenta.

There the blood gives up its wastes and carbon dioxide in exchange for nutrients and oxygen. The blood remaining in the iliac arteries flows through the fetal abdomen and legs, ultimately returning through the inferior vena cava to the heart.

The following three special characteristics enable the fetus to obtain sufficient oxygen from the maternal blood:

- Fetal hemoglobin carries 20% to 30% more oxygen than maternal hemoglobin.
- The hemoglobin concentration of the fetus is about 50% greater than that of the mother.
- The fetal heart rate (FHR) is 110 to 160 beats/min, making the cardiac output per unit of body weight higher than that of an adult.

Hematopoietic System

Hematopoiesis, the formation of blood, occurs in the yolk sac (see Fig. 6-7, *B*) beginning in the third week. Hematopoietic stem cells seed the fetal liver during the fifth week, and hematopoiesis begins there during the sixth week. This accounts for the relatively large size of the liver between the seventh and ninth weeks. Stem cells seed the fetal bone marrow, spleen and thymus, and lymph nodes between weeks 8 and 11 (for more information about stem cells, see http://stemcells.nih.gov/index.asp).

The antigenic factors that determine blood type are present in the erythrocytes soon after the sixth week. For this reason, the Rh-negative woman is at risk for isoimmunization in any pregnancy that lasts longer than 6 weeks after fertilization.

Respiratory System

The respiratory system begins development during embryonic life and continues through fetal life and into childhood. The development of the respiratory tract begins in week 4 and continues through week 17 with formation of the larynx, trachea, bronchi, and lung buds. Between 16 and 24 weeks, the bronchi and terminal bronchioles enlarge and vascular structures and primitive alveoli are formed. Between 24 weeks and term birth, more alveoli form. Specialized alveolar cells, type I and type II cells, secrete pulmonary surfactants to line the interior of the alveoli. After 32 weeks, sufficient surfactant is present in developed alveoli to provide infants with a good chance of survival.

Pulmonary Surfactants

The detection of the presence of pulmonary surfactants, surface-active phospholipids, in amniotic fluid has been used to determine the degree of fetal lung maturity, or the ability of the lungs to function after birth. Lecithin (L) is the most critical alveolar surfactant required for postnatal lung expansion. It is detectable at approximately 21 weeks and increases in amount after week 24. Another pulmonary phospholipid, sphingomyelin (S), remains constant in amount. Thus the measure of lecithin in relation to sphingomyelin, or the L/S ratio, is used to determine fetal lung maturity. When the L/S ratio reaches 2:1, the infant's lungs are considered to be mature. This occurs at approximately 35 weeks of gestation (Mercer, 2009).

Certain maternal conditions that cause decreased maternal placental blood flow, such as maternal hypertension, placental dysfunction, infection, or corticosteroid use, accelerate lung maturity. This apparently is caused by the resulting fetal hypoxia, which stresses the fetus and increases the blood levels of corticosteroids that accelerate alveolar and surfactant development.

Conditions such as gestational diabetes and chronic glomerulonephritis can retard fetal lung maturity. The use of intrabronchial synthetic surfactant in the treatment of respiratory distress syndrome in the newborn has greatly improved the chances of survival for preterm infants.

Fetal respiratory movements have been seen on ultrasound as early as week 11. These fetal respiratory movements may aid in development of the chest wall muscles and regulate lung fluid volume. The fetal lungs produce fluid that expands the air spaces in the lungs. The fluid drains into the amniotic fluid or is swallowed by the fetus.

Shortly before birth, secretion of lung fluid decreases. The normal birth process squeezes out approximately one third of the fluid. Infants of cesarean births do not benefit from this squeezing process; thus they may have more respiratory difficulty at birth. The fluid remaining in the lungs at birth is usually resorbed into the infant's bloodstream within 2 hours of birth.

Gastrointestinal System

During the fourth week, the shape of the embryo changes from being almost straight to a C shape as both ends fold in toward the ventral surface. A portion of the yolk sac is incorporated into the body from head to tail as the primitive gut (digestive system).

The foregut produces the pharynx, part of the lower respiratory tract, the esophagus, the stomach, the first half of the duodenum, the liver, the pancreas, and the gallbladder. These structures evolve during the fifth and sixth weeks. Malformations that can occur in these areas include esophageal atresia, hypertrophic pyloric stenosis, duodenal stenosis or atresia, and biliary atresia (see Chapter 41).

The midgut becomes the distal half of the duodenum, the jejunum and ileum, the cecum and appendix, and the proximal half of the colon. The midgut loop projects into the umbilical cord between weeks 5 and 10. A malformation, omphalocele, results if the midgut fails to return to the abdominal cavity, causing the intestines to protrude from the umbilicus. Meckel diverticulum is the most common malformation of the midgut. It occurs when a remnant of the yolk stalk that failed to degenerate attaches to the ileum, leaving a blind sac.

The hindgut develops into the distal half of the colon, the rectum and parts of the anal canal, the urinary bladder, and the urethra. Anorectal malformations are the most common abnormalities of the digestive system.

The fetus swallows amniotic fluid beginning in the fifth month. Gastric emptying and intestinal peristalsis occur. Fetal nutrition and elimination needs are taken care of by the placenta. As the fetus nears term, fetal waste products accumulate in the intestines as dark-green to black, tarry meconium. Normally this substance is passed through the rectum within 24 hours of birth. Sometimes with a breech presentation or fetal hypoxia, meconium is passed in utero into the amniotic fluid. The failure to pass meconium after birth may indicate atresia somewhere in the digestive tract; an imperforate anus (Fig. 6-15); or meconium ileus, in which a firm meconium plug blocks passage (seen in infants with cystic fibrosis).

The metabolic rate of the fetus is relatively low, but the infant has great growth and development needs. Beginning in week 9, the fetus synthesizes glycogen for storage in the liver. Between 26 and 30 weeks, the fetus begins to lay down stores of brown fat in preparation for extrauterine cold stress. Thermoregulation in the neonate requires increased metabolism and adequate oxygenation.

The gastrointestinal system is mature by 36 weeks. Digestive enzymes (except pancreatic amylase and lipase) are present in sufficient quantity to facilitate digestion. The neonate cannot digest starches or fats efficiently. Little saliva is produced.

FIG 6-15 Anorectal malformation (imperforate anus). (From Chessell GSJ, Jamieson MJ, Morton RA, et al: *Diagnostic picture tests in clinical medicine* (vol 2), St Louis, 1984, Mosby.)

Hepatic System

The liver and biliary tract develop from the foregut during the fourth week of gestation. Hematopoiesis begins during the sixth week and requires that the liver be large. The embryonic liver is prominent, occupying most of the abdominal cavity. Bile, a constituent of meconium, begins to form in the twelfth week.

Glycogen is stored in the fetal liver beginning at week 9 or 10. At term, glycogen stores are twice those of the adult. Glycogen is the major source of energy for the fetus and for the neonate stressed by in utero hypoxia, extrauterine loss of the maternal glucose supply, the work of breathing, or cold stress.

Iron is also stored in the fetal liver. If maternal intake is sufficient, the fetus can store enough iron to last for 5 months after birth.

During fetal life, the liver does not have to conjugate bilirubin for excretion because the unconjugated bilirubin is cleared by the placenta. Therefore the glucuronyl transferase enzyme needed for conjugation is present in the fetal liver in amounts less than those required after birth. This predisposes the neonate, especially the preterm infant, to hyperbilirubinemia.

Coagulation factors II, VII, IX, and X cannot be synthesized in the fetal liver because of the lack of vitamin K synthesis in the sterile fetal gut. This coagulation deficiency persists after birth for several days and is the rationale for the prophylactic administration of vitamin K to the newborn.

Renal System

The kidneys form during the fifth week and begin to function approximately 4 weeks later. Urine is excreted into the amniotic fluid and forms a major part of the amniotic fluid volume. Oligohydramnios is indicative of renal dysfunction. Because the placenta acts as the organ of excretion and maintains fetal water and electrolyte balance, the fetus does not need functioning kidneys while in utero. At birth, however, the kidneys are required immediately for excretory and acid-base regulatory functions.

A fetal renal malformation can be diagnosed in utero. Corrective or palliative fetal surgery may treat the malformation successfully, or plans can be made for treatment immediately after birth.

At term, the fetus has fully developed kidneys. However, the glomerular filtration rate (GFR) is low, and the kidneys lack the ability to concentrate urine. This makes the newborn more susceptible to both overhydration and dehydration.

Neurologic System

The nervous system originates from the ectoderm during the third week after fertilization. The open neural tube forms during the fourth week. It initially closes at what will be the junction of the brain and spinal cord, leaving both ends open. The embryo folds in on itself lengthwise at this time, forming a head fold in the neural tube at this junction. The cranial end of the neural tube closes, and then the caudal end closes. During week 5, different growth rates cause more flexures in the neural tube, delineating three brain areas: the forebrain, the midbrain, and the hindbrain.

The forebrain develops into the eyes (cranial nerve II) and cerebral hemispheres. The development of all areas of the cerebral cortex continues throughout fetal life and into childhood. The olfactory system (cranial nerve I) and thalamus also develop from the forebrain. Cranial nerves III and IV (oculomotor and trochlear) form from the midbrain. The hindbrain forms the medulla, the pons, the cerebellum, and the remainder of the cranial nerves. Brain waves can be recorded on an electroencephalogram by week 8.

The spinal cord develops from the long end of the neural tube. Another ectodermal structure, the neural crest, develops into the peripheral nervous system. By the eighth week, nerve fibers traverse throughout the body. By week 11 or 12 the fetus makes respiratory movements, moves all extremities, and changes position in utero. The fetus can suck his or her thumb, swim in the amniotic fluid pool, and turn somersaults and can occasionally tie a knot in the umbilical cord.

At term, the fetal brain is approximately one-fourth the size of an adult brain. Neurologic development continues. Stressors on the fetus and neonate (e.g., chronic poor nutrition or hypoxia, drugs, environmental toxins, trauma, disease) damage the central nervous system long after the vulnerable embryonic time for malformations in other organ systems. Neurologic insult can result in cerebral palsy, neuromuscular impairment, intellectual disability, and learning disabilities.

Sensory Awareness

Purposeful movements of the fetus have been demonstrated in response to a firm touch transmitted through the mother's abdomen. Because it can feel, the fetus requires anesthesia when invasive procedures are done.

Fetuses respond to sound by 24 weeks. Different types of music evoke different movements. The fetus can be soothed by the sound of the mother's voice. Acoustic stimulation can be used to evoke a fetal heart rate response. The fetus becomes accustomed (habituates) to noises heard repeatedly. Hearing is fully developed at birth.

The fetus is able to distinguish taste. By the fifth month, when the fetus is swallowing amniotic fluid, a sweetener added to the fluid causes the fetus to swallow faster. The fetus also reacts to temperature changes. A cold solution placed into the amniotic fluid can cause fetal hiccups.

The fetus can see. Eyes have both rods and cones in the retina by the seventh month. A bright light shone on the mother's abdomen in late pregnancy causes abrupt fetal movements. During sleep time, rapid eye movements (REMs) have been observed similar to those occurring in children and adults while dreaming.

Endocrine System

The thyroid gland develops along with structures in the head and neck during the third and fourth weeks. The secretion of thyroxine

begins during the eighth week. Maternal thyroxine does not readily cross the placenta; therefore the fetus that does not produce thyroid hormones will be born with congenital hypothyroidism. If untreated, hypothyroidism can result in severe intellectual disability. Screening for hypothyroidism is typically included in newborn screening after birth.

The adrenal cortex is formed during the sixth week and produces hormones by the eighth or ninth week. As term approaches, the fetus produces more cortisol. This is believed to aid in initiation of labor by decreasing the maternal progesterone and stimulating production of prostaglandins.

The pancreas forms from the foregut during the fifth through eighth weeks. The islets of Langerhans develop during the twelfth week. Insulin is produced by week 20. In fetuses of mothers with uncontrolled diabetes, maternal hyperglycemia produces fetal hyperglycemia, stimulating hyperinsulinemia and islet cell hyperplasia. This results in a macrosomic (large) fetus. The hyperinsulinemia also blocks lung maturation, placing the neonate at risk for respiratory distress and hypoglycemia when the maternal glucose source is lost at birth. Control of the maternal glucose level before and during pregnancy minimizes problems for the fetus and infant.

Reproductive System

Sex differentiation begins in the embryo during the seventh week. Female and male external genitalia are indistinguishable until after the ninth week. Distinguishing characteristics appear around the ninth week and are fully differentiated by the twelfth week. When a Y chromosome is present, testes are formed. By the end of the embryonic period, testosterone is being secreted and causes formation of the male genitalia. By week 28, the testes begin descending into the scrotum. After birth, low levels of testosterone continue to be secreted until the pubertal surge.

The female, with two X chromosomes, forms ovaries and female external genitalia. By the sixteenth week, oogenesis has been established. At birth, the ovaries contain the female's lifetime supply of ova. Most female hormone production is delayed until puberty. However, the fetal endometrium responds to maternal hormones, and withdrawal bleeding or vaginal discharge **(pseudomenstruation)** may occur at birth when these hormones are lost. The high level of maternal estrogen also stimulates mammary engorgement and secretion of fluid ("witch's milk") in newborn infants of both sexes.

Musculoskeletal System

Bones and muscles develop from the mesoderm by the fourth week of embryonic development. At that time, the cardiac muscle is already beating. The mesoderm next to the neural tube forms the vertebral column and ribs. The parts of the vertebral column grow toward each other to enclose the developing spinal cord. Ossification, or bone formation, begins. If there is a defect in the bony fusion, various forms of spina bifida can occur. A large defect affecting several vertebrae may allow the membranes and spinal cord to pouch out from the back, producing neurologic deficits and skeletal deformity.

The flat bones of the skull develop during the embryonic period, and ossification continues throughout childhood. At birth, connective tissue sutures exist where the bones of the skull meet. The areas where more than two bones meet (called fontanels) are especially prominent. The sutures and fontanels allow the bones of the skull to mold, or move during birth, enabling the head to pass through the birth canal.

The bones of the shoulders, arms, hips, and legs appear in the sixth week as a continuous skeleton with no joints. Differentiation occurs, producing separate bones and joints. Ossification will continue through childhood to allow growth. Beginning in the seventh week, muscles contract spontaneously. Arm and leg movements are visible on ultrasound examination although the mother does not perceive them until sometime between 16 and 20 weeks.

Integumentary System

The epidermis begins as a single layer of cells derived from the ectoderm at 4 weeks. By the seventh week, there are two layers of cells. The cells of the superficial layer are sloughed and become mixed with the sebaceous gland secretions to form the white, cheesy **vernix caseosa,** the material that protects the skin of the fetus. The vernix is thick at 24 weeks but becomes scant by term.

The basal layer of the epidermis is the germinal layer, which replaces lost cells. Until 17 weeks, the skin is thin and wrinkled, with blood vessels visible underneath. The skin thickens, and all layers are present at term. After 32 weeks, as subcutaneous fat is deposited under the dermis, the skin becomes less wrinkled and red in appearance.

By 16 weeks, the epidermal ridges are present on the palms of the hands, the fingers, the bottom of the feet, and the toes. These handprints and footprints are unique to that infant.

Hairs form from hair bulbs in the epidermis that project into the dermis. Cells in the hair bulb keratinize to form the hair shaft. As the cells at the base of the hair shaft proliferate, the hair grows to the surface of the epithelium. Very fine hairs, called **lanugo,** appear first at 12 weeks on the eyebrows and upper lip. By 20 weeks, they cover the entire body. At this time, the eyelashes, eyebrows, and scalp hair are beginning to grow. By 28 weeks, the scalp hair is longer than the lanugo, which thins and may disappear by term gestation.

Fingernails and toenails develop from thickened epidermis at the tips of the digits beginning during the tenth week. They grow slowly. Fingernails usually reach the fingertips by 32 weeks, and toenails reach toe tips by 36 weeks.

Immunologic System

During the third trimester, albumin and globulin are present in the fetus. The only immunoglobulin (Ig) that crosses the placenta, IgG, provides passive acquired immunity to specific bacterial toxins. The fetus produces IgM by the end of the first trimester. This is produced in response to blood group antigens, gram-negative enteric organisms, and some viruses. IgA is not produced by the fetus; however, colostrum, the precursor to breast milk, contains large amounts of IgA and can provide passive immunity to the neonate who is breastfed.

The normal term neonate can fight infection but not as effectively as an older child. The preterm infant is at much greater risk for infection.

Table 6-1 summarizes embryonic and fetal development.

MULTIFETAL PREGNANCY

Twins

The incidence of twinning is 1 in 43 pregnancies. There has been a steady rise in multiple births since 1973 (Benirschke, 2009). This is partly attributed to the availability of assisted reproductive technologies and the increasing age at which women give birth (Malone and D'Alton, 2009).

TABLE 6-1 MILESTONES IN HUMAN DEVELOPMENT BEFORE BIRTH SINCE LAST MENSTRUAL PERIOD (LMP)

4 WEEKS	8 WEEKS	12 WEEKS
External Appearance		
Body flexed, C shaped; arm and leg buds present; head at right angles to body	Body fairly well formed; nose flat, eyes far apart; digits well formed; head elevating; tail almost disappeared; eyes, ears, nose, and mouth recognizable	Nails appearing; resembles a human; head erect but disproportionately large; skin pink, delicate
Crown-to-Rump Measurement; Weight		
0.4 to 0.5 cm; 0.4 g	2.5 to 3 cm; 2 g	6 to 9 cm; 19 g
Gastrointestinal System		
Stomach at midline and fusiform; conspicuous liver; esophagus short; intestine a short tube	Intestinal villi developing; small intestines coil within umbilical cord; palatal folds present; liver very large	Bile secreted; palatal fusion complete; intestines have withdrawn from cord and assume characteristic positions
Musculoskeletal System		
All somites present	First indication of ossification—occiput, mandible, and humerus; fetus capable of some movement; definitive muscles of trunk, limbs, and head well represented	Some bones well outlined, ossification spreading; upper cervical to lower sacral arches and bodies ossify; smooth muscle layers indicated in hollow viscera
Circulatory System		
Heart develops, double chambers visible, begins to beat; aortic arch and major veins completed	Main blood vessels assume final plan; enucleated red cells predominate in blood	Blood forming in marrow
Respiratory System		
Primary lung buds appear	Pleural and pericardial cavities forming; branching bronchioles; nostrils closed by epithelial plugs	Lungs acquire definite shape; vocal cords appear
Renal System		
Rudimentary ureteral buds appear	Earliest secretory tubules differentiating; bladder-urethra separates from rectum	Kidneys able to secrete urine; bladder expands as a sac
Nervous System		
Well-marked midbrain flexure; no hindbrain or cervical flexures; neural groove closed	Cerebral cortex begins to acquire typical cells; differentiation of cerebral cortex, meninges, ventricular foramina, cerebrospinal fluid circulation; spinal cord extends entire length of spine	Brain structural configuration almost complete; cord shows cervical and lumbar enlargements; fourth ventricle foramina are developed; sucking present
Sensory Organs		
Eye and ear appearing as optic vessel and otocyst	Primordial choroid plexuses develop; ventricles large relative to cortex; development progressing; eyes converging rapidly; internal ears developing	Earliest taste buds indicated; characteristic organization of eyes attained
Genital System		
Genital ridge appears (fifth week)	Testes and ovaries distinguishable; external genitalia sexless but begin to differentiate	Sex recognizable; internal and external sex organs specific

Continued

TABLE 6-1 MILESTONES IN HUMAN DEVELOPMENT BEFORE BIRTH SINCE LAST MENSTRUAL PERIOD (LMP)—cont'd

16 WEEKS	20 WEEKS	24 WEEKS
External Appearance		
Head still dominant; face looks human; eyes, ears, and nose approach typical appearance on gross examination; arm/leg ratio proportionate; scalp hair appears	Vernix caseosa appears; lanugo appears; legs lengthen considerably; sebaceous glands appear	Body lean but fairly well proportioned; skin red and wrinkled; vernix caseosa present; sweat glands forming
Crown-to-Rump Measurement; Weight		
11.5 to 13.5 cm; 100 g	16 to 18.5 cm; 300 g	23 cm; 600 g
Gastrointestinal System		
Meconium in bowel; some enzyme secretion; anus open	Enamel and dentine depositing; ascending colon recognizable	
Musculoskeletal System		
Most bones distinctly indicated throughout body; joint cavities appear; muscular movements can be detected	Sternum ossifies; fetal movements strong enough for mother to feel	
Circulatory System		
Heart muscle well developed; blood formation active in spleen		Blood formation increases in bone marrow and decreases in liver
Respiratory System		
Elastic fibers appear in lungs; terminal and respiratory bronchioles appear	Nostrils reopen; primitive respiratory-like movements begin	Alveolar ducts and sacs present; lecithin begins to appear in amniotic fluid (weeks 26 to 27)
Renal System		
Kidneys in position; attain typical shape		
Nervous System		
Cerebral lobes delineated; cerebellum assumes some prominence	Brain grossly formed; cord myelination begins; spinal cord ends at level of first sacral vertebra (S-1)	Cerebral cortex layered typically; neuronal proliferation in cerebral cortex ends
Sensory Organs		
General sense organs differentiated	Nose and ears ossify	Can hear
Genital System		
Testes in position for descent into scrotum; vagina open		Testes at inguinal ring in descent to scrotum

TABLE 6-1 MILESTONES IN HUMAN DEVELOPMENT BEFORE BIRTH SINCE LAST MENSTRUAL PERIOD (LMP)—cont'd

28 WEEKS	30-31 WEEKS	36 AND 40 WEEKS
External Appearance Lean body, less wrinkled and red; nails appear	Subcutaneous fat beginning to collect; more rounded appearance; skin pink and smooth; has assumed birth position 	***36 Weeks*** Skin pink, body rounded; general lanugo disappearing; body usually plump ***40 Weeks*** Skin smooth and pink; scant vernix caseosa; moderate to profuse hair; lanugo on shoulders and upper body only; nasal and alar cartilage apparent
Crown-to-Rump Measurement; Weight 27 cm; 1100 g	31 cm; 1800 to 2100 g	***36 Weeks*** 35 cm; 2200 to 2900 g ***40 Weeks*** 40 cm; 3200+ g
Musculoskeletal System Astragalus (talus, ankle bone) ossifies; weak, fleeting movements, minimum tone	Middle fourth phalanxes ossify; permanent teeth primordia seen; can turn head to side	***36 Weeks*** Distal femoral ossification centers present; sustained, definite movements; fair tone; can turn and elevate head ***40 Weeks*** Active, sustained movement; good tone; may lift head
Respiratory System Lecithin forming on alveolar surfaces	L/S ratio = 1.2 : 1	***36 Weeks*** L/S ratio ≥2 : 1 ***40 Weeks*** Pulmonary branching only two-thirds complete
Renal System		***36 Weeks*** Formation of new nephrons ceases
Nervous System Appearance of cerebral fissures, convolutions rapidly appearing; indefinite sleep-wake cycle; cry weak or absent; weak suck reflex		***36 Weeks*** End of spinal cord at level of third lumbar vertebra (L-3); definite sleep-wake cycle ***40 Weeks*** Myelination of brain begins; patterned sleep-wake cycle with alert periods; cries when hungry or uncomfortable; strong suck reflex
Sensory Organs Eyelids reopen; retinal layers completed, light receptive; pupils capable of reacting to light	Sense of taste present; aware of sounds outside mother's body	
Genital System	Testes descending to scrotum	***40 Weeks*** Testes in scrotum; labia majora well developed

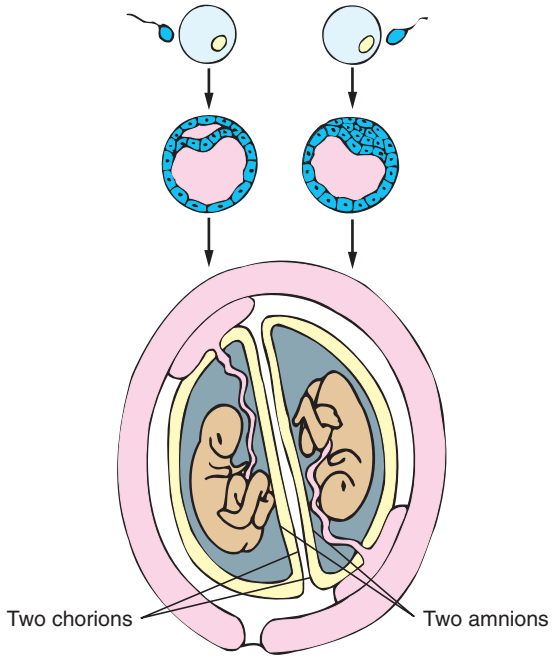

FIG 6-16 Formation of dizygotic twins. There is fertilization of two ova, two implantations, two placentas, two chorions, and two amnions.

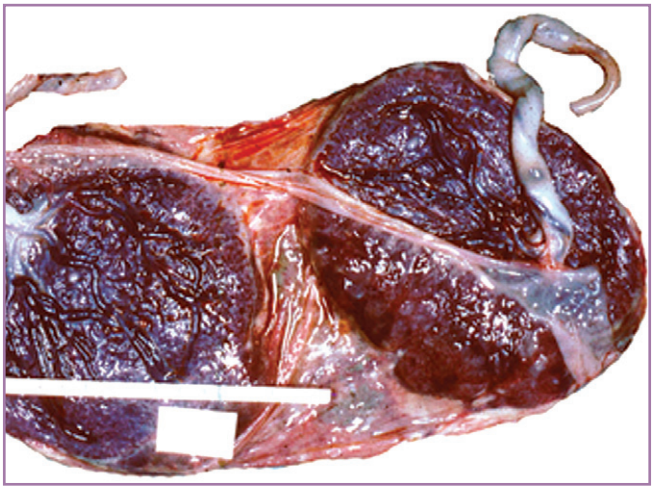

FIG 6-17 Diamniotic dichorionic (separate) twin placentas. (From Benirschke K: Multiple gestation: the biology of twinning. In Creasy R, Resnik R, Iams J, et al, editors: *Creasy & Resnik's maternal-fetal medicine: principles and practice,* ed 6, Philadelphia, 2009, Saunders.)

Dizygotic Twins

When two mature ova are produced in one ovarian cycle, both have the potential to be fertilized by separate sperm. This results in two zygotes, or dizygotic twins (Fig. 6-16). There are always two amnions, two chorions, and two placentas that may be fused (Fig. 6-17). These dizygotic or fraternal twins may be the same sex or different sexes and are genetically no more alike than siblings born at different times. Dizygotic twinning occurs in families with a history of twinning, more often among African-American women than Caucasian women, and least often among Asian-American women. Dizygotic twinning increases in frequency with maternal age up to 35 years, with parity, and with the use of fertility drugs.

Monozygotic Twins

Identical or monozygotic twins develop from one fertilized ovum, which then divides (Fig. 6-18). They are the same sex and have the same genotype. If division occurs soon after fertilization, two embryos, two amnions, two chorions, and two placentas that may be fused will develop. Most often, division occurs between 4 and 8 days after fertilization, and there are two embryos, two amnions, one chorion, and one placenta. Rarely, division occurs after the eighth day after fertilization. In this case, there are two embryos within a common amnion and a common chorion with one placenta. This often causes circulatory problems because the umbilical cords may tangle together and one or both fetuses may die. If division occurs very late, cleavage may not be complete and conjoined or "Siamese" twins could result. Monozygotic twinning occurs in approximately 3.5 to 4 per 1000 births (Benirschke, 2009). There is no association with race, heredity, maternal age, or parity. Fertility drugs increase the incidence of monozygotic twinning.

Conjoined Twins

Conjoined twins are a type of monozygotic twins in which there is incomplete embryonic division at 13 to 15 days postconception (see Fig. 6-18). The estimated frequency is 1 in 50,000 births (Malone and D'Alton, 2009). Prenatal diagnosis is possible with three-dimensional ultrasonography. Cesarean birth minimizes trauma to mother and fetuses.

Other Multifetal Pregnancies

The occurrence of multifetal pregnancies with three or more fetuses has increased with the use of fertility drugs and in vitro fertilization. Triplets occur in about 1 of 1341 pregnancies (Benirschke, 2009). They can occur from the division of one zygote into two, with one of the two dividing again, producing identical triplets. Triplets can also be produced (1) from two zygotes, one dividing into a set of identical twins and the second zygote a single fraternal sibling or (2) from three zygotes. Quadruplets, quintuplets, sextuplets, and so on have similar possible derivations.

NONGENETIC FACTORS INFLUENCING DEVELOPMENT

Congenital disorders may be inherited or may be caused by environmental factors or by inadequate maternal nutrition. *Congenital* means that the condition was present at birth. Some congenital malformations may be the result of teratogens, that is, environmental substances or exposures that result in functional or structural disability. In contrast to other forms of developmental disabilities, disabilities caused by teratogens are theoretically totally preventable. Known human teratogens are drugs and chemicals, infections, exposure to radiation, and certain maternal conditions such as diabetes and PKU (Box 6-2). A teratogen has the greatest effect on the organs and parts of an embryo during its periods of rapid growth and differentiation. This occurs during the embryonic period, specifically from days 15 to 60. During the first 2 weeks of development, teratogens either have no effect on the embryo or have effects so severe that they cause miscarriage. Brain

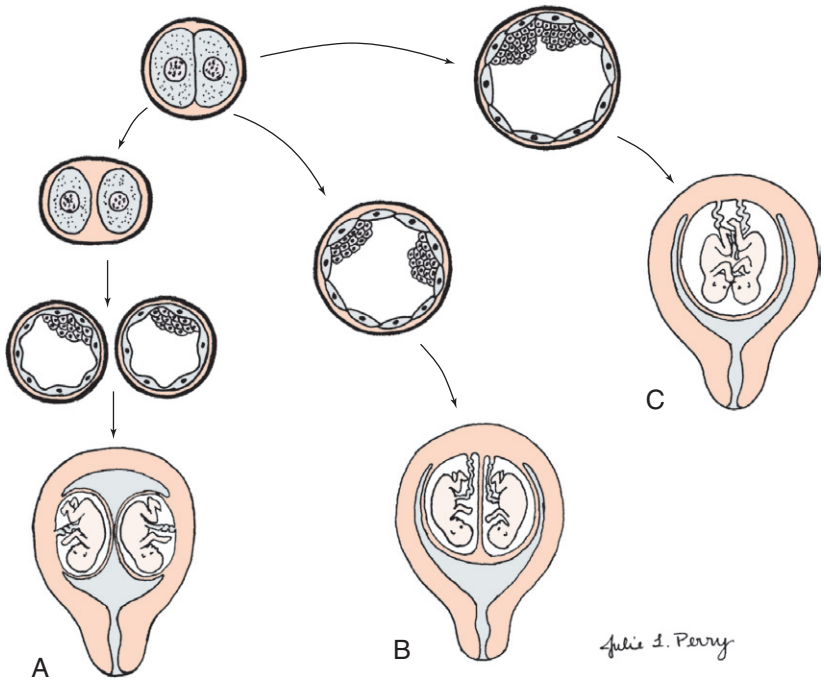

FIG 6-18 Formation of monozygotic twins. **A,** One fertilization: blastomeres separate, resulting in two implantations, two placentas, and two sets of membranes. **B,** One blastomere with two inner cell masses, one fused placenta, one chorion, and separate amnions. **C,** One blastomere with incomplete separation of cell mass resulting in conjoined twins.

BOX 6-2 ETIOLOGY OF HUMAN MALFORMATIONS

Environmental

- Maternal conditions
  - Alcoholism, diabetes, endocrinopathies, phenylketonuria, smoking, nutritional problems
- Infectious agents
  - Rubella, toxoplasmosis, syphilis, herpes simplex, cytomegalic inclusion disease, varicella, Venezuelan equine encephalitis
- Mechanical problems (deformations)
  - Amniotic band constrictions, umbilical cord constraint, disparity in uterine size and uterine contents
- Chemicals, drugs, radiation, hyperthermia

Genetic

- Single-gene disorders
- Chromosomal abnormalities

Unknown

- Polygenic/multifactorial (gene-environment interactions)
- "Spontaneous" errors of development
- Other unknowns

Adapted from Parikh AS, Wiesner GL: Congenital anomalies. In Martin RJ, Fanaroff AA, Walsh MC, editors: *Fanaroff and Martin's neonatal-perinatal medicine: diseases of the fetus and infant,* ed 9, Philadelphia, 2011, Mosby.

growth and development continue during the fetal period, and teratogens can severely affect mental development throughout gestation (Fig. 6-19).

In addition to genetic makeup and the influence of teratogens, the adequacy of maternal nutrition influences development. The embryo and fetus must obtain the nutrients they need from the mother's diet; they cannot tap the maternal reserves. Malnutrition during pregnancy produces low-birth-weight newborns who are susceptible to infection. Malnutrition also affects brain development during the latter half of gestation and can result in learning disabilities in the child. Inadequate folic acid is associated with neural tube defects.

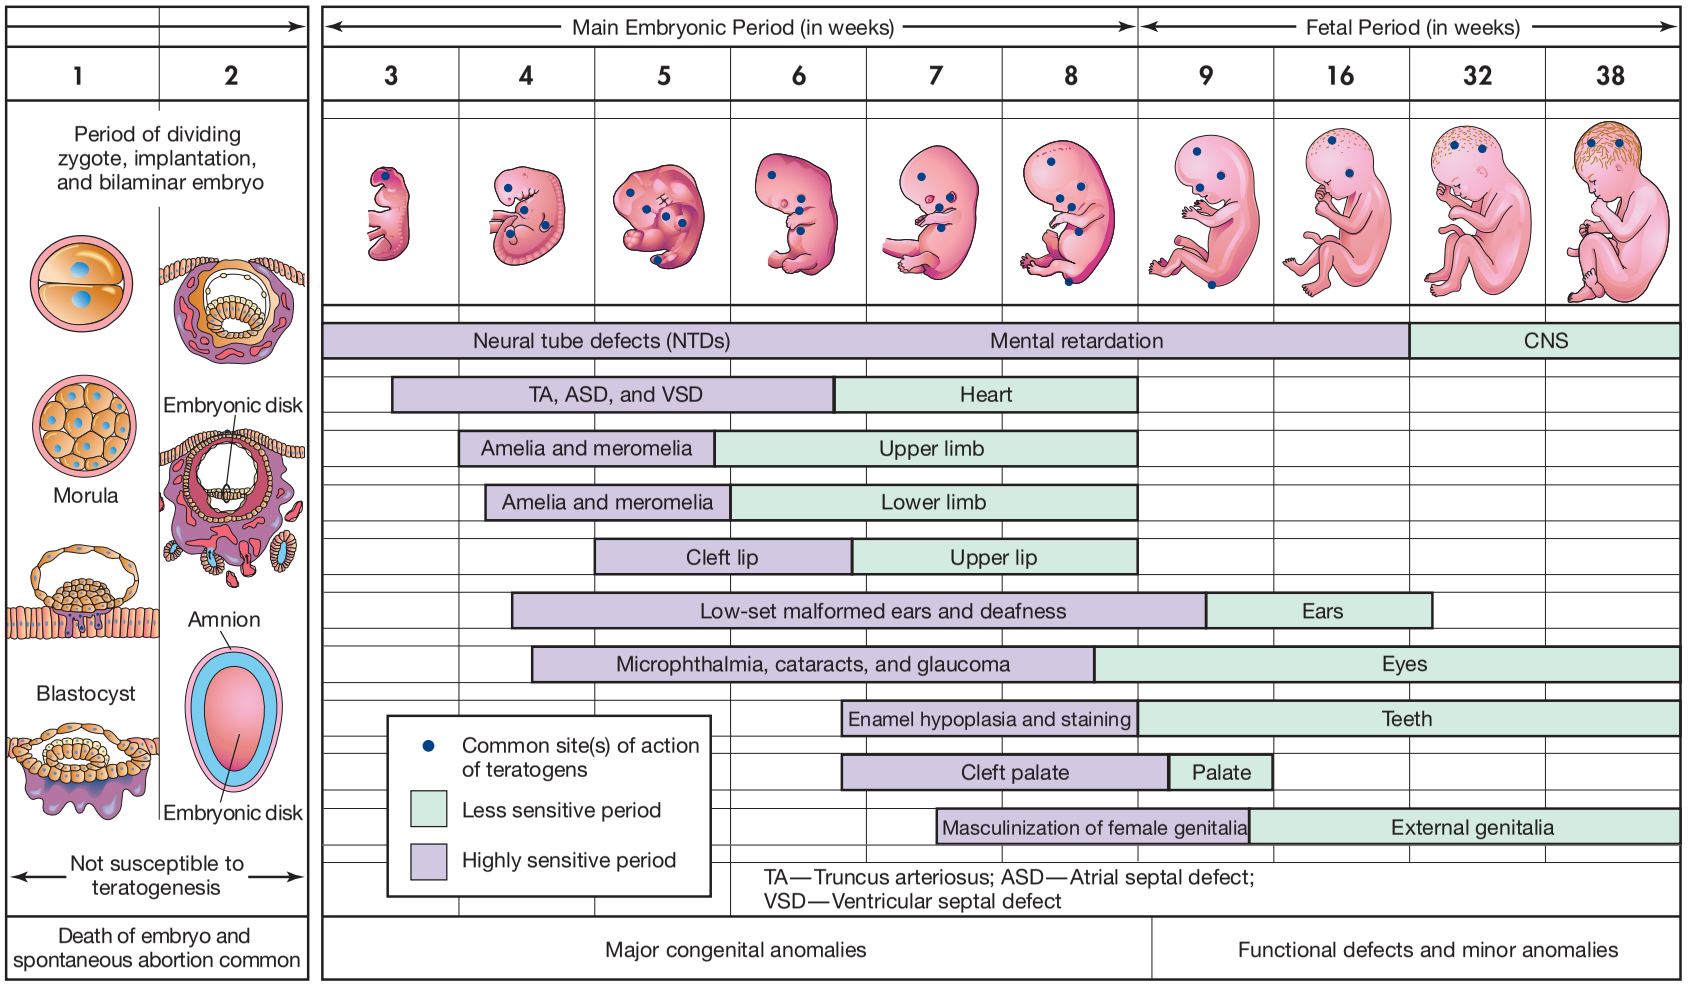

FIG 6-19 Critical periods in human development. *Dark color* denotes highly sensitive periods; *light color* indicates stages that are less sensitive to teratogens. *CNS,* Central nervous system. (From Moore KL, Persaud TVN, Torchia MG: *Before we are born: essentials of embryology and birth defects,* ed 8, Philadelphia, 2013, Saunders.)

KEY POINTS

- Genetic disease affects people of all ages, from all socioeconomic levels, and from all racial and ethnic backgrounds.
- Nurses in all clinical specialties with advanced preparation are assuming important roles in genetic counseling.
- Pharmacogenomics will probably be the most immediate clinical application of the Human Genome Project.
- Genes are the basic units of heredity responsible for all human characteristics. They comprise 23 pairs of chromosomes: 22 pairs of autosomes and one pair of sex chromosomes.
- Chromosomal abnormalities occur in both autosomes and sex chromosomes.
- Multifactorial inheritance includes both genetic and environmental contributions.
- Human gestation is approximately 280 days after the LMP or 266 days after conception.
- Fertilization occurs in the uterine tube within 24 hours of ovulation. The zygote undergoes mitotic divisions, creating a 16-cell morula.
- The organ systems and external features develop during the embryonic period, that is, the third to the eighth week after fertilization.
- During critical periods in human development, the embryo and fetus are vulnerable to environmental teratogens.
- There has been a steady rise in the incidence of multifetal pregnancies, which is partly due to ART and the increasing age at which women give birth.

CHAPTER

7

Anatomy and Physiology of Pregnancy

Kathryn R. Alden

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Determine gravidity and parity using the two- and five-digit systems.
- Describe the various types of pregnancy tests, including the timing of tests and interpretation of results.
- Explain the expected maternal anatomic and physiologic adaptations to pregnancy.
- Differentiate among presumptive, probable, and positive signs of pregnancy.
- Identify maternal hormones produced during pregnancy, their target organs, and their major effects on pregnancy.
- Compare the characteristics of the abdomen, vulva, and cervix of the nullipara and multipara.

The goal of maternity care is a healthy pregnancy with a physically safe and emotionally satisfying outcome for mother, infant, and family. Consistent health supervision and surveillance are of utmost importance. However, many maternal adaptations are unfamiliar to pregnant women and their families. Helping the pregnant woman recognize the relationship between her physical status and the plan for her care assists her in making decisions and encourages her to participate in her own care.

GRAVIDITY AND PARITY

An understanding of the following terms used to describe pregnancy and the pregnant woman (Cunningham, Leveno, Bloom, et al., 2010) is essential to the study of maternity care:

Gravida—A woman who is pregnant

Gravidity—Pregnancy

Multigravida—A woman who has had two or more pregnancies

Multipara—A woman who has completed two or more pregnancies to 20 weeks of gestation or more

Nulligravida—A woman who has never been pregnant and is not currently pregnant

Nullipara—A woman who has not completed a pregnancy with a fetus or fetuses beyond 20 weeks of gestation

Parity—The number of pregnancies in which the fetus or fetuses have reached 20 weeks of gestation, not the number of fetuses (e.g., twins) born. Parity is not affected by whether the fetus is born alive or is stillborn (i.e., showing no signs of life at birth).

Postdate or postterm—A pregnancy that goes beyond 42 weeks of gestation

Preterm—A pregnancy that has reached 20 weeks of gestation but ends before completion of 37 weeks of gestation

Primigravida—A woman who is pregnant for the first time

Primipara—A woman who has completed one pregnancy with a fetus or fetuses who have reached 20 weeks of gestation

Term—A pregnancy from the beginning of week 38 of gestation to the end of week 42 of gestation

Viability—The capacity to live outside the uterus; there are no clear limits of gestational age or weight. Infants born at 22 to 25 weeks of gestation are considered to be on the threshold of viability and are especially vulnerable to brain injury if they survive.

Gravidity and parity information is obtained during history-taking interviews. Obtaining and documenting this information accurately is important in planning care for the pregnant woman.

! NURSING ALERT

Information may be recorded in patient records in a variety of ways because no one standardized system exists. It is important that the nurse understand the documentation system used by the health care facility.

Two commonly used systems of summarizing the obstetric history are discussed here. Gravidity and parity can be described with only two digits: the first digit indicates the number of pregnancies the woman has had, including the present one, and parity the number of pregnancies that have reached 20 weeks of gestation. For example, the abbreviation gravida 1 para 0 (1/0) means that a woman is pregnant for the first time (primigravida) and has not carried a pregnancy to 20 weeks (nullipara). If a woman had twins at 36 weeks with her first pregnancy, she would also be gravida 1, para 1 (remember that para refers to pregnancies, not fetuses) (Cunningham, Leveno, Bloom, et al., 2010).

Another system, consisting of five digits separated by hyphens, is commonly used in maternity centers. This system provides more information about the woman's obstetric history, although it may not provide accurate information about parity since it provides information about births and not pregnancies reaching 20 weeks of gestation (Beebe, 2005). The first digit represents gravidity; the second digit represents the total number of term births; the third indicates the number of preterm births; the fourth identifies the number of abortions (miscarriage or elective termination of pregnancy); and the fifth is the number of children currently living. The acronym *GTPAL* (gravidity, term, preterm, abortions, living children) may be helpful in remembering this system of notation. For example, if a woman pregnant only once gives birth at week 35 and the infant survives, the abbreviation that represents this information is "1-0-1-0-1." During her next pregnancy the abbreviation is "2-0-1-0-1." Additional examples are in Table 7-1.

PREGNANCY TESTS

Early detection of pregnancy allows for early initiation of care. Human chorionic gonadotropin (hCG) is the earliest biologic marker for pregnancy. Pregnancy tests are based on the recognition of hCG or a beta (β) subunit of hCG. Production of β-hCG begins as early as the day of implantation and can be detected in maternal serum or urine as early as 7 to 8 days after ovulation. The level of hCG rises until it peaks at 60 to 70 days and then declines until about 16 weeks. Plasma levels of hCG remain at this lower level for the remainder of the pregnancy. Higher-than-normal levels of hCG are associated with abnormal gestation (e.g., fetus with Down syndrome, gestational trophoblastic disease) or multiple gestation. Abnormally slow increase in hCG or lower levels can indicate impending miscarriage or ectopic pregnancy (Cunningham, Leveno, Bloom, et al., 2010).

Serum and urine pregnancy tests are performed in clinics, offices, women's health centers, and laboratory settings. Urine pregnancy tests may be performed at home (see Community Focus box). Both serum and urine tests can provide accurate results. A 7- to 10-mL sample of venous blood is collected for serum testing. Most urine tests require a first-voided morning urine specimen because it contains levels of hCG approximately the same as those in serum. Random urine samples usually have lower levels. Urine tests are less expensive and provide more immediate results than serum tests.

Many different pregnancy tests are available (Fig. 7-1). The wide variety of tests precludes discussion of each. The nurse should read the manufacturer's directions for the test to be used and determine if the woman understands the directions. A study by Wallace, Zite, and Homewood (2009) reported that instructions for most home pregnancy tests do not comply with the recommended guidelines for use of plain language and that most instructions were written at a seventh-grade level or above.

Enzyme-linked immunosorbent assay (ELISA) testing is the most popular method of testing for pregnancy. It uses a specific monoclonal antibody (anti-hCG) with enzymes that bond with hCG in urine. ELISA technology is the basis for most over-the-counter home pregnancy tests. With these one-step tests, the woman usually applies urine to a strip or absorbent-tipped applicator and reads the results. The test kits come with directions for collection of the specimen, the testing procedure, and reading of results. A positive test result is indicated by a simple color change reaction or a digital reading. Most manufacturers of the kits provide a toll-free telephone number to call if users have concerns and questions about

COMMUNITY FOCUS

Home Pregnancy Test Kits

Visit a pharmacy in your neighborhood. How many different types of home pregnancy test kits are available in the pharmacy? Read the labels on three different types of home pregnancy test kits. Do the kits include material for more than one test? Are the directions printed in more than one language? After reading the directions, do you have questions about how to perform the test or how to interpret the results? If so, what does that say about the likelihood that the tests will be used correctly?

TABLE 7-1 OBSTETRIC HISTORY USING FIVE-DIGIT AND TWO-DIGIT SYSTEM

	FIVE-DIGIT SYSTEM					TWO-DIGIT SYSTEM

PATIENT TEACHING

Home Pregnancy Testing

1. Follow the manufacturer's instructions carefully. Do not omit steps.
2. Review the manufacturer's list of foods, medications, and other substances that can affect the test results.
3. Use a first-voided morning urine specimen.
4. If the test done at the time of your missed period is negative, repeat the test in 1 week if you still have not had a period.
5. If you have questions about the test, contact the manufacturer.
6. Contact your health care provider for follow-up if the test result is positive or if the test result is negative and you still have not had a period.

test procedures or results. A common error in performing home pregnancy tests is doing the test too early in pregnancy before a significant rise in hCG level; this can cause a false negative result (Pagana and Pagana, 2011).

Interpreting the results of pregnancy tests requires some judgment. The type of pregnancy test and its degree of sensitivity (the ability to detect low levels of a substance) and specificity (the ability to discern the absence of a substance) must be considered in conjunction with the woman's history. This includes the date of her last normal menstrual period, her usual cycle length, and results of previous pregnancy tests. It is important to know if the woman abuses substances and what medications she is taking. Medications such as anticonvulsants and tranquilizers can cause false-positive results, whereas diuretics and promethazine can cause false-negative results (Pagana and Pagana, 2011). Improper collection of the specimen, hormone-producing tumors, and laboratory errors can also cause inaccurate results.

Women who use a home pregnancy test should be advised about the variations in accuracy and to use caution when interpreting results. Whenever there is any question, further evaluation or retesting may be appropriate (see Patient Teaching box).

ADAPTATIONS TO PREGNANCY

Maternal physiologic adaptations are attributed to the hormones of pregnancy and to mechanical pressures arising from the enlarging uterus and other tissues. These adaptations protect the woman's normal physiologic functioning, meet the metabolic demands that pregnancy imposes on her body, and provide a nurturing environment for fetal development and growth (see Critical Thinking Case Study). Although pregnancy is a normal phenomenon, problems can occur.

CRITICAL THINKING CASE STUDY

Awareness of Physiologic Changes of Pregnancy

Marlys is pregnant with her first child, and Janice is pregnant with her third child. They are both at approximately 18 weeks of gestation and have come to a prenatal appointment. While they are in the waiting room, you overhear Marlys asking Janice about some "old wives' tales" that she has heard:

- If she raises her arms above her head, the cord will wrap around the baby's neck.
- Putting a knife under the bed while she is laboring will "cut" the pain.
- If she dangles a needle in front of her abdomen, she will be able to tell if the baby is a boy or a girl.
- A rapid fetal heartbeat means that the baby will be a boy.

Marlys says that she has not felt her baby move yet, whereas Janice says that she has been feeling fetal movement for over 2 weeks. Marlys also has questions about some of the changes in her body that she has experienced or expects to experience. Janice bases her responses on her own experience. Based on the conversation you have overheard, you identify a need to spend some time with Marlys and Janice discussing physiologic changes of pregnancy.

1. Evidence—Is there sufficient evidence to draw conclusions about the normal physiologic changes in pregnancy in primigravidas and multiparas that the nurse should discuss with Marlys and Janice?
2. Assumptions—Describe an underlying assumption about each of the following topics:
   a. Differences in the normal physiologic changes in pregnancy between primigravidas and multiparas
   b. Reversibility of these physiologic changes in pregnancy
   c. Information provided by the health care provider
   d. Deviations from normal in the physiologic changes of pregnancy
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

Signs of Pregnancy

Some physiologic adaptations are recognized as the signs and symptoms of pregnancy. Three commonly used categories of these signs and symptoms are:

- Presumptive—those changes felt by the woman (e.g., amenorrhea, fatigue, breast changes)
- Probable—those changes observed by an examiner (e.g., Hegar sign, ballottement, pregnancy tests)
- Positive—those signs attributed only to the presence of the fetus (e.g., hearing fetal heart tones, visualizing the fetus, palpating fetal movements)

Table 7-2 summarizes these signs of pregnancy in relation to when they might occur and gives other possible causes for their occurrence.

Reproductive System and Breasts

Uterus

Changes in Size, Shape, and Position. High levels of estrogen and progesterone stimulate phenomenal uterine growth in the first

TABLE 7-2 SIGNS OF PREGNANCY

TIME OF OCCURRENCE (GESTATIONAL AGE)	SIGN	OTHER POSSIBLE CAUSE
Presumptive		
3-4 wk	Breast changes	Premenstrual changes, oral contraceptives
4 wk	Amenorrhea	Stress, vigorous exercise, early menopause, endocrine problems, malnutrition
4-14 wk	Nausea, vomiting	Gastrointestinal virus, food poisoning
6-12 wk	Urinary frequency	Infection, pelvic tumors
12 wk	Fatigue	Stress, illness
16-20 wk	Quickening	Gas, peristalsis
Probable		
5 wk	Goodell sign	Pelvic congestion
6-8 wk	Chadwick sign	Pelvic congestion
6-12 wk	Hegar sign	Pelvic congestion
4-12 wk	Positive pregnancy test (serum)	Hydatidiform mole, choriocarcinoma
6-12 wk	Positive pregnancy test (urine)	False-positive result may be caused by pelvic infection, tumors
16 wk	Braxton Hicks contractions	Myomas, other tumors
16-28 wk	Ballottement	Tumors, cervical polyps
Positive		
5-6 wk	Visualization of fetus by real-time ultrasound examination	No other causes
6 wk	Fetal heart tones detected by ultrasound	No other causes
16 wk	Visualization of fetus by radiographic study	No other causes
8-17 wk	Fetal heart tones detected by Doppler ultrasound stethoscope	No other causes
17-19 wk	Fetal heart tones detected by fetal stethoscope	No other causes
19-22 wk	Fetal movements palpated	No other causes
Late pregnancy	Fetal movements visible	No other causes

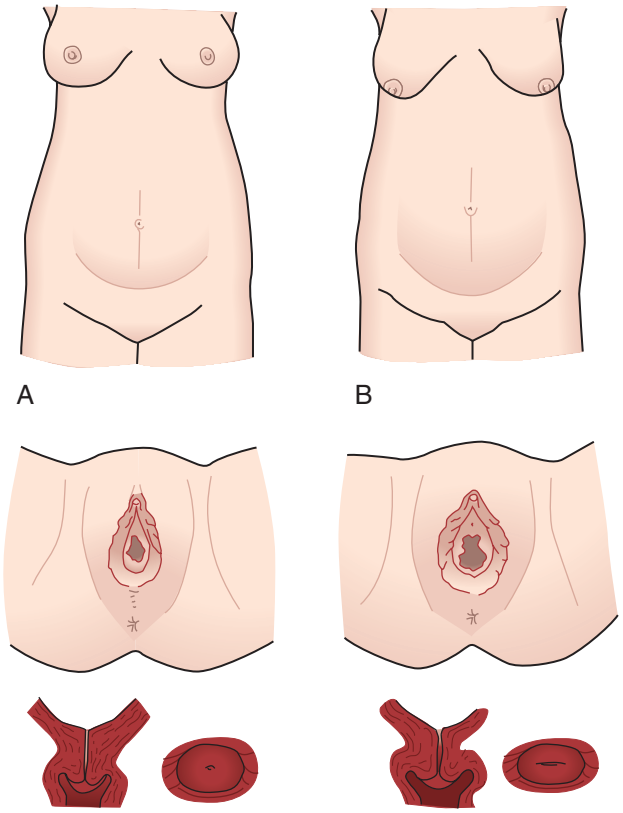

FIG 7-2 Comparison of abdomen, vulva, and cervix in **A,** nullipara, and **B,** multipara, at the same stage of pregnancy.

trimester. Early uterine enlargement results from increased vascularity and dilation of blood vessels, hyperplasia (production of new muscle fibers and fibroelastic tissue) and hypertrophy (enlargement of preexisting muscle fibers and fibroelastic tissue), and development of the decidua. By 7 weeks of gestation, the uterus is the size of a large hen's egg; by 10 weeks, it is the size of an orange (twice its nonpregnant size); and by 12 weeks, it is the size of a grapefruit. After the third month, uterine enlargement is primarily the result of mechanical pressure of the growing fetus.

As the uterus enlarges, it also changes in shape and position. At conception, the uterus is shaped like an upside-down pear. During the second trimester, as the muscular walls strengthen and become more elastic, the uterus becomes spherical or globular. Later, as the fetus lengthens, the uterus becomes larger and more ovoid and rises out of the pelvis into the abdominal cavity.

The pregnancy may "show" after the fourteenth week, although this depends to some degree on the woman's height and weight. Abdominal enlargement may be less apparent in the nullipara with good abdominal muscle tone (Fig. 7-2). Posture also influences the type and degree of abdominal enlargement that occurs. In normal pregnancies, the uterus enlarges at a predictable rate.

As the uterus grows, it may be palpated above the symphysis pubis sometime between the twelfth and fourteenth weeks of pregnancy (Fig. 7-3). The uterus rises gradually to the level of the umbilicus at 22 to 24 weeks of gestation and nearly reaches the xiphoid process at term. Between weeks 38 and 40, fundal height decreases as the fetus begins to descend and engage in the pelvis **(lightening)** (see Fig. 7-3, *dashed line*). Generally, lightening occurs in the nullipara about 2 weeks before the onset of labor and in the multipara at the start of labor.

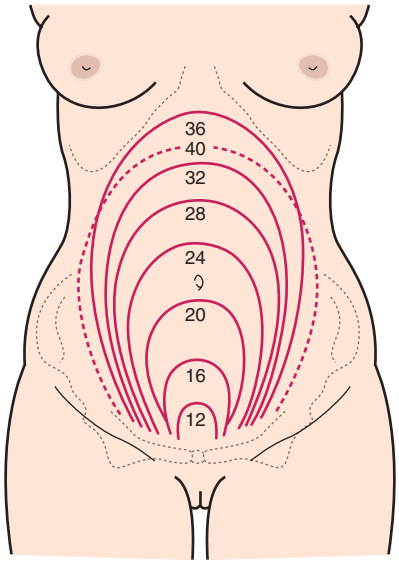

FIG 7-3 Height of fundus by weeks of normal gestation with a single fetus. *Dashed line,* Height after lightening. (From Seidel HM, Ball JW, Dains JE, et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

Uterine enlargement is determined by measuring fundal height (see Fig. 8-7). This measurement is commonly used to estimate the duration of pregnancy. However, variation in the position of the fundus or the fetus, variations in the amount of amniotic fluid present, the presence of more than one fetus, maternal obesity, and variation in examiner technique can reduce the accuracy of this estimation.

Generally the uterus rotates to the right as it elevates, probably because of the presence of the rectosigmoid colon on the left side. However, the extensive hypertrophy (enlargement) of the round ligaments keeps the uterus in the midline. Eventually the growing uterus touches the anterior abdominal wall and displaces the intestines to either side of the abdomen (Fig. 7-4). When a pregnant woman is standing, most of her uterus rests against the anterior abdominal wall and contributes to altering her center of gravity.

At approximately 6 weeks of gestation, softening and compressibility of the lower uterine segment (uterine isthmus) occurs (Hegar sign) (Fig. 7-5). This results in exaggerated uterine anteflexion during the first 3 months of pregnancy. In this position, the uterine fundus presses on the urinary bladder, causing the woman to have urinary frequency.

Changes in Contractility. Soon after the fourth month of pregnancy, uterine contractions can be felt through the abdominal wall. These contractions are referred to as **Braxton Hicks contractions.** Braxton Hicks contractions are irregular and painless contractions that occur intermittently throughout pregnancy. Although Braxton Hicks contractions are not painful, some women complain that they are annoying. After the twenty-eighth week, these contractions become more definite but they usually cease with walking or exercise. Braxton Hicks contractions can be mistaken for true labor; however, they do not increase in intensity or duration or cause cervical dilation. Conversely, premature labor contractions can be mistaken for Braxton Hicks contractions and lead to a delay in seeking treatment.

Uteroplacental Blood Flow. Placental perfusion depends on the maternal blood flow to the uterus. Blood flow increases rapidly as the uterus increases in size. Although uterine blood flow increases twentyfold, the fetoplacental unit grows even more rapidly. Consequently, more oxygen is extracted from the uterine blood during the latter part of pregnancy (Cunningham, Leveno, Bloom, et al., 2010). In a normal term pregnancy, one sixth of the total maternal blood volume is within the uterine vascular system. The rate of blood flow through the uterus averages 450 to 650 mL/min at term, and oxygen consumption of the gravid uterus increases to meet fetal needs. Three factors known to decrease uterine blood flow are low maternal arterial pressure, contractions of the uterus, and maternal supine position. Estrogen stimulation may increase uterine blood flow. Doppler ultrasound examination can be used to measure uterine blood flow velocity, especially in pregnancies at risk because of conditions associated with decreased placental perfusion (e.g., hypertension, intrauterine growth restriction, diabetes mellitus, multiple gestation) (Blackburn, 2013).

Using an ultrasound device or a fetal stethoscope, the examiner may hear the uterine souffle or bruit, a rushing or blowing sound of maternal blood flowing through uterine arteries to the placenta that is synchronous with the maternal pulse. The **funic souffle,** which is synchronous with the fetal heart rate and is caused by fetal blood coursing through the umbilical cord, may also be heard, as well as the actual heartbeat of the fetus (see Fig. 8-8).

Cervical Changes. In a normal, unscarred cervix, softening of the cervical tip may be observed about the beginning of the sixth week. This probable sign of pregnancy, **Goodell sign,** is brought about by increased vascularity, slight hypertrophy, and hyperplasia (increase in number of cells). The muscle and its collagen-rich connective tissue become loose, edematous, highly elastic, and increased in volume. The glands near the external os proliferate beneath the stratified squamous epithelium, giving the cervix the velvety appearance characteristic of pregnancy. Friability (tissue is easily damaged) is increased and can result in slight bleeding after vaginal examination or after coitus with deep penetration.

Pregnancy can also cause the squamocolumnar junction, the site for obtaining cells for cervical cancer screening, to be located away from the cervix. Because of these changes, evaluation of abnormal Papanicolaou (Pap) tests during pregnancy can be complicated. However, careful assessment of all pregnant women is important because approximately 3% of all invasive cervical cancers occur during pregnancy (Salani, Eisenhauer, and Copeland, 2012). The cervix of the nullipara is rounded. Lacerations of the cervix almost always occur during the birth process. After childbirth, with or without lacerations, the cervix becomes more oval in the horizontal plane and the external os appears as a transverse slit (see Fig. 7-2).

Changes Related to the Presence of the Fetus. Passive movement of the unengaged fetus is called **ballottement** and can be identified generally between the sixteenth and eighteenth week. Ballottement is a technique of palpating a floating structure by bouncing it gently and feeling it rebound. To palpate the fetus, the examiner places a finger within the vagina and taps gently upward on the cervix, causing the fetus to rise. The fetus then sinks, and a gentle tap is felt on the finger.

The first recognition of fetal movements, or "feeling life," by the multiparous woman may occur as early as 14 to 16 weeks. The nulliparous woman may not notice these sensations until the eighteenth week or later. **Quickening** is commonly described as a flutter and is difficult to distinguish from peristalsis. Fetal movements gradually increase in intensity and frequency as pregnancy progresses. The week in which quickening occurs provides a tentative clue in dating the duration of gestation.

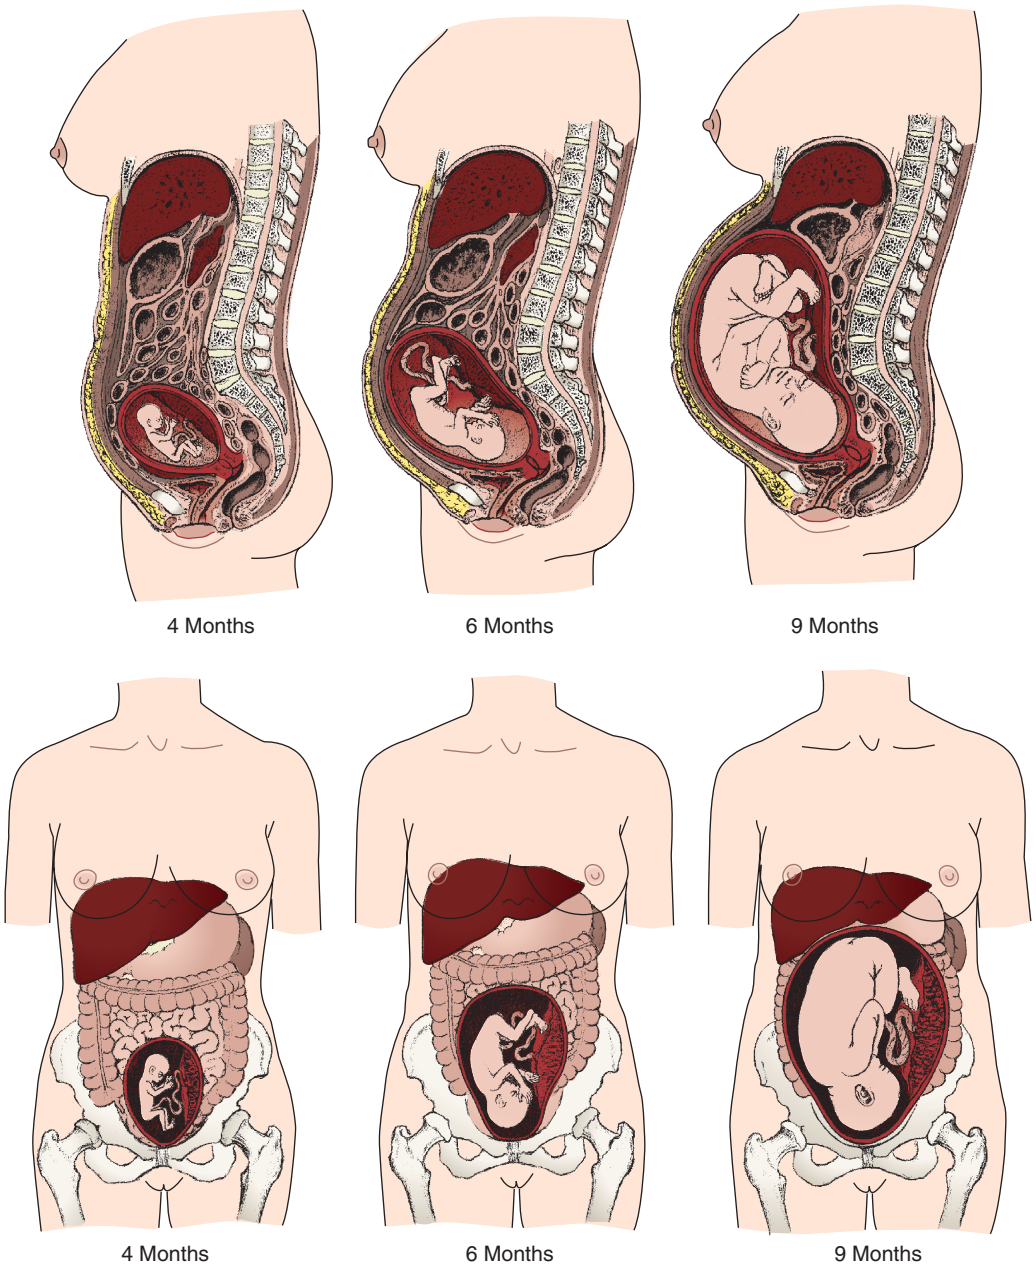

FIG 7-4 Displacement of internal abdominal structures and diaphragm by the enlarging uterus at 4, 6, and 9 months of gestation.

Vagina and Vulva

Pregnancy hormones prepare the vagina for stretching during labor and birth by causing the vaginal mucosa to thicken, the connective tissue to loosen, the smooth muscle to hypertrophy, and the vaginal vault to lengthen. Increased vascularity results in a violet-bluish color of the vaginal mucosa and cervix. The deepened color, termed **Chadwick sign,** can be evident as early as the sixth week but is easily noted by the eighth week of pregnancy (Blackburn, 2013).

Leukorrhea is a white or slightly gray mucoid discharge with a faint musty odor. This copious mucoid fluid occurs in response to cervical stimulation by estrogen and progesterone. The fluid is whitish because of the presence of many exfoliated vaginal epithelial cells caused by the hyperplasia of normal pregnancy. This vaginal discharge is never pruritic or blood stained. The mucus fills the endocervical canal, resulting in the formation of the mucus plug **(operculum)** (Fig. 7-6). The operculum acts as a barrier against bacterial invasion during pregnancy.

During pregnancy, the pH of vaginal secretions is more acidic, ranging from about 3.5 to about 6.0 (nonpregnant, 4.0 to 5.0), because of increased production of lactic acid (Cunningham, Leveno, Bloom, et al., 2010). Although this acidic environment provides more protection from some organisms, the pregnant woman is more vulnerable to other infections, especially yeast infections, because the glycogen-rich environment of the vagina is more susceptible to *Candida albicans* (Duff, Sweet, and Edwards, 2009).

The increased vascularity of the vagina and other pelvic viscera results in a marked increase in sensitivity. The increased sensitivity may lead to a high degree of sexual interest and arousal, especially

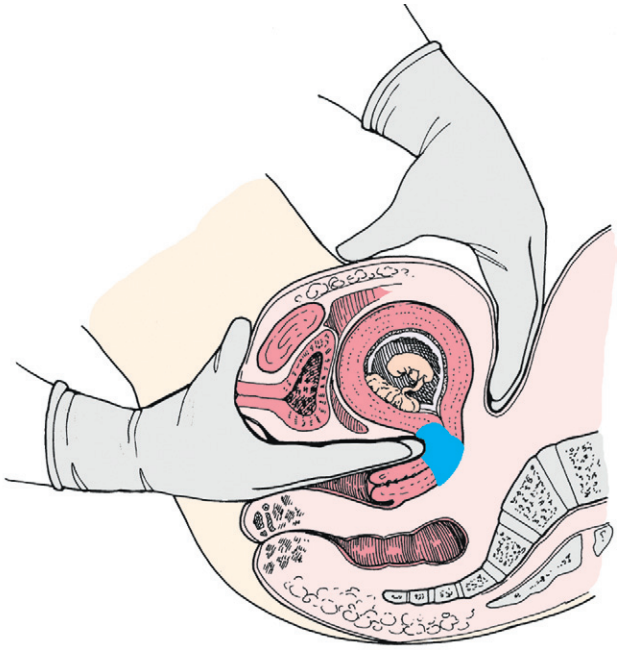

FIG 7-5 Hegar sign. Bimanual examination for assessing compressibility and softening of isthmus (lower uterine segment) while the cervix is still firm.

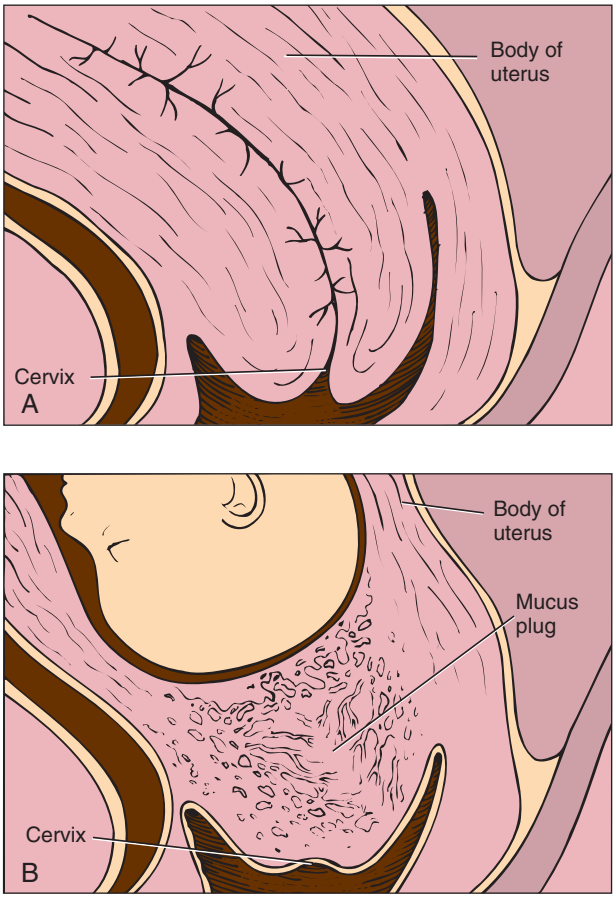

FIG 7-6 **A,** Cervix in nonpregnant woman. **B,** Cervix during pregnancy.

during the second trimester of pregnancy. The increased congestion, plus the relaxed walls of the blood vessels and the heavy uterus, may result in edema and varicosities of the vulva. The edema and varicosities usually resolve during the postpartum period.

External structures of the perineum are enlarged during pregnancy because of an increase in vasculature, hypertrophy of the perineal body, and deposition of fat (Fig. 7-7). The labia majora of nullipara women approximate (come together) and obscure the vaginal introitus; those of the parous woman separate and gape after childbirth and perineal or vaginal injury. See Fig. 7-2 for a comparison of the nullipara and the multipara in relation to the pregnant abdomen, vulva, and cervix.

Breasts

Fullness, heightened sensitivity, tingling, and heaviness of the breasts begin in the early weeks of gestation in response to increased levels of estrogen and progesterone. Breast sensitivity varies from mild tingling to sharp pain. Nipples and areolae become more pigmented; secondary pinkish areolae develop, extending beyond the primary areolae; and nipples become more erectile. Hypertrophy of the sebaceous (oil) glands embedded in the primary areolae, called **Montgomery tubercles,** may be seen around the nipples. Within the tubercles are sebaceous and sweat glands that secrete lubricating and antiinfective substances to help protect the nipples and areolae during breastfeeding.

The richer blood supply causes the vessels beneath the skin to dilate. Once barely noticeable, the blood vessels become visible, often appearing in an intertwining blue network beneath the surface of the skin. Venous congestion in the breasts is more obvious in primigravidas. **Striae gravidarum,** or stretch marks, can appear at the outer aspects of the breasts.

During the second and third trimesters, growth of the mammary glands accounts for the progressive breast enlargement (Fig. 7-8). The high levels of luteal and placental hormones in pregnancy promote proliferation of the lactiferous ducts and lobule-alveolar tissue so that palpation of the breasts reveals a generalized coarse nodularity. Glandular tissue displaces connective tissue, resulting in the tissue becoming softer and looser.

Although development of the mammary glands is functionally complete by midpregnancy, lactation is inhibited until the estrogen level decreases after birth. A thin, clear, viscous secretory material (precolostrum) can be found in the acini cells by the third month of gestation. Colostrum, the creamy, white-to-yellowish-to-orange premilk fluid secreted during the second trimester may be expressed from the nipples as early as 16 weeks of gestation (Lawrence and Lawrence, 2011). See Chapter 24 for a discussion of lactation.

General Body Systems

Cardiovascular System

Maternal adjustments to pregnancy involve extensive anatomic and physiologic changes in the cardiovascular system. Cardiovascular adaptations protect the woman's normal physiologic functioning, meet the metabolic demands pregnancy imposes on her body, and provide for fetal developmental and growth needs.

Slight cardiac hypertrophy (enlargement) is probably secondary to increased blood volume and cardiac output that occur in pregnancy. The heart returns to its normal size after childbirth. As the diaphragm is displaced upward by the enlarging uterus, the heart is elevated upward and rotated forward to the left (Fig. 7-9). The apical impulse, point of maximal intensity, is shifted upward and laterally about 1 to 1.5 cm (0.4 to 0.6 cm). The degree of shift depends on the duration of pregnancy and the size and position of the uterus.

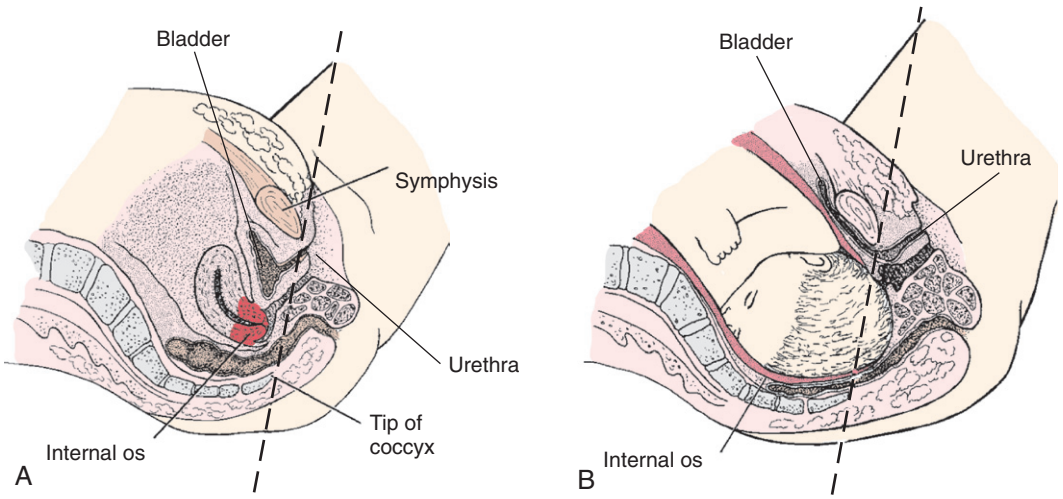

FIG 7-7 A, Pelvic floor in nonpregnant woman. **B,** Pelvic floor at end of pregnancy. Note marked hypertrophy and hyperplasia below *dotted line* joining tip of coccyx and inferior margin of symphysis. Note elongation of bladder and urethra as a result of compression. Fat deposits are increased.

FIG 7-8 Enlarged breasts in pregnancy with venous network and darkened areolae and nipples. (From Seidel HM, Ball JW, Dains JE, et al: *Mosby's guide to physical examination*, ed 7, St Louis, 2011, Mosby.)

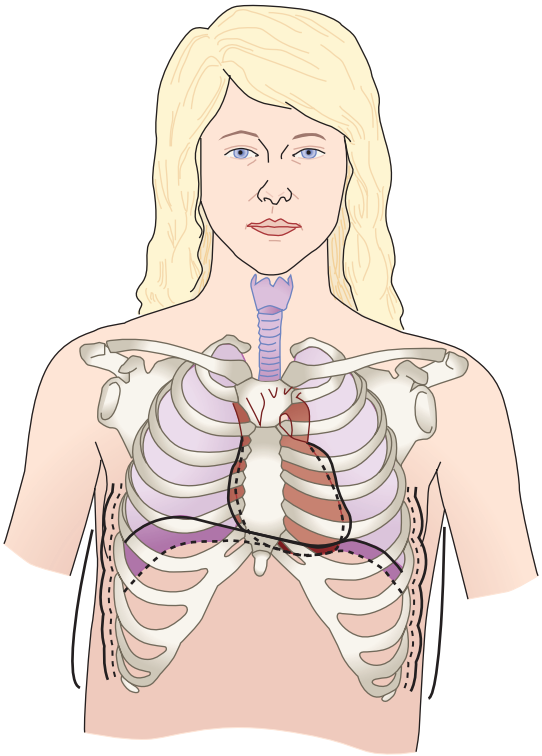

FIG 7-9 Changes in position of heart, lungs, and thoracic cage in pregnancy. *Broken line,* Nonpregnant state; *solid line,* change that occurs in pregnancy.

The changes in heart size and position and the increases in blood volume and cardiac output contribute to auscultatory changes common in pregnancy. There is more audible splitting of S_1 and S_2, and S_3 may be readily heard after 20 weeks of gestation. In addition, systolic and diastolic murmurs may be heard over the pulmonic area. These changes are transient and disappear in most women shortly after they give birth (Cunningham, Leveno, Bloom, et al., 2010).

Between 14 and 20 weeks of gestation, the pulse increases about 10 to 15 beats/min, and this persists to term. Palpitations may occur. In twin gestations, the maternal heart rate increases significantly in the third trimester (Blackburn, 2013).

The cardiac rhythm may be disturbed. The pregnant woman may experience sinus dysrhythmia, premature atrial contractions, and premature ventricular systole. In the healthy woman with no underlying heart disease, no therapy is needed. Women with pre-existing heart disease need close medical and obstetric supervision during pregnancy (see Chapter 11).

Blood Pressure. Arterial blood pressure (brachial artery) varies with age, activity level, presence of health problem, circadian rhythm, use of alcohol, smoking, and pain. Additional factors to consider during pregnancy include maternal position and type of blood pressure apparatus. Maternal anxiety can elevate readings. If an elevated reading is found, the woman is given time to rest and the reading is repeated.

Maternal position affects readings. Brachial blood pressure is highest when the woman is sitting; lowest when she is lying in the

BOX 7-1 BLOOD PRESSURE MEASUREMENT

1. Use correct cuff size; cuff should cover approximately 80% of the upper arm or be 1.5 times the length of the upper arm.
2. Measure blood pressure (BP) after the woman sits for 5 minutes.
3. Instruct the woman to refrain from tobacco or caffeine use 30 minutes before BP measurement.
4. Measure BP with the woman sitting or semi-reclining with her feet flat, not dangling.
5. The arm should be supported on a desk at the level of the heart.
6. Measurements with an automated device should be checked with a manual device.
7. Diastolic pressure should be recorded at Korotkoff phase V (disappearance of sound).
8. If the BP is elevated, have the woman rest for 5 to 10 minutes and then retake it.
9. BP may vary by >10 mm Hg from one arm to the other; record the higher reading.
10. Take the average of two readings at least 1 minute apart.

Data from Peters R: High blood pressure in pregnancy, *Nurs Womens Health* 12(5):412–421, 2008.

lateral recumbent position; and intermediate when she is supine, except for some women who experience hypotensive syndrome (see later discussion). Therefore, at each prenatal visit, the reading should be obtained in the same arm and with the woman in a seated position with her back and arm supported and her upper arm at the level of the right atrium (Monga, 2009; Pickering, Hall, Appel, et al., 2005). The position and arm used should be recorded along with the reading.

The proper-size cuff is essential for accurate readings. The cuff should have a bladder length that is 80% of the upper arm length and a width that is at least 40% of the upper arm circumference. For example, an adult-size cuff (16 cm × 30 cm [6.3 × 11.8 in]) should be used for an arm circumference of 27 to 34 cm (10.6 to 13.4 in). A cuff that is too small yields a falsely high reading; a cuff that is too large yields a falsely low reading (Box 7-1).

! NURSING ALERT

Caution should be used when comparing auscultatory and oscillatory blood pressure readings because discrepancies can occur. Automated monitors can give inaccurate readings in women with hypertensive conditions.

Systolic blood pressure usually remains the same as the prepregnancy level but may decrease slightly as pregnancy advances. Diastolic blood pressure begins to decrease in the first trimester, continues to drop until 24 to 32 weeks, and gradually increases and returns to prepregnancy levels by term (Blackburn, 2013).

Calculating the mean arterial pressure (MAP) (mean of the blood pressure in the arterial circulation) can increase the diagnostic value of the findings. Normal MAP readings in the nonpregnant woman are 86 ± 7.5 mm Hg. MAP readings for a pregnant woman at term are slightly higher at 90 ± 5.8 (Cunningham, Leveno, Bloom, et al., 2010). Box 7-2 illustrates one way to calculate MAP.

Some degree of compression of the vena cava occurs in all women who lie on their back during the second half of pregnancy. Some women experience a fall of more than 30 mm Hg in their systolic pressure. After 4 to 5 minutes, a reflex bradycardia is noted, cardiac output is reduced by half, and the woman feels faint. This condition is called **supine hypotensive syndrome** (Cunningham, Leveno, Bloom, et al., 2010).

BOX 7-2 CALCULATION OF MEAN ARTERIAL PRESSURE

Blood pressure: 106/70
Formula:
Systolic + 2 (Diastolic) / 3
106 + 2 (70) / 3
106 + 140 / 3
246 / 3 = 82 mm Hg

FIG 7-10 Hemorrhoids. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Compression of the iliac veins and inferior vena cava by the uterus causes increased venous pressure and reduced blood flow in the legs, except when the woman is in the lateral position. These alterations contribute to the dependent edema, varicose veins in the legs and vulva, and hemorrhoids that develop in the latter part of term pregnancy (Fig. 7-10).

Blood Volume and Composition. The degree of blood volume expansion varies considerably. Blood volume increases by approximately 1500 mL, or 40% to 50% above nonpregnancy levels (Cunningham, Leveno, Bloom, et al., 2010). This increase consists of 1000 mL of plasma plus 450 mL of red blood cells (RBCs). The increase in volume starts at weeks 10 to 12, peaks at weeks 32 to 34, and decreases slightly at week 40. The volume in a multiple gestation increases above that for a single fetus (Blackburn, 2013). Increased blood volume is a protective mechanism. It is essential for meeting the blood volume needs of the hypertrophied vascular system of the enlarged uterus, for adequately hydrating fetal and maternal tissues when the woman assumes an erect or supine position, and for providing a fluid reserve to compensate for blood loss during birth and postpartum. Peripheral vasodilation allows for a normal blood pressure despite the increased blood volume in pregnancy.

During pregnancy, there is an accelerated production of RBCs (nonpregnant, 4.2 to 5.4 million/mm^3). The percentage of increase depends on the amount of iron available. The RBC mass increases by 20% to 30% (Blackburn, 2013).

Because the plasma increase is greater than the increase in RBC production, there is a decrease in normal hemoglobin values (12 to 16 g/dL blood) and hematocrit values (37% to 47%). This state of hemodilution is referred to as **physiologic anemia.** The decrease is more noticeable during the second trimester, when rapid expansion of blood volume occurs faster than RBC production. If the hemoglobin value drops to 11 g/dL or less during the first or third trimester or less than 10.5 g/dL during the second trimester or if the hematocrit decreases to 32% or less, the woman is considered anemic (Hark and Catalano, 2012).

The total white blood cell count increases during the second trimester and peaks during the third trimester. This increase is primarily in the granulocytes; the lymphocyte count stays about the same throughout pregnancy. See Table 7-3 for laboratory values during pregnancy.

Cardiac Output. Cardiac output increases from 30% to 50% over the nonpregnant rate by week 32 of pregnancy; it declines to about a 20% increase at 40 weeks of gestation. This elevated cardiac output is largely a result of increased stroke volume and heart rate and occurs in response to increased tissue demands for oxygen (Monga, 2009).

Cardiac output in late pregnancy is appreciably higher when the woman is in the lateral recumbent position than when she is supine. In the supine position, the large, heavy uterus often impedes venous return to the heart and affects blood pressure. Cardiac output increases with any exertion such as labor and birth. Table 7-4 summarizes cardiovascular changes in pregnancy.

Circulation and Coagulation Times. The circulation time decreases slightly by week 32. It returns to near normal by term. There is a greater tendency for blood to coagulate (clot) during pregnancy because of increases in various clotting factors (i.e.,

TABLE 7-3 LABORATORY VALUES FOR PREGNANT AND NONPREGNANT WOMEN

VALUES	NONPREGNANT	PREGNANT
Hematologic		
Complete Blood Count		
Hemoglobin, g/dL	12-16*	>11*
Hematocrit, packed cell volume, %	37-47	>33*
RBC volume, per mL	1400	1650
Plasma volume, per mL	2400	40%-60% increase
RBC count, million/mm^3	4.2-5.4	5-6.25
White blood cells, total per mm^3	5000-10,000	5000-15,000
Neutrophils, %	55-70	60-85
Lymphocytes, %	20-40	15-40
Erythrocyte sedimentation rate, mm/hr	20	Elevated in second and third trimesters
Mean corpuscular hemoglobin concentration, g/dL packed RBCs	32-36	No change
Mean corpuscular hemoglobin, pg	27-31	No change
Mean corpuscular volume per mm^3	80-95	No change
Blood Coagulation and Fibrinolytic Activity†		
Factor VII	65-140	Increases in pregnancy, returns to normal in early puerperium
Factor VIII	55-145	Increases during pregnancy and immediately after birth
Factor IX	60-140	Same as factor VII
Factor X	45-155	Same as factor VII
Factor XI	65-135	Decreases in pregnancy
Factor XII	50-150	Same as factor VII
Prothrombin time, sec	11-12.5	Decreases slightly in pregnancy
Partial thromboplastin time, sec	60-70	Decreases slightly in pregnancy and decreases during second and third stages of labor (indicates clotting at placental site)
Bleeding time, min	1-9 (Ivy method)	No appreciable change
Coagulation time, min	6-10 (Lee-White method)	No appreciable change
Platelets, per mm^3	150,000-400,000	No significant change until 3-5 days after birth and then increases rapidly (may predispose woman to thrombosis) and gradually returns to normal
Fibrinolytic activity		Decreases in pregnancy and then abruptly returns to normal (protection against thromboembolism)
Fibrinogen, mg/dL	200-400	Levels increase late in pregnancy

Continued

TABLE 7-3 LABORATORY VALUES FOR PREGNANT AND NONPREGNANT WOMEN—cont'd

VALUES	NONPREGNANT	PREGNANT
Hematologic—cont'd		
Mineral/Vitamin Concentrations		
Vitamin B_{12}, folic acid, ascorbic acid	Normal	Moderate decrease
Serum Proteins		
Total, g/dL	6.4-8.3	5.5-7.5
Albumin, g/dL	3.5-5	Slight increase
Globulin, total, g/dL	2.3-3.4	3.0-4.0
Blood Glucose		
Fasting, mg/dL	70-105	Decreases
2-hr postprandial, mg/dL	<140	<140 after a 100-g carbohydrate meal is considered normal
Acid-Base Values in Arterial Blood		
Po_2, mm Hg	80-100	104-108 (increased)
Pco_2, mm Hg	35-45	27-32 (decreased)
Sodium bicarbonate (HCO_3), mEq/L	21-28	18-31 (decreased)
Blood pH	7.35-7.45	7.40-7.45 (slightly increased, more alkaline)
Hepatic		
Bilirubin, total, mg/dL	≤1	Unchanged
Serum cholesterol, mg/dL	120-200	Increases from 16-32 wk of pregnancy; remains at this level until after birth
Serum alkaline phosphatase, units/L	30-120	Increases from wk 12 of pregnancy to 6 wk after birth
Serum albumin, g/dL	3.5-5	Increases slightly
Renal		
Bladder capacity, mL	1300	1500
Renal plasma flow, mL/min	490-700	Increases by 25%-30%
Glomerular filtration rate, mL/min	88-128	Increases by 30%-50%
Nonprotein nitrogen, mg/dL	25-40	Decreases
Blood urea nitrogen, mg/dL	10-20	Decreases
Serum creatinine, mg/dL	0.5-1.1	Decreases
Serum uric acid, mg/dL	2.7-7.3	Decreases but returns to prepregnancy level by end of pregnancy
Urine glucose	Negative	Present in 20% of pregnant women
Intravenous pyelogram	Normal	Slight to moderate hydroureter and hydronephrosis; right kidney larger than left kidney

NOTE: Abbreviations should not be used in practice.

*At sea level. Permanent residents of higher levels (e.g., Denver) require higher levels of hemoglobin.

†Pregnancy represents a hypercoagulable state.

factors VII, VIII, IX, X, and fibrinogen). This tendency, combined with the fact that fibrinolytic activity (the splitting up or dissolving of a clot) is depressed during pregnancy and the postpartum period, provides a protective function to decrease the chance of bleeding but also makes the woman more vulnerable to thrombosis, especially after cesarean birth.

Respiratory System

Structural and ventilatory adaptations occur during pregnancy to provide for maternal and fetal needs. Maternal oxygen requirements increase in response to the acceleration in metabolic rate and the need to add to the tissue mass in the uterus and breasts. In addition, the fetus requires oxygen and a way to eliminate carbon dioxide.

TABLE 7-4 CARDIOVASCULAR CHANGES IN PREGNANCY

PARAMETER	CHANGE
Heart rate	Increases 10-15 beats/min
Blood pressure	
Systolic	Slight or no decrease from prepregnancy levels
Diastolic	Slight decrease to midpregnancy (24-32 wk) and gradual return to prepregnancy levels by end of pregnancy
Blood volume	Increases by 1500 mL or 40%-50% above prepregnancy level
Red blood cell mass	Increases 17%
Hemoglobin	Decreases
Hematocrit	Decreases
White blood cell count	Increases in second and third trimesters
Cardiac output	Increases 30%-50%

Data from Gordon M: Maternal physiology. In Gabbe SG, Niebyl JR, Simpson JL, et al, editors: *Obstetrics: normal and problem pregnancies,* ed 6, Philadelphia, 2012, Saunders.

Elevated levels of estrogen cause the ligaments of the rib cage to relax, permitting increased chest expansion (see Fig. 7-9). The transverse diameter of the thoracic cage increases by about 2 cm (0.8 in) and the circumference by 6 cm (2.4 in) (Cunningham, Leveno, Bloom, et al., 2010). The costal angle increases, and the lower rib cage appears to flare out. The chest may not return to its prepregnant state after birth (Seidel, Ball, Dains, et al., 2011).

The diaphragm is displaced by as much as 4 cm (1.6 in) during pregnancy. With advancing pregnancy, chest breathing replaces abdominal breathing and it becomes less possible for the diaphragm to descend with inspiration. Thoracic breathing is accomplished primarily by the diaphragm rather than by the costal muscles (Blackburn, 2013).

The upper respiratory tract becomes more vascular in response to elevated levels of estrogen. As the capillaries become engorged, edema and hyperemia develop within the nose, pharynx, larynx, trachea, and bronchi. This congestion within the tissues of the respiratory tract gives rise to several conditions commonly seen during pregnancy, including nasal and sinus stuffiness, epistaxis (nosebleed), changes in the voice, and marked inflammatory response to even a mild upper respiratory infection.

Increased vascularity of the upper respiratory tract also can cause the tympanic membranes and eustachian tubes to swell, giving rise to symptoms of impaired hearing, earaches, or a sense of fullness in the ears.

Pulmonary Function. Respiratory changes in pregnancy are related to the elevation of the diaphragm and changes in the chest wall. Changes in the respiratory center result in a lowered threshold for carbon dioxide. The actions of progesterone and estrogen are presumed to be responsible for the increased sensitivity of the respiratory center to carbon dioxide. See Table 7-5 for respiratory changes in pregnancy. Although pulmonary function is not impaired by pregnancy, diseases of the respiratory tract can be more serious during this time (Cunningham, Leveno, Bloom, et al., 2010). One important factor responsible for this can be the increase in oxygen requirements.

TABLE 7-5 RESPIRATORY CHANGES IN PREGNANCY

PARAMETER	CHANGE
Respiratory rate	Unchanged or slightly increased
Tidal volume	Increased 30%-40%
Vital capacity	Unchanged
Inspiratory capacity	Increased
Expiratory reserve volume	Decreased
Total lung capacity	Unchanged to slightly decreased
Oxygen consumption	Increased 20%-40%

Data from Gordon M: Maternal physiology. In Gabbe SG, Niebyl JR, Simpson JL, et al, editors: *Obstetrics: normal and problem pregnancies,* ed 6, Philadelphia, 2012, Saunders.

Basal Metabolic Rate. The basal metabolic rate (BMR) increases during pregnancy. The elevation in BMR reflects increased oxygen demands of the uterine-placental-fetal unit and greater oxygen consumption because of increased maternal cardiac work. This increase varies considerably, depending on the prepregnancy nutritional status of the woman and fetal growth. By the third trimester, the BMR is increased by 10% to 20% over the nonpregnant state (Cunningham, Leveno, Bloom, et al., 2010). The BMR returns to nonpregnant levels by 5 to 6 days after birth. Peripheral vasodilation and acceleration of sweat gland activity help dissipate the excess heat resulting from the increased BMR during pregnancy. Pregnant women may experience heat intolerance. Lassitude and fatigability after only slight exertion are experienced by many women in early pregnancy. These feelings, along with a greater need for sleep, may persist and may be caused in part by the increased metabolic activity.

Acid-Base Balance. By about the tenth week of pregnancy, there is a decrease of about 5 mm Hg in the partial pressure of carbon dioxide (P_{CO_2}). Progesterone may be responsible for increasing the sensitivity of the respiratory center receptors so that tidal volume increases and P_{CO_2} decreases, the base excess (HCO_3, or bicarbonate) decreases, and pH increases slightly (Cunningham, Leveno, Bloom, et al., 2010). These alterations in acid-base balance indicate that pregnancy is a state of respiratory alkalosis (Gordon, 2012) (see Table 7-3). These changes also facilitate the transport of CO_2 from the fetus and O_2 release from the mother to the fetus.

Renal System

The kidneys are responsible for maintaining electrolyte and acid-base balance, regulating extracellular fluid volume, excreting waste products, and conserving essential nutrients.

Anatomic Changes. Changes in renal structure result from hormonal activity (estrogen and progesterone), pressure from an enlarging uterus, and an increase in blood volume. As early as the tenth week of pregnancy, the renal pelves and the ureters dilate. Dilation of the ureters is more pronounced above the pelvic brim, in part because they are compressed between the uterus and the pelvic brim. In most women, the ureters below the pelvic brim are normal size. The smooth-muscle walls of the ureters undergo hyperplasia and hypertrophy and muscle tone relaxation. The ureters elongate, become tortuous, and form single or double curves. In the latter part of pregnancy, the renal pelvis and ureter dilate more on

the right side than on the left because the heavy uterus is displaced to the right by the sigmoid colon.

Because of these changes, a larger volume of urine is held in the pelves and ureters and urine flow rate is slowed. Urinary stasis or stagnation has several consequences:

- A lag occurs between the time urine is formed and when it reaches the bladder. Therefore clearance test results may reflect substances contained in glomerular filtrate several hours before.
- Stagnated urine is an excellent medium for the growth of microorganisms. In addition, the urine of pregnant women contains more nutrients, including glucose, that increase the pH (making the urine more alkaline). This makes pregnant women more susceptible to urinary tract infection.

Bladder irritability, nocturia, and urinary frequency and urgency (without dysuria) are commonly reported in early pregnancy. These bladder symptoms may return near term, especially after lightening occurs.

Urinary frequency results initially from increased bladder sensitivity and later from compression of the bladder (see Fig. 7-7). In the second trimester, the bladder is pulled up out of the true pelvis into the abdomen. The urethra lengthens to 7.5 cm (3 in) as the bladder is displaced upward. The pelvic congestion that occurs in pregnancy is reflected in hyperemia of the bladder and urethra. This increased vascularity causes the bladder mucosa to be easily traumatized. Bladder tone may decrease, which increases the bladder capacity to 1500 mL. At the same time, the bladder is compressed by the enlarging uterus, resulting in the urge to void even if the bladder contains only a small amount of urine.

Functional Changes. In normal pregnancy, renal function is altered considerably. Glomerular filtration rate (GFR) and renal plasma flow increase early in pregnancy (Monga, 2009). These changes are caused by pregnancy hormones; an increase in blood volume; and the woman's posture, physical activity, and nutritional intake. The woman's kidneys must manage the increased metabolic and circulatory demands of the maternal body as well as the excretion of fetal waste products.

Renal function is most efficient when the woman lies in the lateral recumbent position and least efficient when the woman assumes a supine position. A side-lying position increases renal perfusion, which increases urine output and decreases edema. When the pregnant woman is lying supine, the heavy uterus compresses the vena cava and the aorta and cardiac output decreases. As a result, blood flow to the brain and heart is continued at the expense of other organs, including the kidneys and uterus.

Fluid and Electrolyte Balance. Selective renal tubular reabsorption maintains sodium and water balance, regardless of changes in dietary intake and losses through sweat, vomitus, or diarrhea. About 900 mEq of sodium is normally retained during pregnancy to meet fetal needs, although maternal serum levels of sodium decrease by 3 to 4 mmol/L (Gordon, 2012). To prevent excessive sodium depletion, the maternal kidneys undergo a significant adaptation by increasing tubular reabsorption. Because of the need for increased maternal intravascular and extracellular fluid volume, additional sodium is needed to expand fluid volume and maintain an isotonic state. As efficient as the renal system is, it can be overstressed by excessive dietary sodium intake or restriction or by use of diuretics. Severe hypovolemia and reduced placental perfusion are two consequences of using diuretics during pregnancy.

The capacity of the kidneys to excrete water is more efficient during the early weeks than later in pregnancy. As a result, some women feel thirsty in early pregnancy because of the greater amount of water loss. The pooling of fluid in the legs in the latter part of pregnancy decreases renal blood flow and GFR. This pooling is sometimes referred to as physiologic or dependent edema and requires no treatment. The normal diuretic response to the water load is triggered when the woman lies down, preferably on her side, and the pooled fluid reenters general circulation.

Normally the kidney reabsorbs almost all the glucose and other nutrients from the plasma filtrate. However, in pregnant women, tubular reabsorption of glucose is impaired, causing glucosuria to occur at varying times and to varying degrees. Normal values range from 0 to 20 mg/dL, meaning that during any day, the urine is sometimes positive and sometimes negative for glucose. In nonpregnant women, blood glucose levels must be at 160 to 180 mg/dL before glucose is "spilled" into the urine (not resorbed). During pregnancy, glucosuria occurs when maternal glucose levels are lower than 160 mg/dL. Why glucose, as well as other nutrients such as amino acids, is wasted during pregnancy is not understood, nor has the exact mechanism been discovered. Although glucosuria may be found in normal pregnancies (2+ levels can be seen with increased anxiety states), the possibility of diabetes mellitus and gestational diabetes must be considered.

Proteinuria does not usually occur in normal pregnancy except during labor or after birth (Cunningham, Leveno, Bloom, et al., 2010). However, the increased amounts of amino acids that must be filtered may exceed the capacity of the renal tubules to absorb them, and small amounts of protein may be lost in the urine. The amount of protein excreted is not an indication of the severity of renal disease, nor does an increase in protein excretion in a pregnant woman with known renal disease necessarily indicate a progression in her disease. However, a pregnant woman with hypertension and proteinuria must be evaluated carefully because she may be at greater risk for an adverse pregnancy outcome (Gordon, 2012).

Integumentary System

Alterations in hormone balance and mechanical stretching are responsible for several changes in the integumentary system during pregnancy. Hyperpigmentation is stimulated by the anterior pituitary hormone *melanotropin,* which is increased during pregnancy. Darkening of the nipples, areolae, axillae, and vulva occurs at about the sixteenth week of gestation. **Melasma** (also called chloasma or mask of pregnancy) is a blotchy, brownish hyperpigmentation of the skin over the cheeks, nose, and forehead, especially in pregnant women with dark complexions. Melasma appears in 50% to 70% of pregnant women, beginning after the sixteenth week and increasing gradually until term. The sun intensifies this pigmentation in susceptible women. Melasma caused by normal pregnancy usually fades after birth but often recurs with oral contraceptive use or subsequent pregnancies (Kroumpouzos, 2012).

The **linea nigra** (Fig. 7-11) is a pigmented line extending from the symphysis pubis to the top of the fundus in the midline. This line is known as the linea alba before hormone-induced pigmentation. In primigravidas, the extension of the linea nigra, beginning in the third month, keeps pace with the rising height of the fundus; in multigravidas, the entire line often appears earlier than the third month. Not all pregnant women develop linea nigra, and some women notice hair growth along the line with or without the change in pigmentation.

Striae gravidarum, or "stretch marks," (seen over the lower abdomen in Fig. 7-11) appear in 50% to 90% of pregnant women

FIG 7-11 Striae gravidarum and linea nigra in a dark-skinned person. (Courtesy Shannon Perry, Phoenix, AZ.)

during the second half of pregnancy. These may be caused by the action of adrenocorticosteroids. Striae reflect separation within the underlying connective (collagen) tissue of the skin. These slightly depressed streaks tend to occur over areas of maximum stretch (the abdomen, thighs, and breasts). The stretching sometimes causes a sensation that resembles itching. The tendency to develop striae may be familial. After birth, they usually fade, although they never disappear completely. Color of striae varies, depending on the pregnant woman's skin color. The striae appear pinkish on a woman with light skin and are lighter than the surrounding skin in dark-skinned women. In the multipara, in addition to the striae of the present pregnancy, glistening silvery lines (in light-skinned women) or purplish lines (in dark-skinned women) are commonly seen. These represent the scars of striae from previous pregnancies.

Angiomas are commonly referred to as vascular spiders. These tiny, star-shaped or branched, slightly raised, and pulsating end-arterioles are usually found on the neck, thorax, face, and arms. They occur as a result of elevated levels of circulating estrogens. The spiders are bluish in color and do not blanch with pressure. Vascular spiders appear during the second to fifth month of pregnancy in about 65% of Caucasian women and 10% of African-American women. The spiders usually disappear after birth (Blackburn, 2013).

Pinkish red, diffusely mottled, or well-defined blotches are seen over the palmar surfaces of the hands in about two thirds of Caucasian women and one third of African-American women during pregnancy (Cunningham, Leveno, Bloom, et al., 2010). These color changes, called **palmar erythema,** are related primarily to increased estrogen levels.

! NURSING ALERT

Integumentary system changes vary greatly among women of different racial backgrounds. Therefore, when performing physical assessments, the color of a woman's skin should be noted along with any changes that may be attributed to pregnancy.

Some dermatologic conditions have been identified as unique to pregnancy or as having an increased incidence during pregnancy. Mild pruritus is a relatively common dermatologic symptom during pregnancy. The goal of management is to relieve the itching; this is done through the use of oral antihistamines and topical corticosteroid creams. The problem usually resolves during the postpartum period (Cunningham, Leveno, Bloom, et al., 2010). Systemic diseases can also cause pruritus, but these causes are uncommon or rare. Pre-existing skin diseases can complicate pregnancy or can improve during pregnancy.

! NURSING ALERT

The effect of pregnancy on acne is unpredictable, although in some women, acne improves during pregnancy. Women with severe acne taking isotretinoin (Accutane) should avoid pregnancy while receiving the treatment because it is teratogenic and associated with major fetal malformations.

Gum hypertrophy may occur. An **epulis** (gingival granuloma gravidarum) is a red, raised nodule on the gums that bleeds easily. This lesion may develop around the third month and usually continues to enlarge as pregnancy progresses. It is usually managed by avoiding trauma to the gums (e.g., using a soft toothbrush). An epulis usually regresses spontaneously after birth.

Nail growth may be accelerated. Some women may notice thinning and softening of the nails. Oily skin and acne vulgaris may occur during pregnancy. In some women, the skin clears and looks radiant. Hirsutism, the excessive growth of hair or growth of hair in unusual places, is commonly reported. An increase in fine hair growth may occur but tends to disappear after pregnancy. However, growth of coarse or bristly hair does not usually disappear after pregnancy. The rate of scalp hair loss slows during pregnancy; increased hair loss may be noted in the postpartum period.

Increased blood supply to the skin leads to increased perspiration. Women feel hotter during pregnancy, possibly related to a progesterone-induced increase in body temperature and the increased BMR.

Musculoskeletal System

The gradually changing body and increasing weight of the pregnant woman usually cause noticeable changes in her posture (Fig. 7-12). The great abdominal distention gives the pelvis a forward tilt, decreased abdominal muscle tone, and increased weight bearing. The woman's center of gravity shifts forward, requiring a realignment of the spinal curvatures. An increase in the normal lumbosacral curve (lordosis) develops, and a compensatory curvature in the cervicodorsal region (exaggerated anterior flexion of the head) develops to help her maintain balance. Aching, numbness, and weakness of the upper extremities may result. Large breasts and a stoop-shouldered stance further accentuate the lumbar and dorsal curves. The ligamentous and muscular structures of the middle and lower spine may be severely stressed. These and related changes often cause musculoskeletal discomfort, especially in older women or those with a back disorder or a faulty sense of balance.

Slight relaxation and increased mobility of the pelvic joints are normal during pregnancy. These adaptations permit enlargement of pelvic dimensions to facilitate labor and birth. The degree of relaxation varies, but considerable separation of the symphysis pubis and the instability of the sacroiliac joints may cause pain and difficulty

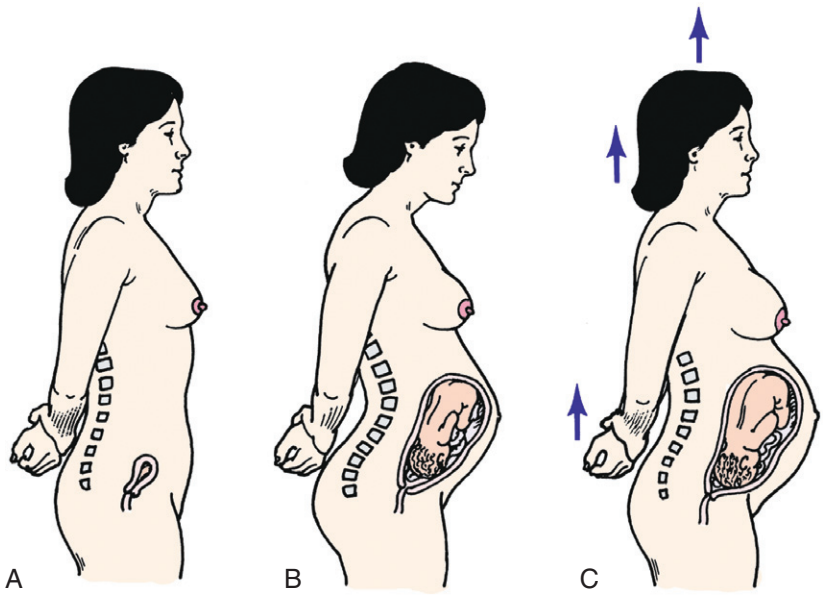

FIG 7-12 Postural changes during pregnancy. **A,** Nonpregnant. **B,** Incorrect posture during pregnancy. **C,** Correct posture during pregnancy.

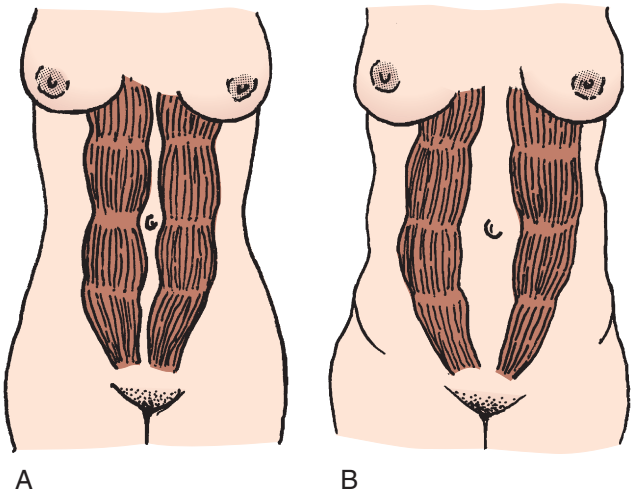

FIG 7-13 Possible change in rectus abdominis muscles during pregnancy. **A,** Normal position in nonpregnant woman. **B,** Diastasis recti abdominis in pregnant woman.

in walking. A waddling gait is common. Obesity or multifetal pregnancy tends to increase the pelvic instability. Peripheral joint laxity also increases as pregnancy progresses, but the cause is not known (Murray and Hassall, 2009).

The muscles of the abdominal wall stretch and ultimately lose some tone. During the third trimester, the rectus abdominis muscles may separate (Fig. 7-13), allowing abdominal contents to protrude at the midline. The umbilicus flattens or protrudes. After birth, the muscles gradually regain tone. However, separation of the muscles **(diastasis recti abdominis)** may persist.

Neurologic System

Little is known regarding specific alterations in function of the neurologic system during pregnancy aside from hypothalamic-pituitary neurohormonal changes. Specific physiologic alterations resulting from pregnancy may cause the following neurologic or neuromuscular symptoms:

- Compression of pelvic nerves or vascular stasis caused by enlargement of the uterus may result in sensory changes in the legs.
- Dorsolumbar lordosis may cause pain because of traction on nerves or compression of nerve roots.
- Edema involving the peripheral nerves may result in **carpal tunnel syndrome** during the last trimester. The syndrome is characterized by paresthesia (abnormal sensation such as burning or tingling) and pain in the hand, radiating to the elbow. The sensations are caused by edema that compresses the median nerve beneath the carpal ligament of the wrist. Smoking and alcohol consumption can impair the microcirculation and may worsen the symptoms. The dominant hand is usually affected most, although many women report symptoms in both hands. Symptoms usually regress after pregnancy. In some cases, surgical treatment is necessary (Cunningham, Leveno, Bloom, et al., 2010).
- Acroesthesia (numbness and tingling of the hands) is caused by the stoop-shouldered stance (see Fig. 7-12, *B*) assumed by some women during pregnancy. The condition is associated with traction on segments of the brachial plexus.
- Tension headache is common when anxiety or uncertainty complicates pregnancy. However, vision problems such as refractive errors, sinusitis, or migraine may also be responsible for headaches.
- "Light-headedness," faintness, and even syncope (fainting) are common during early pregnancy. Vasomotor instability, postural hypotension, or hypoglycemia may be responsible.
- Hypocalcemia can cause neuromuscular problems such as muscle cramps or tetany.

Gastrointestinal System

Appetite. During pregnancy, the woman's appetite and food intake fluctuate. Early in pregnancy, some women have nausea

with or without vomiting (morning sickness), possibly in response to increasing levels of hCG and altered carbohydrate metabolism. Morning sickness or nausea and vomiting of pregnancy (NVP) appears at about 4 to 6 weeks of gestation and usually subsides by the end of the third month (first trimester) of pregnancy (see Chapter 8). Severity varies from mild distaste for certain foods to more severe vomiting. The condition may be triggered by the sight or odor of various foods. By the end of the second trimester, the appetite increases in response to increasing metabolic needs. Rarely does NVP have harmful effects on the embryo, the fetus, or the woman. Whenever the vomiting is severe or persists beyond the first trimester or when it is accompanied by fever, pain, or weight loss, further evaluation is necessary and medical intervention is likely.

Women may have changes in their sense of taste, leading to cravings and changes in dietary intake. Some women have nonfood cravings **(pica)** such as for ice, clay, and laundry starch. Pica is often a manifestation of iron deficiency (Kilpatrick, 2009). Usually the subjects of these cravings, if consumed in moderation, are not harmful to the pregnancy if the woman has adequate nutrition with appropriate weight gain. (Cunningham, Leveno, Bloom, et al., 2010). See Chapter 9 for a discussion of nutrition in pregnancy.

Mouth. The gums become hyperemic, spongy, and swollen during pregnancy. They tend to bleed easily because the increasing levels of estrogen cause selective increased vascularity and connective tissue proliferation (a nonspecific gingivitis). Epulis (discussed in the section on the integumentary system) may develop at the gum line. Some pregnant women complain of **ptyalism** (excessive salivation), which may be caused by the unconscious decrease in swallowing by the woman when nauseated or caused by stimulation of salivary glands by eating starch (Cunningham, Leveno, Bloom, et al., 2010).

Esophagus, Stomach, and Intestines. Increased progesterone production causes decreased tone and motility of smooth muscles, resulting in esophageal regurgitation (reflux), slower emptying time of the stomach, and reverse peristalsis. As a result, the woman may experience "acid indigestion" or heartburn **(pyrosis)** beginning as early as the first trimester and intensifying through the third trimester.

The incidence of hiatal hernia is increased during pregnancy as a result of the upward displacement of the stomach by the enlarging uterus, which causes a widening of the hiatus of the diaphragm. Hiatal hernia occurs more often in multiparas and older or obese women.

Increased estrogen production causes decreased secretion of hydrochloric acid. This is associated with a decreased incidence of peptic ulcer disease (PUD) during pregnancy. Existing PUD tends to improve during pregnancy (Kelly and Savides, 2012).

In response to increased needs during pregnancy, iron is absorbed more readily in the small intestine. Even when the woman is deficient in iron, it will continue to be absorbed in sufficient amounts for the fetus to have a normal hemoglobin level.

Smooth muscle relaxation and reduced peristalsis caused by increased progesterone result in an increase in water absorption from the colon and may cause constipation. Constipation can also result from food choices, lack of fluids, iron supplementation, decreased activity level, abdominal distention by the pregnant uterus, and displacement and compression of the intestines. If the pregnant woman has hemorrhoids (see Fig. 7-10) and is constipated, the hemorrhoids can evert or bleed during straining at stool.

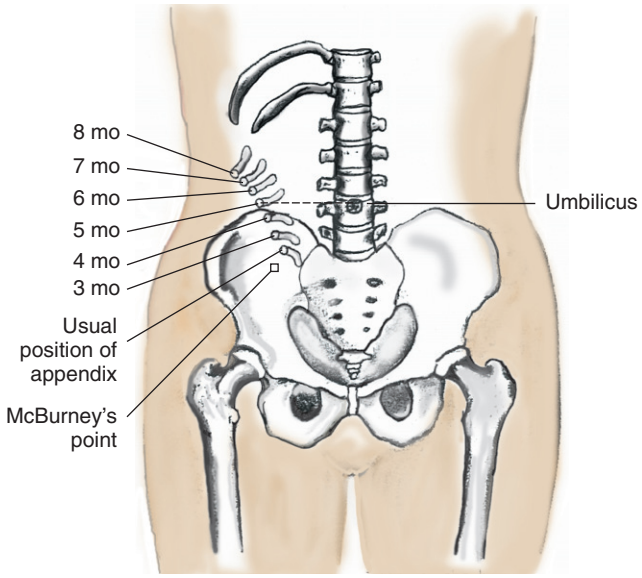

FIG 7-14 Change in position of appendix in pregnancy. Note McBurney's point.

Gallbladder and Liver. The gallbladder is often distended because of its decreased muscle tone during pregnancy. Increased emptying time and thickening of bile caused by prolonged retention are typical changes. These features, together with slight hypercholesterolemia from increased progesterone levels, may account for the development of gallstones during pregnancy.

Hepatic function is difficult to appraise during pregnancy. However, only minor changes in liver function develop. Occasionally, intrahepatic cholestasis (retention and accumulation of bile in the liver caused by factors within the liver) occurs late in pregnancy in response to placental steroids. It may result in **pruritus gravidarum** (severe itching) with or without jaundice. These distressing symptoms are difficult to treat during pregnancy and may be associated with fetal risk. However, symptoms subside after birth (Williamson and Mackillop, 2009).

Abdominal Discomfort. Intraabdominal alterations that can cause discomfort include pelvic heaviness or pressure, round ligament tension, flatulence, distention and bowel cramping, and uterine contractions. In addition to displacement of intestines, pressure from the expanding uterus causes an increase in venous pressure in the pelvic organs. Although most abdominal discomfort is a consequence of normal maternal alterations, the health care provider must be constantly alert to the possibility of disorders such as bowel obstruction or an inflammatory process.

Appendicitis may be difficult to diagnose in pregnancy because the appendix is displaced upward and laterally, high and to the right, away from McBurney's point (Fig. 7-14).

Endocrine System

Profound endocrine changes are essential for pregnancy maintenance, normal fetal growth, and postpartum recovery. Hormones, their sources, and their effects on the pregnancy are presented in Table 7-6.

TABLE 7-6 HORMONES AND EFFECTS OF CHANGES DURING PREGNANCY

HORMONE	SOURCE	EFFECTS OF CHANGES DURING PREGNANCY
Human chorionic gonadotropin	Fertilized ovum and chorionic villi	Maintains corpus luteum production of estrogen and progesterone until placenta takes over the function
Progesterone	Corpus luteum until 14 wk of gestation, then the placenta	Suppresses secretion of FSH and LH by the anterior pituitary; maintains pregnancy by relaxing smooth muscles, decreasing uterine contractility; causes fat to deposit in subcutaneous tissues over the maternal abdomen, back, and upper thighs; decreases mother's ability to use insulin
Estrogen	Corpus luteum until 14 wk of gestation, then the placenta	Suppresses secretion of FSH and LH by the anterior pituitary; causes fat to deposit in subcutaneous tissues over the maternal abdomen, back, and upper thighs; promotes enlargement of genitals, uterus, and breasts; increases vascularity; relaxes pelvic ligaments and joints; interferes with folic acid metabolism; increases the level of total body proteins; promotes retention of sodium and water; decreases secretion of hydrochloric acid and pepsin; decreases mother's ability to use insulin
Serum prolactin	Anterior pituitary	Prepares breasts for lactation
Oxytocin	Posterior pituitary	Stimulates uterine contractions; stimulates milk ejection from breasts
Human chorionic somatomammotropin (previously called *human placental lactogen*)	Placenta	Acts as a growth hormone; contributes to breast development; decreases maternal metabolism of glucose; increases the amount of fatty acids for metabolic needs
Thyroxine-binding globulin, thyroxine, triiodothyronine	Thyroid	Causes moderate enlargement of the thyroid gland but woman remains euthyroid; possibly plays role in early neural development of the fetus
Parathyroid	Parathyroid	Controls calcium and magnesium metabolism
Insulin	Pancreas	Increases production of insulin to compensate for insulin antagonism caused by placental hormones; effect of insulin antagonists is to decrease tissue sensitivity to insulin or ability to use insulin
Cortisol	Adrenal glands	Stimulates production of insulin; increases peripheral resistance to insulin
Aldosterone	Adrenal glands	Stimulates reabsorption of excess sodium from the renal tubules

FSH, Follicle-stimulating hormone; *LH,* luteinizing hormone.

KEY POINTS

- The biochemical, physiologic, and anatomic adaptations that occur during pregnancy are profound and revert to the nonpregnant state after birth and lactation.
- Maternal adaptations are attributed to the hormones of pregnancy and to mechanical pressures arising from the enlarging uterus and other tissues.
- Adaptations to pregnancy protect the woman's normal physiologic functioning, meet the metabolic demands that pregnancy imposes, and provide for fetal developmental and growth needs.
- ELISA testing, with monoclonal antibody technology, is the most popular method of pregnancy testing and is the basis for most over-the-counter home pregnancy tests.
- Presumptive, probable, and positive signs of pregnancy aid in the diagnosis of pregnancy; only positive signs (identification of a fetal heart tone, verification of fetal movements, and visualization of the fetus) can establish the diagnosis of pregnancy.
- Although the pH of the pregnant woman's vaginal secretions is more acidic than in the nonpregnant state, she is more vulnerable to some vaginal infections, especially yeast infections.
- Increased vascularity and sensitivity of the vagina and other pelvic viscera may lead to a high degree of sexual interest and arousal.
- Some adaptations to pregnancy result in discomforts such as fatigue, urinary frequency, nausea, constipation, and breast sensitivity.
- Balance and coordination are affected by changes in joints and in the woman's center of gravity as pregnancy progresses.

CHAPTER

8

Nursing Care of the Family During Pregnancy

Kathryn R. Alden

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe the processes of confirming pregnancy and estimating the date of birth.
- Summarize the physical, psychosocial, and behavioral changes that usually occur as the mother and other family members adapt to pregnancy.
- Evaluate the benefits of prenatal care and problems of accessibility for some women.
- Outline the patterns of health care used to assess maternal and fetal health status at the initial visit and follow-up visits during pregnancy.
- Conceptualize common nursing assessments, diagnoses, interventions, and methods of evaluation in providing care for the pregnant woman.
- Plan education needed by pregnant women to understand physical discomforts related to pregnancy and to recognize the signs and symptoms of potential complications.
- Examine the effect of culture, age, parity, and number of fetuses on the response of the family to the pregnancy and on the prenatal care provided.
- Determine the scope of childbirth and perinatal education in the community.
- Compare philosophies underlying maternal choices for childbirth.
- Describe the available options for health care providers and birth setting choices.

The prenatal period is a time of physical and psychologic preparation for birth and parenthood. Becoming a parent is one of the maturational milestones of adult life. It is a time of intense learning for parents and those close to them. The prenatal period provides a unique opportunity for nurses and other members of the health care team to influence family health. During this period, essentially healthy women seek regular care and guidance. The nurse's health-promotion interventions can affect the well-being of the woman, her unborn child, and the rest of her family for many years.

Regular prenatal visits, ideally beginning soon after the first missed menstrual period, offer opportunities to optimize the health of the expectant mother and her fetus. Prenatal health care permits diagnosis and treatment of preexisting maternal disorders and those that may develop during the pregnancy. Care is designed to monitor the growth and development of the fetus and identify abnormalities that can interfere with the course of normal labor and birth. The woman and her family can seek support to reduce stress and learn parenting skills.

In recent years, the concept of preconception care has been recognized as an important contributor to good pregnancy outcomes (see Chapter 3). If women can be taught healthy lifestyle behaviors and then practice them before conception—specifically, good nutrition, entering pregnancy with as healthy a weight as possible, adequate intake of folic acid, avoidance of alcohol and tobacco use, prevention of sexually transmitted infections (STIs) and other health hazards—a healthier pregnancy may result. Likewise, women who have health problems related to chronic diseases such as diabetes mellitus can be counseled regarding their special needs with the intent to minimize maternal and fetal complications.

Pregnancy spans 9 calendar months. However, health care providers use the concept of lunar months, which last 28 days (or 4 weeks), to describe the duration of pregnancy or gestational age. Thus normal pregnancy lasts about 10 lunar months, that is, 40 weeks, or 280 days. Pregnancy is divided into three 3-month periods, or trimesters. The first trimester covers weeks 1 through 13; the second, weeks 14 through 26; and the third, weeks 27 through term gestation (38 to 40 weeks). The focus of this chapter is on working with the expectant family to promote a healthy pregnancy that culminates in the birth of a healthy baby.

DIAGNOSIS OF PREGNANCY

Women often suspect pregnancy when they miss a menstrual period. Many women come to the first visit after a positive home pregnancy test; however, the clinical diagnosis of pregnancy before the second missed period can be difficult in some women. Physical variations, obesity, or tumors, for example, can confound even the experienced examiner. Accuracy is important because emotional, social, medical, or legal consequences related to an inaccurate diagnosis, either positive or negative, can be extremely serious. A correct date for the first day of the last (normal) menstrual period (LMP), the date of intercourse, and a basal body temperature record can be of great value in the accurate diagnosis of pregnancy (see Chapter 5).

Signs and Symptoms

Great variability is possible in the subjective symptoms and objective signs of pregnancy. Therefore the diagnosis of pregnancy may be uncertain for a time. It is based on signs and symptoms that are reported during history taking or found during physical examination. These signs and symptoms are classified as *presumptive, probable,* and *positive* (see Table 8-2).

Estimating Date of Birth

When pregnancy is confirmed, the woman's first question usually concerns when she will give birth. This date has traditionally been called the *estimated date of confinement* or *estimated date of delivery.* However, to promote a more positive perception of both pregnancy and birth, the term *estimated date of birth (EDB)* is now used. Accurate dating of pregnancy and calculation of the EDB have implications for timing of specific prenatal screening tests, assessing fetal growth, and making critical decisions for managing pregnancy complications. Ultrasound dating of gestational age is accurate, especially during the first half of pregnancy (ACOG, 2009).

Because the exact date of conception is usually unknown, several formulas have been suggested for calculating the EDB. None of these guides are infallible, but **Nägele's rule** is reasonably accurate and a commonly used method.

Nägele's rule is as follows: after determining the first day of the LMP, subtract 3 months, add 7 days and 1 year; or add 7 days to the LMP and count forward 9 months. For example, if the first day of the LMP was September 10, 2014, the EDB is June 17, 2015.

Nägele's rule assumes that the woman has a 28-day menstrual cycle and that the pregnancy occurred on the fourteenth day of the cycle. An adjustment is in order if the cycle is longer or shorter than 28 days. Only about 5% of pregnant women give birth spontaneously on the EDB as determined by Nägele's rule. Most women give birth during the period extending from 7 days before to 7 days after the EDB.

ADAPTATION TO PREGNANCY

Pregnancy affects all family members, and each family member must adapt to the pregnancy and interpret its meaning in light of his or her own needs. This process of family adaptation to pregnancy takes place within a cultural environment influenced by societal trends. Dramatic changes have occurred in Western society in recent years, and the nurse must be prepared to support not only traditional families but also single-parent families, reconstituted families, dual-career families, and alternative families.

Much of the research on family dynamics in pregnancy in the United States and Canada has been done with Caucasian, middle-class nuclear families. Therefore findings may not apply to families who do not fit the traditional North American model. Adaptation of terms is appropriate to avoid offense to the family and embarrassment to the nurse. Additional research is needed on a variety of families to determine if study findings generated in traditional families are applicable to others.

Maternal Adaptation

Women of all ages use the months of pregnancy to adapt to the maternal role—a complex process of social and cognitive learning.

Pregnancy is a maturational milestone that can be stressful but also rewarding as the woman prepares for a new level of caring and responsibility. Her self-concept changes in readiness for parenthood as she prepares for her new role. She moves gradually from being self-contained and independent to being committed to a lifelong concern for another human being. This growth requires mastery of certain developmental tasks: accepting the pregnancy, identifying with the role of mother, reordering the relationships between herself and her mother and between herself and her partner, establishing a relationship with the unborn child, and preparing for the birth experience. The partner's presence and emotional support are important factors in the successful accomplishment of these developmental tasks. Single women with limited support may have difficulty making this adaptation.

Accepting the Pregnancy

The first step in adapting to the maternal role is accepting the idea of pregnancy and assimilating the pregnant state into the woman's way of life. Mercer (1995) described this process as *cognitive restructuring* and credited Rubin (1975, 1984) as the nurse theorist who pioneered our understanding of maternal role attainment.

The degree of acceptance is reflected in the woman's emotional responses. Initially, many women are dismayed at finding themselves pregnant, especially if the pregnancy is unplanned or unintended. Eventual acceptance of pregnancy parallels the growing acceptance of the reality of a child. Nonacceptance of the pregnancy should not be equated with rejection of the child. A woman may dislike being pregnant but feel love for the child to be born.

Women who are happy and pleased about their pregnancy have high self-esteem and tend to be confident about outcomes for themselves, their babies, and other family members. Despite a general feeling of well-being, many pregnant women are surprised to experience *emotional lability,* that is, rapid and unpredictable changes in mood. These swings in emotions and increased sensitivity to others are disconcerting to the expectant mother and those around her. Increased irritability, explosions of tears and anger, and feelings of great joy and cheerfulness alternate, apparently with little or no provocation. Profound hormonal changes that are part of the maternal response to pregnancy may be responsible for mood changes.

Most women have ambivalent feelings during pregnancy, whether or not the pregnancy was intended. Ambivalence—having conflicting feelings at the same time—is considered a normal response for people preparing for a new role. For example, during pregnancy, women may feel great pleasure that they are fulfilling a lifelong dream but they also may feel great regret that life as they now know it is ending.

Even women who are pleased to be pregnant may experience feelings of hostility toward the pregnancy or the unborn child from time to time. Such incidents as a partner's chance remark about the attractiveness of a slim, nonpregnant woman or news of a colleague's promotion can give rise to ambivalent feelings. Body sensations, feelings of dependence, or the realization of the responsibilities of child care also can generate such feelings.

Intense feelings of ambivalence that persist through the third trimester can indicate an unresolved conflict with the motherhood role (Mercer, 1995). After the birth of a healthy child, memories of these ambivalent feelings usually are dismissed. If the child is born with a defect, a woman may look back at the times when she did not want the pregnancy and feel intense guilt. She may believe that her ambivalence caused the birth defect. She will then need reassurance that her feelings were not responsible for the problem.

Identifying with the Mother Role

The process of identifying with the mother role begins early in each woman's life when she is being mothered as a child. Her cultural and social group's perception of what constitutes the feminine role can subsequently influence her toward choosing between motherhood or a career, being married or single, being independent rather than interdependent, or being able to manage multiple roles. Practice roles such as playing with dolls, baby-sitting, and taking care of siblings may increase her understanding of what being a mother entails.

Many women have always wanted a baby; they enjoy children and look forward to motherhood. Their high motivation to become a parent promotes acceptance of pregnancy and eventual prenatal and parental adaptation. Other women apparently have not considered in any detail what motherhood means to them. During pregnancy, these women must resolve conflicts such as not wanting the pregnancy and child-related or career-related decisions.

Reordering Personal Relationships

Close relationships of the pregnant woman undergo change as she prepares emotionally for the new role of mother. As family members learn their new roles, periods of tension and conflict can occur. Promoting effective communication patterns between the expectant mother and her own mother and between the expectant mother and her partner are common nursing interventions provided during the prenatal visits.

The woman's relationship with her mother is significant in adapting to pregnancy and motherhood. Important components in the pregnant woman's relationship with her mother are the mother's availability (past and present), her reactions to the daughter's pregnancy, respect for her daughter's autonomy, and the willingness to reminisce (Mercer, 1995).

The mother's reaction to the daughter's pregnancy signifies her acceptance of the grandchild and of her daughter. If the mother is supportive, the daughter has an opportunity to discuss pregnancy and labor and her feelings of joy or ambivalence with a knowledgeable and accepting woman (Fig. 8-1). Reminiscing about the pregnant woman's early childhood and sharing the prospective grandmother's account of her childbirth experience help the daughter anticipate and prepare for labor and birth.

Although the woman's relationship with her mother is significant in considering her adaptation in pregnancy, the most important person to the pregnant woman is usually the father of her child. Women express two major needs within this relationship during pregnancy: feeling loved and valued and having the child accepted by the partner (Fig. 8-2).

The marital or committed relationship is not static but, instead, evolves over time. The addition of a child changes forever the nature of the bond between partners. This can be a time when couples grow closer and the pregnancy has a maturing effect on the partners' relationship as they assume new roles and discover new aspects of one another. Partners who trust and support each other are able to share mutual dependency needs (Mercer, 1995).

FIG 8-2 Prospective mother and father walk together. Women respond positively to their partner's interest and concern. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

Sexual expression during pregnancy is highly individual. The sexual relationship is affected by physical, emotional, and interactional factors, including misinformation about sex during pregnancy, sexual dysfunction, and physical changes in the woman. An individual may inaccurately attribute anomalies, intellectual disability, and other injuries to the fetus and mother to sexual relations during pregnancy. Some couples fear that the woman's genitalia will be drastically changed by the birth process. Couples may not express their concerns to the health care provider because of embarrassment or because they do not want to appear foolish.

As pregnancy progresses, changes in body shape, body image, and levels of discomfort influence both partners' desire for sexual

expression. During the first trimester, the woman's sexual desire may decrease, especially if she has breast tenderness, nausea, or fatigue. As she progresses into the second trimester, her sense of well-being, combined with the increased pelvic congestion that occurs at this time, may increase her desire for sexual release. In the third trimester, somatic complaints and physical bulkiness may increase her physical discomfort and diminish her interest in sex. Partners need to feel free to discuss their sexual responses during pregnancy with each other and with their health care provider (see later discussion).

Establishing a Relationship with the Fetus

Emotional attachment—feelings of being tied by affection or love—begins during the prenatal period as women use fantasizing and daydreaming to prepare themselves for motherhood (Rubin, 1975). They think of themselves as mothers and imagine maternal qualities they would like to possess. Expectant parents desire to be warm, loving, and close to their child. They try to anticipate changes that the child will bring in their lives and wonder how they will react to noise, disorder, reduced freedom, and caregiving activities. The mother-child relationship progresses through pregnancy as a developmental process that unfolds in three phases.

In phase 1, the woman accepts the biologic fact of pregnancy. She needs to be able to state, "I am pregnant." In phase 2, the woman accepts the growing fetus as distinct from herself and as a person to nurture. She can now say, "I am going to have a baby." Attachment by a mother to her child is enhanced by experiencing a planned pregnancy, and it increases when ultrasound examination and quickening confirm the reality of the fetus. During phase 3, the woman prepares realistically for the birth and parenting of the child. She expresses the thought "I am going to be a mother" and defines the nature and characteristics of the child. For example, she may speculate about the child's sex (if she has not had an ultrasound that confirms the sex) and personality traits based on patterns of fetal activity.

Although the mother alone experiences the child within, both parents and siblings believe the unborn child responds in a very individualized, personal manner. Family members may interact with the unborn child by talking to the fetus and stroking the mother's abdomen, especially when the fetus shifts position. They may sing to, play music for, or read to the fetus. The fetus may have a nickname used by family members.

Parents may occasionally show or voice disappointment over the sex of the child. The parents may experience grief and a sense of loss at birth as they release their fantasized image of the child and begin to accept the real child. However, these negative responses are usually temporary. Providing an accepting environment for parental reactions facilitates the parents' ability to move beyond disappointment to acceptance.

Preparing for Childbirth

Many women actively prepare for birth. They read books and information on various websites, view films, attend parenting classes, and talk to other women. They seek the best caregiver possible for advice, monitoring, and caring. The multipara has her own history of labor and birth, which influences her approach to preparation for this childbirth experience.

Anxiety can arise from concern about safe passage for herself and her child during the birth process (Mercer, 1995; Rubin, 1975). This concern may not be expressed overtly, but cues are given as the nurse listens to plans women make for care of the new baby and other children in case "anything should happen." These feelings persist despite statistical evidence about the safe outcome of pregnancy for mothers and their infants. Many women fear the pain of childbirth or mutilation because they do not understand anatomy and the birth process. Education by the nurse can alleviate many of these fears.

Toward the end of the third trimester, breathing is difficult and fetal movements become vigorous enough to disturb the mother's sleep. Backaches, frequency and urgency of urination, constipation, and varicose veins can become troublesome. The bulkiness and awkwardness of her body interfere with the woman's ability to care for other children, perform routine work-related duties, and assume a comfortable position for sleep and rest. A strong desire to see the end of pregnancy, to be over and done with it, makes women at this stage ready to move on to childbirth.

Paternal Adaptation

The father's beliefs and feelings about the ideal mother and father and his cultural expectation of appropriate behavior during pregnancy affect his response to his partner's need for him. One man may engage in nurturing behavior; another may feel lonely and alienated as the woman becomes physically and emotionally engrossed in the unborn child. The man may seek comfort and understanding outside the home or become interested in a new hobby or involved with his work. Some men view pregnancy as a proof of their masculinity and their dominant role. To others, pregnancy has no meaning in terms of responsibility to either mother or child. However, for most men, pregnancy is a time of preparation for the parental role, fantasy, great pleasure, and intense learning.

Accepting the Pregnancy

The ways fathers adjust to the parental role have been the subject of considerable research. In older societies, the man enacted the ritual couvade; that is, he behaved in specific ways and respected taboos associated with pregnancy and giving birth. In this way, the man's new status was recognized and endorsed. Now some men experience pregnancy-like symptoms, such as nausea, weight gain, and other physical symptoms. This phenomenon is known as the **couvade syndrome.** Changing cultural and professional attitudes have encouraged fathers' participation in the birth experience.

The man's emotional response to becoming a father, his concerns, and his informational needs change during the course of pregnancy. Phases of the developmental pattern become apparent. May (1982) described three phases characterizing the developmental tasks experienced by the expectant father:

- The *announcement phase* may last from a few hours to a few weeks. The developmental task is to accept the biologic fact of pregnancy. Men react to the confirmation of pregnancy with joy or dismay, depending on whether the pregnancy is desired, unplanned, or unwanted. Ambivalence in the early stages of pregnancy is common. If pregnancy is unplanned or unwanted, some men find the alterations in life plans and lifestyles difficult to accept. Some men engage in extramarital affairs for the first time during their partner's pregnancy. Others batter their wives for the first time or escalate the frequency of battering episodes.
- The second phase, the *moratorium phase,* is the period when he adjusts to the reality of pregnancy. The developmental task is to accept the pregnancy. Men appear to put conscious thought of the pregnancy aside for a time. They become more introspective and engage in many discussions about their philosophy of life, religion, childbearing, and childrearing practices and their relationships with family members,

particularly with their father. Depending on the man's readiness for the pregnancy, this phase may be relatively short or persist until the last trimester.

- The third phase, the *focusing phase,* begins in the last trimester and is characterized by the father's active involvement in both the pregnancy and his relationship with his child. The developmental task is to negotiate with his partner the role he is to play in labor and to prepare for parenthood. In this phase, the man concentrates on his experience of the pregnancy and begins to think of himself as a father.

Identifying with the Father Role

Each man brings to pregnancy attitudes that affect the way in which he adjusts to the pregnancy and parental role. His memories of the fathering he received from his own father, the experiences he has had with child care, and the perceptions of the male and father roles within his social group guide his selection of the tasks and responsibilities he will assume. Some men are highly motivated to nurture and love a child. They may be excited and pleased about the anticipated role of father. Others may be more detached or even hostile to the idea of fatherhood.

Reordering Personal Relationships

The partner's main role in pregnancy is to nurture the pregnant woman and to respond supportively to her feelings of vulnerability. The partner also must deal with the reality of the pregnancy. The partner's support indicates involvement in the pregnancy and preparation for attachment to the child.

Some aspects of a partner's behavior indicate rivalry. Direct rivalry with the fetus may be evident, especially during sexual activity. Men may protest that fetal movements prevent sexual gratification or that the fetus is watching them during sexual activity. Feelings of rivalry may be unconscious and not verbalized but expressed in subtle behaviors.

The woman's increased introspection may cause her partner to feel uneasy as she becomes preoccupied with thoughts of the child and of motherhood, with her growing dependence on her physician or midwife, and with her reevaluation of the couple's relationship.

Establishing a Relationship with the Fetus

The father-child attachment can be as strong as the mother-child relationship, and fathers can be as competent as mothers in nurturing their infants. The father-child attachment also begins in pregnancy. A father may rub or kiss the maternal abdomen; try to listen, talk, or sing to the fetus; or play with the fetus as he notes fetal movement. Calling the unborn child by name or nickname helps confirm the reality of pregnancy and promote attachment.

Men prepare for fatherhood in many of the same ways that women prepare for motherhood (i.e., by reading and fantasizing about the baby). Daydreaming about their role as father is common in the last weeks before the birth; men rarely describe their thoughts unless they are reassured that such daydreams are normal. They may adjust work commitments or plan vacations so that they can spend time with their new family.

Nurses can help fathers identify concerns and prepare for the reality of a baby by asking questions such as:

- What do you expect the baby to look and act like?
- What do you think being a father will be like?
- Have you thought about the baby's crying? Changing diapers? Burping the baby? Being awakened at night? Sharing your partner with the baby?

Some fathers may not wish to answer such questions when they are asked but may need time to think them through or discuss them with their partners.

As the birth date approaches, fathers have more questions about fetal and newborn behaviors. Some fathers are shocked or amazed at the small size of the clothes and furniture for the baby. The nurse can tell the father about the unborn child's ability to respond to light, sound, and touch and encourage him to feel and talk to the fetus. A tour of the birthing facility and an opportunity to see newborn infants or have discussions with new fathers, as in childbirth classes, may be welcomed.

Some men become involved by choosing the child's name and anticipating the child's sex if it is not already known. Some couples select the name of the child as early as the first month of pregnancy. Family tradition, religious customs, and the continuation of the parent's name or names of relatives or friends are important in the selection process.

Preparing for Childbirth

The days and weeks immediately before the expected day of birth are characterized by anticipation and anxiety. Boredom and restlessness are common as the couple focuses on the birth process; however, during the last 2 months of pregnancy, many expectant fathers experience a surge of creative energy at home and on the job. They can become dissatisfied with their present living space. When possible, they tend to act on the need to alter the environment (e.g., remodeling, painting). This activity can be overt evidence of their sharing in the childbearing experience. They are able to channel the anxiety and other feelings experienced during the final weeks before birth into productive activities. This behavior earns recognition and compliments from friends, relatives, and their partners.

Major concerns for the man are getting the mother to the birthing facility in time for the birth and not appearing ignorant. Many men want to be able to recognize labor and determine when it is appropriate to leave for the hospital or call the physician or midwife. They fantasize different situations and plan what they will do in response to them; they may rehearse taking various routes to the hospital, timing each route at different times of the day.

Some prospective fathers have questions about the labor suite's furniture, nursing staff, and location, as well as the availability of the physician and anesthesiologist. Others want to know what is expected of them when their partners are in labor. The man may have fears concerning safe passage of his partner and the mutilation or death of his partner or child. It is important that he verbalizes these fears; otherwise he cannot help his mate deal with her unspoken or overt apprehension.

With the exception of childbirth preparation classes, a man has few opportunities to learn ways to be an involved and active partner in this rite of passage into parenthood. The tensions and apprehensions of the unprepared, unsupportive father are readily transmitted to the mother and may increase her fears.

The same fears, questions, and concerns may affect birth partners who are not the biologic fathers. Birth partners need to be kept informed, supported, and included in all activities in which the mother desires their participation. The nurse can do much to promote pregnancy and birth as a family experience.

Sibling Adaptation

Sharing the spotlight with a new brother or sister may be the first major crisis for a child. The older child often experiences a sense of loss or feels jealous at being "replaced" by the new baby. Some of the factors that influence the child's response are age, the parents'

FIG 8-3 Four-year-old likes to examine the pregnant abdomen of his mother. (Courtesy Kara George, Phoenix, AZ.)

attitudes, the father's role, the length of separation from the mother, the hospital's visitation policy, and how the child has been prepared for the change.

A mother with other children must devote time and energy to reorganizing her relationships with these children. She needs to prepare siblings for the birth of the baby (Fig. 8-3 and Box 8-1). She can begin the process of role transition in the family by including the children in the pregnancy and being sympathetic to older children's concerns about losing their places in the family hierarchy. No child willingly gives up a familiar position.

Sibling responses to pregnancy vary with age and dependency needs. The 1-year-old infant seems largely unaware of the process, but the 2-year-old child notices the change in the mother's appearance and may comment, "Mommy's fat." The 2-year-old child's need for sameness in the environment makes the child aware of any change. Toddlers may exhibit more clinging behavior and revert to dependent behaviors in toilet training or eating.

By age 3 or 4 years, children like to be told the story of their own beginning and accept its being compared to the present pregnancy. They like to listen to heartbeats and feel the baby moving in utero (see Fig. 8-3). Sometimes they worry about how the baby is being fed and what it wears.

School-age children take a more clinical interest in their mother's pregnancy. They may want to know in more detail "How did the baby get in there?" and "How will it get out?" Children in this age-group notice pregnant women in stores, churches, and schools and sometimes seem shy if they need to approach a pregnant woman directly. On the whole, they look forward to the new baby, see themselves as "mothers" or "fathers," and enjoy buying baby supplies and readying a place for the baby. Because they still think in concrete terms and base judgments on the here and now, they respond positively to their mother's current good health.

Early and middle adolescents preoccupied with the establishment of their own sexual identity may have difficulty accepting the overwhelming evidence of the sexual activity of their parents. They reason that if they are too young for such activity, certainly their parents are too old. They seem to take on a critical parental role and may ask, "What will people think?" or "How can you let yourself get so fat?" Many pregnant women with teenage children confess that their teenagers are the most difficult factor in their current pregnancy.

BOX 8-1 TIPS FOR SIBLING PREPARATION

Prenatal

- Adjust the timing and content of information about the expected infant to the age and understanding of the older child.
- Take your child on a prenatal visit. Let the child listen to the fetal heartbeat and feel the baby move.
- Involve the child in preparations for the baby such as helping decorate the baby's room.
- Move the child to a bed (if still sleeping in a crib) at least 2 months before the baby is due.
- Read books, show videos, or take child to sibling preparation classes (Fig. 8-4), including a hospital tour.
- Answer your child's questions about the coming birth, what babies are like, and any other questions.
- Take your child to the homes of friends who have babies so that the child has realistic expectations of what babies are like.

During the Hospital Stay

- Have someone bring the child to the hospital to visit you and the baby (unless you plan to have the child attend the birth).
- Make sure you are not holding the new baby when the child arrives.
- Don't force interactions between the child and the baby. Often the child will be more interested in seeing you and being reassured of your love.
- Help the child explore the infant by showing how and where to touch the baby.
- Give the child a gift (from you or from you, your partner, and the baby).

Going Home

- Leave the child at home with a relative or baby-sitter.
- Have someone else carry the baby from the car so that you can hug the child first.

Adjustment After the Baby Is Home

- Arrange for a special time for the child to be alone with each parent.
- Don't exclude the child during infant feeding times. The child can sit with you and the baby and feed a doll or drink juice or milk with you or sit quietly with a game.
- Prepare small gifts for the child so that, when the baby receives gifts, the sibling won't feel left out. The child can also help open the baby gifts.
- Praise the child for acting age appropriately (so that being a baby does not seem better than being older).

Late adolescents do not appear to be unduly disturbed. They realize that they soon will be gone from home. Parents usually report that late adolescents are comforting and act more like other adults than children.

Grandparent Adaptation

Every pregnancy affects all family relationships. For expectant grandparents, a first pregnancy in a child is undeniable evidence that they are growing older. Many think of a grandparent as old, white-haired, and becoming feeble of mind and body; however, some people face grandparenthood while still in their 30s or 40s. A mother-to-be announcing her pregnancy to her mother may be greeted by a negative response that indicates she is not ready to be a grandmother. Both daughter and mother may be startled and hurt by the response.

FIG 8-4 Preschoolers in a sibling class learn about childbirth and infant care using dolls and a bunny. (Courtesy Julie and Darren Nelson, Loveland, CO.)

FIG 8-5 Great-grandmother and grandmother admiring new baby. (Courtesy Barbara Wilson, West Jordan, UT.)

In some family units, expectant grandparents are nonsupportive and may inadvertently decrease the self-esteem of the parents-to-be. Mothers may talk about their terrible pregnancies; fathers may discuss the endless cost of rearing children; and mothers-in-law may complain that their sons are neglecting them because their concern is now directed toward the pregnant daughters-in-law.

However, most grandparents are delighted with the prospect of a new baby in the family. It reawakens their feelings of their own youth, the excitement of giving birth, and their delight in the behavior of the parents-to-be when they were infants. They set up a memory store of their child's first smiles, first words, and first steps that can be used later for "claiming" the newborn as a member of the family. Their satisfaction and that of the parents come with the realization that continuity between past and present is guaranteed.

The grandparent is the historian who transmits the family history, a resource person who shares knowledge based on experience, a role model, and a support person. The grandparent's presence and support can strengthen family systems by widening the circle of support and nurturance (Fig. 8-5). Other sources of information cannot replace the unique contribution that grandparents make (www.grandparents.com; www.grandparenting.org).

CARE MANAGEMENT

The goal of prenatal care is to promote the health and well-being of the pregnant woman, her fetus, the newborn, and the family (Gregory, Niebyl, and Johnson, 2012). Major emphasis is placed on preventive aspects of care, primarily to motivate the pregnant woman to practice optimal self-management and report unusual changes early so that problems can be minimized or prevented. In holistic care, nurses provide information and guidance about not only the physical changes but also the psychosocial impact of pregnancy on the woman and members of her family. Therefore the goals of prenatal nursing care are to promote positive pregnancy outcomes, to foster a safe birth for the infant and mother, and to promote satisfaction of the mother and family with the pregnancy and birth experience.

According to the National Center for Health Statistics, based on data from 27 states and Puerto Rice, 71% of women received prenatal care in the first trimester. Only 7% of women started prenatal care late (during third trimester) or had no prenatal care. The subgroups most likely to receive late or no prenatal care were American Indian, Alaska Native, African-American, and Hispanic (Osterman, Martin, Mathews, et al., 2011). Although women of middle or high socioeconomic status routinely seek prenatal care, women living in poverty or those who lack health insurance are not always able to use public health care services or gain access to private care. Lack of culturally sensitive care providers and barriers in communication caused by differences in language also interfere with access to care. Immigrant women from cultures in which prenatal care is not emphasized may not know to seek routine prenatal care. Thus birth outcomes in these populations are less positive, with higher rates of maternal and fetal or newborn complications. In particular, problems with low birth weight (LBW) (less than 2500 g [5.5 lb]) and infant mortality have been associated with inadequate prenatal care (Cunningham, Leveno, Bloom, et al., 2010).

Barriers to obtaining health care during pregnancy include a lack of motivation to seek care, especially for unintended pregnancies; inadequate finances; lack of transportation; unpleasant clinic personnel, facilities, or procedures; inconvenient clinic hours; child care problems; and personal attitudes (Novick, 2009; Phillippi, 2009). The availability and accessibility of prenatal care may be improved by increasing the use of advanced practice nurses in collaborative practice with physicians or midwives. A regular schedule of home visits by nurses aids in reducing barriers to care and contributes to improved maternal and infant outcomes (Agency for Healthcare Research and Quality [AHRQ] Healthcare Innovations Exchange, 2012).

The traditional model for provision of prenatal care has been used for more than a century. The initial visit usually occurs in the first trimester, with monthly visits through week 28 of pregnancy. Thereafter, visits are scheduled every 2 weeks until week 36 and then every week until birth. More recently, the trend is toward individualizing the schedule of care. Women with low-risk pregnancies may have fewer routine prenatal visits, whereas those at risk for complications may be seen more frequently than the traditional schedule (American Academy of Pediatrics [AAP] Committee on Fetus and Newborn and American College of Obstetricians and Gynecologists [ACOG] Committee on Obstetric Practice, 2012).

Group prenatal care is an alternative model to traditional care during pregnancy. In group prenatal care, authority is shifted from the provider to the woman and other women who have similar due dates. The model creates an atmosphere that facilitates learning, encourages discussion, and develops mutual support. Centering-Pregnancy (https://www.centeringhealthcare.org/) is a well-known model of group prenatal care that involves three components: health care assessment, education, and peer support. Most care takes place in the group setting after the initial visit and continues for ten 2-hour sessions that begin at about 16 weeks. At each meeting, the first 30 to 40 minutes consists of assessments (by the woman herself and by the health care provider) and the remaining 60 to 75 minutes is spent in group discussion of specific issues such as discomforts of pregnancy and preparation for labor and birth. Families and partners are encouraged to participate. Benefits associated with group prenatal care include improved birth outcomes such as lower rates of preterm birth, increased knowledge, improved satisfaction, and higher breastfeeding initiation rates (Herrman, Rogers, and Ehrenthal, 2012; Picklesimer, Billings, Hale, et al., 2012; Rotundo, 2011; Robertson, Aycock, and Darnell, 2009).

Prenatal care is ideally a multidisciplinary activity in which nurses work with nurse-midwives, nutritionists, physicians, social workers, and others. Collaboration among these individuals is necessary to provide holistic care. The case management model, which makes use of care maps and critical pathways, is one system that promotes comprehensive care with limited overlap in services. To emphasize the nursing role, care management for the initial visit and follow-up visits is organized around the central elements of the nursing process: assessment, nursing diagnoses, expected outcomes, plan of care and interventions, and evaluation.

In recent years, the concept of preconception care has been recognized as an important contributor to good pregnancy outcomes (see Chapter 3). If women can be taught healthy lifestyle behaviors and then practice them before conception—specifically, good nutrition, entering pregnancy with as healthy a weight as possible, adequate intake of folic acid, avoidance of alcohol and tobacco use, prevention of sexually transmitted infections (STIs) and other health hazards—a healthier pregnancy may result. Likewise, women who have health problems related to chronic diseases such as diabetes mellitus can be counseled regarding their special needs with the intent to minimize maternal and fetal complications.

Initial Visit

Once the pregnancy is confirmed and the woman's desire to continue the pregnancy has been validated, prenatal care is begun. The assessment process begins at the initial visit and is continued throughout the pregnancy. Assessment techniques include the interview, physical examination, and laboratory tests. Because the initial visit and follow-up visits are distinctly different in content and process, they are described separately.

Interview

The pregnant woman and her partner or family members who may be present should be told that the first prenatal visit is longer and more detailed than future visits. The initial evaluation includes a comprehensive health history emphasizing the current pregnancy, previous pregnancies, the family, a psychosocial profile, a physical assessment, diagnostic testing, and an overall risk assessment.

The therapeutic relationship between the nurse and the woman is established during the initial assessment interview. Two types of data are collected: the woman's subjective appraisal of her health status and the nurse's objective observations.

FIG 8-6 Prenatal interview. (Courtesy Dee Lowdermilk, Chapel Hill, NC.)

With the woman's permission, include persons accompanying her in the initial prenatal interview (Fig. 8-6). Observations and information about the woman's partner and/or family are then included in the database. For example, if the woman has small children with her, the nurse can ask about her plans for child care during the time of labor and birth. Note any special needs at this time (e.g., wheelchair access, assistance in getting on and off the examining table, and cognitive deficits).

Reason for Seeking Care

Although pregnant women are scheduled for "routine" prenatal visits, they often come to the health care provider seeking information or reassurance about a particular concern. When the woman is asked a broad, open-ended question such as "How have you been feeling?" she may reveal problems that could otherwise be overlooked. The woman's chief concerns should be recorded in her own words to alert other personnel to the priority of needs identified by her. At the initial visit, a typical desire is for information about the normal course of pregnancy.

Current Pregnancy

The presumptive signs of pregnancy, such as nausea and vomiting, may be of great concern to the woman. A review of symptoms she is experiencing and how she is coping with them helps establish a database to develop a plan of care. Some early teaching may be provided at this time.

Childbearing and Female Reproductive System History

Data are gathered on the woman's age at menarche; menstrual history; contraceptive history; history of infertility or gynecologic conditions; history of any STIs; her sexual history; and a detailed history of all her pregnancies, including the present one, and their outcomes. The date of the last Papanicolaou (Pap) test and the result are noted. The date of her LMP is obtained to establish the EDB.

Health History

The health history includes those physical or surgical procedures that can affect the pregnancy or that can be affected by the pregnancy. For example, a pregnant woman who has diabetes or epilepsy requires special care. Because most women are anxious during the initial interview, the nurse's reference to cues such as a MedicAlert bracelet prompts the woman to explain allergies; chronic diseases;

or medications being taken such as cortisone, insulin, or anticonvulsants.

The woman should also describe any previous surgical procedures. If a woman has had uterine surgery or extensive repair of the pelvic floor, a cesarean birth may be necessary; previous appendectomy rules out appendicitis as a cause of right lower quadrant pain in pregnancy; spinal surgery may contraindicate the use of spinal or epidural anesthesia; and breast augmentation or reduction procedures may influence the ability to breastfeed. Note any injury involving the pelvis.

Women may forget to mention chronic or handicapping conditions during the initial assessment because they have adapted to them. Special shoes or a limp may indicate the existence of a pelvic structural defect—an important consideration in pregnant women. The nurse who observes these special characteristics and sensitively inquires about them can obtain individualized data that will provide the basis for a comprehensive nursing care plan to help optimize pregnancy outcomes (Signore, Spong, Krotoski, et al., 2011). Observations are a vital component of the interview process because they prompt the nurse and the woman to focus on the specific needs of the woman and her family.

Nutritional History

The nutritional status of a pregnant woman has a direct effect on the growth and development of the fetus. A dietary assessment can reveal special diet practices, food allergies, eating behaviors, the practice of pica, and other factors related to her nutritional status (see Box 9-7). Pregnant women are usually motivated to learn about good nutrition and respond well to nutritional advice generated by this assessment.

It is essential that obese women receive counseling about weight gain, nutrition, and food choices. They should also be advised about their risk for complications for themselves and increased risk for congenital abnormalities (Davies, Maxwell, McLeod, et al., 2010). Women with a history of bariatric surgery are nutritionally at risk and should be followed closely throughout pregnancy to promote maternal and fetal well-being (Magdaleno, Pereira, Chaim, et al., 2012).

History of Use of Drugs and Herbal Preparations

A woman's past and present use of drugs, both legal (over-the-counter [OTC], prescription, and herbal drugs; caffeine; alcohol; nicotine) and illegal (marijuana, cocaine, heroin), must be assessed because many substances cross the placenta and can harm the developing fetus. See Chapter 11 for discussion of substance abuse during pregnancy. Increasing numbers of individuals are using herbal preparations, and this includes pregnant women. Therefore it is important for health care providers to question pregnant women regarding the use of herbal preparations and document their responses.

LEGAL TIP: Testing for Drug Use

Health care providers must obtain informed consent from a pregnant woman before she can be tested for drug use (Wong, Ordean, and Kahan, 2011).

Family History

The family history provides information about the woman's family, including parents, grandparents, siblings, and children. These data help identify familial or genetic disorders or conditions that could affect the present health status of the woman or her fetus.

Social, Experiential, and Occupational History

Situational factors such as the family's ethnic and cultural background and socioeconomic status are assessed while the history is obtained. The following information may be obtained over several encounters. The woman's perception of this pregnancy is explored by asking her such questions as:

- Is this pregnancy planned or unintended?
- Is the woman/couple pleased or displeased, accepting or nonaccepting?
- What problems related to finances, career, or living accommodations may arise as a result of the pregnancy?

The family support system is determined by asking her such questions as:

- Who is her primary support?
- Which roles does she expect her significant other or father of the baby to play?
- Are changes needed to promote adequate support?
- What are the existing relationships among mother, father/partner, siblings, and in-laws?
- What preparations are being made for her care and that of dependent family members during labor and for the care of the infant after birth?
- Is financial, educational, or other support needed from the community?
- What are the woman's ideas about childbearing, her expectations of the infant's behavior, and her outlook on life and the female role?

Other questions that should be asked include:

- What does the woman think it will be like to have a baby in the home?
- How is her life going to change by having a baby?
- What plans are interrupted by having a baby at this time?

During interviews throughout the pregnancy, the nurse should remain alert for the appearance of potential parenting problems such as depression, lack of family support, and inadequate living conditions. The nurse must assess the woman's attitude toward health care, particularly during childbearing; her expectations of health care providers; and her view of the relationship between herself and the nurse.

Coping mechanisms and patterns of interacting are identified. Early in the pregnancy, the nurse should determine the woman's knowledge of pregnancy, maternal changes, fetal growth, self-management, and care of the newborn, including feeding. It is important to ask about attitudes toward unmedicated or medicated childbirth and about her knowledge of the availability of parenting skills classes. Before planning for nursing care, the nurse needs information about the woman's decision-making abilities and living habits (e.g., exercise, sleep, diet, diversional interests, personal hygiene, clothing). Common stressors during childbearing include the baby's welfare, the labor and birth process, the behaviors of the newborn, the relationship with the baby's father or partner and her family, changes in body image, and physical symptoms.

Explore attitudes concerning the range of acceptable sexual behavior during pregnancy by asking, for example, What has your family (partner, friends) told you about sex during pregnancy? The woman's sexual self-concept is given emphasis by asking such questions as: How do you feel about the changes in your appearance? How does your partner feel about your body now? How do you feel about wearing maternity clothes?

Women should be questioned regarding their occupation, past and present, since this may adversely affect maternal and fetal health. For some women, heavy lifting and exposure to chemicals and radiation may be part of their daily work, and these activities can

negatively affect the pregnancy. For others, long hours of sitting at a desk working on a computer can contribute to carpal tunnel syndrome or circulatory stasis in the legs.

History of Physical Abuse

All women should be assessed for a history of or risk for physical abuse, particularly because the likelihood of intimate partner violence (IPV) increases during pregnancy (see Chapter 3). This screening should be done at the first prenatal visit, at least once each trimester, and at the postpartum visit (American College of Obstetricians and Gynecologists Committee on Health Care for Underserved Women, 2012a). It is essential that the screening is done in a safe, private setting with the woman alone. Nurses can ask the woman screening questions with routine assessments during pregnancy. Examples of questions that might be asked include:

- Are you with a spouse or partner who threatens or physically hurts you? If yes, who?
- Within the past year or in this pregnancy, has anyone hit, slapped, kicked, or otherwise hurt you? If yes, who? Are you currently with that person?
- Has anyone forced you to have sexual activities that made you uncomfortable? If yes, who? Are you currently with that person?

Although visual cues from the woman's appearance or behavior may suggest the possibility of abuse, no one profile of the battered woman exists. Identification of abuse and immediate clinical intervention that includes information about safety can result in behavior that may prevent future abuse and increase the safety and well-being of the woman and her infant. During pregnancy, the target body parts change during abusive episodes. Women report physical blows directed to the head, breasts, abdomen, and genitalia. Sexual assault is common.

Battering and pregnancy in teenagers constitutes a particularly difficult situation. Adolescents may be trapped in the abusive relationship because of their inexperience. Routine screening for abuse and sexual assault is recommended for pregnant adolescents. Because pregnancy in young adolescent girls is commonly the result of sexual abuse, the nurse should assess the girl's desire to maintain the pregnancy.

Nurses should be aware that victims of **human trafficking** may be seen in prenatal settings because of unintended pregnancy. These women or young girls are forced or deceived into commercial sex acts (prostitution) with little or no pay. They are under strict control by their traffickers. Similar to victims of IPV, these women are likely to exhibit signs of physical abuse or neglect such as scars, bruises, burns, unusual bald patches, or tattoos that may be a sign of branding. They are likely to be accompanied by someone who never leaves them alone and speaks for them. They may not speak English and may lack identification documents. If the woman is alone, she may have her cell phone on and in speaker mode so that the person on the other end can hear everything that is said during the visit. Nurses and other health care providers must be creative in getting the woman alone for questioning. Strategies might include sending the other person to the front desk to fill out paperwork, interviewing the woman in the restroom, or telling her she needs to go for testing and cannot take her cell phone. With the consent of suspected or confirmed victims of human trafficking, intervention plans can be developed. An excellent resource is the National Human Trafficking Resource Center (1-888-373-7888) (Dovydaitis, 2010; Tracy and Konstantopoulos, 2012).

Review of Systems

During the review of systems, ask the woman to identify and describe pre-existing or concurrent problems in any of the body systems and assess her mental status. Question the woman about physical symptoms she has experienced such as shortness of breath or pain. Pregnancy affects and is affected by all body systems; therefore information on the present status of body systems is important in planning care. For each sign or symptom described, the following additional data should be obtained: body location, quality, quantity, chronology, aggravating or alleviating factors, and associated manifestations (onset, character, and course) (Seidel, Ball, Dains, et al., 2011).

Physical Examination

The initial physical examination provides the baseline for assessing subsequent changes. The examiner should determine the woman's needs for basic information regarding reproductive anatomy and provide this information, along with a demonstration of the equipment that may be used during the examination and an explanation of the procedure itself. The interaction requires an unhurried, sensitive, and gentle approach with a matter-of-fact attitude.

The physical examination begins with assessment of vital signs, including blood pressure (BP), height, and weight (for calculation of body mass index [BMI]) (see Chapter 9). The bladder should be empty before pelvic examination.

Each examiner develops a routine for proceeding with the physical examination; most choose the head-to-toe progression. Heart and lung sounds are evaluated, and extremities are examined. The skin is assessed for changes in pigmentation, rashes, and edema. Distribution, amount, and quality of body hair are of particular importance because the findings reflect nutritional status, endocrine function, and attention to hygiene. The thyroid gland is assessed carefully, as are the breasts and abdomen. The height of the fundus is noted if the first examination occurs after the first trimester of pregnancy. During the examination, the examiner must remain alert to the woman's cues that give direction to the remainder of the assessment and that indicate imminent untoward response, such as feeling lightheaded or dizzy. See Chapter 3 for a detailed description of the physical examination.

Whenever a pelvic examination is performed, the tone of the pelvic musculature and the woman's knowledge of Kegel exercises are assessed. Particular attention is paid to the size of the uterus because this is an indication of the duration of gestation. The nurse present during the examination can coach the woman at this time in breathing and relaxation techniques as needed. One vaginal examination during pregnancy is recommended; another is usually not done unless indicated for medical reasons.

Laboratory Tests

The data yielded by laboratory examination of specimens obtained during the examination add important information concerning the symptoms of pregnancy and the woman's health status.

Specimens are collected at the initial visit so that any abnormal findings can be treated. Blood is drawn for a variety of tests (Table 8-1). A sickle cell screen is recommended for women of African, Asian, or Middle Eastern heritage. Testing for antibody to the human immunodeficiency virus (HIV) is strongly recommended for all pregnant women; this testing must be voluntary and without coercion (ACOG Committee on Obstetric Practice, 2011a; Centers for Disease Control and Prevention [CDC], 2010) (Box 8-2). The folate level is measured when indicated. Cystic fibrosis (CF) carrier screening tests should be offered to all pregnant women; if the woman is a CF carrier, the father of the baby should be tested. Concurrent testing is recommended if there are time constraints related to prenatal diagnostic evaluation (ACOG Committee on Genetics, 2011).

TABLE 8-1 LABORATORY TESTS IN THE PRENATAL PERIOD

LABORATORY TEST	PURPOSE
Hemoglobin, hematocrit/WBC, differential	Detects anemia/detects infection
Hemoglobin electrophoresis	Identifies women with hemoglobinopathies (e.g., sickle cell anemia, thalassemia)
Blood type, Rh, and irregular antibody	Identifies fetuses at risk for developing erythroblastosis fetalis or hyperbilirubinemia in neonatal period
Rubella titer	Determines immunity to rubella
Tuberculin skin testing; chest film after 20 wk of gestation in women with reactive tuberculin tests	Screens for exposure to tuberculosis
Urinalysis, including microscopic examination of urinary sediment; pH, specific gravity, color, glucose, albumin, protein, RBCs, WBCs, casts, acetone; hCG	Identifies women with glycosuria, renal disease, hypertensive disease of pregnancy; infection; occult hematuria
Urine culture	Identifies women with asymptomatic bacteriuria
Renal function tests: BUN, creatinine, electrolytes, creatinine clearance, total protein excretion	Evaluates level of possible renal compromise in women with a history of diabetes, hypertension, or renal disease
Papanicolaou test	Screens for cervical intraepithelial neoplasia; if a liquid-based test is used, may also screen for HPV
Vaginal or rectal smear for *Neisseria gonorrhoeae,* chlamydia, HPV, GBS	Screens high risk population for asymptomatic infection; GBS done at 35-37 wk
RPR/VDRL/FTA-ABS	Identifies women with untreated syphilis
HIV antibody,* hepatitis B surface antigen, toxoplasmosis	Screens for the specific infection
1-hr glucose tolerance	Screens for gestational diabetes; done at initial visit for women with risk factors; done at 24-28 wk for pregnant women at risk whose initial screen was negative; women with low risk usually not tested
3-hr glucose tolerance	Screens for diabetes in women with elevated glucose level after 1-hr test; must have two elevated readings for diagnosis
Cardiac evaluation: ECG, chest x-ray film, and echocardiogram	Evaluates cardiac function in women with a history of hypertension or cardiac disease

BUN, Blood urea nitrogen; *ECG,* electrocardiogram; *FTA-ABS,* fluorescent treponemal antibody absorption test; *GBS,* group B streptococcus; *hCG,* human chorionic gonadotropin; *HIV,* human immunodeficiency virus; *HPV,* human papilloma virus; *RBC,* red blood cell; *RPR,* rapid plasma reagin; *VDRL,* Venereal Disease Research Laboratories; *WBC,* white blood cell.
*With patient permission.

A urine specimen is collected for cultures and metabolic function tests. A purified protein derivative tuberculin test may be administered to assess exposure to tuberculosis. During the pelvic examination, cervical and vaginal smears can be obtained for cytologic studies and for diagnosis of infection (e.g., chlamydia, gonorrhea).

Recognition of risk factors during pregnancy may indicate the need to repeat some tests at other times. For example, exposure to tuberculosis or an STI would necessitate repeat testing. STIs are common in pregnancy and may have negative effects on mother and fetus (see Table 4-5 on p. 98). Careful assessment and thorough screening are essential.

Follow-Up Visits

Monthly visits are scheduled routinely during the first and second trimesters, although additional appointments may be made as the need arises. During the third trimester, the possibility for complications increases and closer monitoring is necessary. Starting with week 28, visits are scheduled every 2 weeks until week 36; then visits are scheduled every week until birth unless the health care provider individualizes the schedule. Individual needs, complications, and risks of the pregnant woman may warrant visits more or less often. The pattern of interviewing the woman first and then assessing physical changes and performing laboratory tests is maintained.

In prenatal care models that use a reduced-frequency screening schedule or in group prenatal care models such as CenteringPregnancy, the timing of follow-up visits will be different but assessments and care will be similar.

Interview

Follow-up visits are less intensive than the initial prenatal visit. At each of these follow-up visits, the woman is asked to summarize relevant events that have occurred since the previous visit. She is asked about her general emotional and physical well-being, complaints or problems, and questions she may have. Personal and family needs are identified and explored.

A woman's emotional state can affect her and her family's general well-being. Therefore the nurse asks whether the woman has had any mood swings, reactions to changes in her body image, bad dreams, or worries. Positive feelings (her own and those of her family) are also noted. The reactions of family members to the pregnancy and the woman's progression through the developmental tasks of pregnancy are also assessed and recorded.

During the third trimester, current family situations and their effect on the woman are assessed (e.g., the response of partner, siblings, and grandparents to the pregnancy and the coming child). The nurse needs to assess the parents' understanding of the following: the warning signs that indicate emergencies such as bleeding

BOX 8-2 HUMAN IMMUNODEFICIENCY VIRUS SCREENING

- Pregnant women are ethically obligated to seek reasonable care during pregnancy and to avoid causing harm to the fetus. Women's health nurses should be advocates for the fetus while accepting of the pregnant woman's decision regarding testing and/or treatment for HIV.
- The incidence of perinatal transmission from an HIV-positive mother to her fetus ranges from 16% to 25%. Triple drug antiviral or highly active antiretroviral therapy (HAART) during pregnancy decreases perinatal transmission to as low as 1% to 2% (Burr, 2011).
- The CDC (2010) recommends testing for HIV infections for all pregnant women as early as possible in pregnancy and a second test in the third trimester, ideally before 36 weeks. This is especially important for women known to be at high risk for HIV infection.
- Testing has the potential to identify HIV-positive women who can then be treated. Health care providers have an obligation to ensure that pregnant women are well informed about HIV symptoms, testing, and methods of decreasing maternal-fetal transmission. The Centers for Disease Control and Prevention (CDC) and the American College of Obstetricians and Gynecologists (ACOG) recommend universal opt-out screening, which means that all pregnant women are offered HIV screening but have the opportunity to opt out if desired (ACOG Committee on Obstetric Practice, 2011; CDC, 2010). The Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN, 2008) supports this system of HIV screening that allows all pregnant women to be offered screening.

Data from American College of Obstetricians and Gynecologists Committee on Obstetric Practice: Committee opinion no. 418: prenatal and perinatal human immunodeficiency virus testing—expanded recommendations, *Obstet Gynecol* 104(5 Part 1):1119–1124, 2011; AWHONN: *HIV screening procedures for pregnant women and newborns—policy position statement,* Washington, DC, 2008, Author; Burr C: Reducing maternal-infant HIV transmission. In Coffey S, editor: *Guide for HIV/AIDS clinical care,* Rockville, MD, 2011, US Department of Health and Human Services, Health Resources and Services Administration, http://hab.hrsa.gov/deliverhivaidscare/clinicalguide11/cg-402_pmtct.html; Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines, *Morb Mortal Wkly Rep* 59(RR12):1–110, 2010.

and abdominal pain, the signs of preterm and term labor, the labor process and anxieties about labor, fetal development, and methods to assess fetal well-being. The nurse should ascertain whether the woman is planning to attend childbirth preparation classes and what she knows about the control of discomfort during labor. If she is having a home birth, she should be queried as to whether all the necessary supplies have been obtained.

A review of the woman's physical systems is appropriate at each visit, and any suggestive signs or symptoms are assessed in depth. Discomforts reflecting adaptations to pregnancy are identified. Special inquiries are made about possible infections (e.g., genitourinary tract, respiratory tract). The woman's knowledge of and success with self-management measures are assessed, as well as outcomes of prescribed therapy.

Physical Examination

Reevaluation is a constant aspect of a pregnant woman's care. Each woman reacts differently to pregnancy. As a result, careful monitoring of the pregnancy and her reactions to care is vital. Physiologic changes are documented as the pregnancy progresses and reviewed for possible deviations.

FIG 8-7 Measurement of fundal height from symphysis that **A,** includes the upper curve of the fundus and **B,** does not include the upper curve of the fundus. Note position of hands and measuring tape. (Courtesy Chris Rozales, San Francisco, CA.)

EMERGENCY

Supine Hypotension

Signs and Symptoms

- Pallor
- Dizziness, faintness, breathlessness
- Tachycardia
- Nausea
- Clammy (damp, cool) skin; sweating

Intervention

- Position woman on her side until her signs and symptoms subside and vital signs stabilize within normal limits.

At each visit, physical parameters are measured. BP is taken at every visit, using the same arm and with the woman seated. Her weight is measured, and the appropriateness of the weight gain is evaluated in relation to her BMI. The woman is asked to empty her bladder. Urine may be checked by dipstick. The presence and degree of edema are noted. For examination of the abdomen, the woman lies on her back with her arms by her side and head supported by a pillow; a small wedge should be placed under her right hip to prevent supine hypotension. Supine hypotension can occur when the woman lies on her back and the weight of the abdominal contents compresses the vena cava and aorta, causing a decrease in BP and a feeling of faintness (see Emergency box). Abdominal inspection is followed by measurement of the height of the fundus (Fig. 8-7).

TABLE 8-2 SIGNS OF POTENTIAL COMPLICATIONS DURING THE FIRST, SECOND, AND THIRD TRIMESTERS

SIGNS AND SYMPTOMS	POSSIBLE CAUSES
First Trimester	
Severe vomiting	Hyperemesis gravidarum
Chills, fever	Infection
Burning on urination	Infection
Diarrhea	Infection
Abdominal cramping; vaginal bleeding	Miscarriage, ectopic pregnancy
Second and Third Trimesters	
Persistent, severe vomiting	Hyperemesis gravidarum, hypertension, preeclampsia
Sudden discharge of fluid from vagina before 37 weeks	Premature rupture of membranes
Vaginal bleeding, severe abdominal pain	Miscarriage, placenta previa, abruptio placentae
Chills, fever, burning on urination, diarrhea	Infection
Severe backache or flank pain	Kidney infection or stones; preterm labor
Change in fetal movements: absence of fetal movements after quickening, any unusual change in pattern or amount	Fetal jeopardy or intrauterine fetal death
Uterine contractions; pressure; cramping before 37 weeks	Preterm labor
Visual disturbances: blurring, double vision, or spots	Hypertensive conditions, preeclampsia
Swelling of face or fingers and over sacrum	Hypertensive conditions, preeclampsia
Headaches: severe, frequent, or continuous	Hypertensive conditions, preeclampsia
Muscular irritability or convulsions	Hypertensive conditions, preeclampsia
Epigastric or abdominal pain (perceived as severe stomachache)	Hypertensive conditions, preeclampsia, abruptio placentae
Glycosuria, positive glucose tolerance test reaction	Gestational diabetes mellitus

The information provided during the interview and physical examination reflects the status of maternal adaptations. When any of the findings is suspicious, an in-depth examination is performed. For example, careful interpretation of BP is important in the risk factor analysis of all pregnant women. BP is evaluated on the basis of absolute values and the length of gestation and is interpreted in the light of modifying factors. See Chapter 12 for an in-depth discussion of problems associated with hypertension. Signs and symptoms other than hypertension also may be present that indicate potential complications (Table 8-2).

Fetal Assessment

Toward the end of the first trimester, before the uterus is an abdominal organ, the fetal heart tones (FHTs) can be heard with an ultrasound fetoscope or an ultrasound stethoscope (Fig. 8-8). To hear the FHTs, place the instrument in the midline just above the symphysis pubis and apply firm pressure. The woman and her family should be offered the opportunity to listen to the FHTs. The health status of the fetus is assessed at each visit for the remainder of the pregnancy.

Fundal Height. During the second trimester, the uterus becomes an abdominal organ. The fundal height, or measurement of the height of the uterus above the symphysis pubis, is used as one indicator of fetal growth.

The measurement also provides a gross estimate of the duration of pregnancy. From gestational weeks (GW) 18 to 32, the height of the fundus in centimeters is approximately the same as the number of weeks of gestation (±2 GW) if the woman's bladder is empty at the time of measurement. As much as a 3-cm variation is possible if the bladder is full (Cunningham, Leveno, Bloom, et al., 2010). For example, the fundal height of a woman of 28 weeks of gestation with an empty bladder would measure from 26 to 30 cm. In addition, the fundal height measurement may aid in the identification of risk factors. A stable or decreased fundal height may indicate the presence of intrauterine growth restriction (IUGR); an excessive increase could indicate the presence of multifetal gestation (more than one fetus) or polyhydramnios (excessive amniotic fluid).

A disposable paper metric tape measure is preferred for measuring fundal height. To increase the reliability of the measurement, the same person examines the pregnant woman at each of her prenatal visits; however, often this is not possible. All clinicians who examine a particular pregnant woman should be consistent in their measurement technique. Ideally, each prenatal setting should establish a protocol for fundal height measurement that specifies the woman's position on the examining table, the measuring device, and the technique to be used. Fig. 8-7 presents two methods of measuring fundal height.

Gestational Age. In an uncomplicated pregnancy, fetal gestational age is estimated after the duration of pregnancy and the EDB are determined. Fetal gestational age is determined from the menstrual history, contraceptive history, pregnancy test results, and the following findings obtained from the clinical evaluation:

- First uterine evaluation: date, size
- Fetal heart first heard: date, method (Doppler stethoscope, fetoscope)
- Date of quickening
- Current fundal height, estimated fetal weight
- Current week of gestation by history of LMP or ultrasound examination (or both)
- Ultrasound examination: date, week of gestation, biparietal diameter
- Reliability of dates

Quickening ("feeling life") refers to the mother's first perception of fetal movement. It usually occurs between weeks 16 and 20 of gestation and is initially experienced as a fluttering sensation. The mother's report should be recorded. Multiparas often perceive fetal movement earlier than do primigravidas.

The use of ultrasound examination (also called a *sonogram*) in early pregnancy has become routine, and many health care providers have this equipment available in the office. This procedure can be used to establish the duration of pregnancy if the woman cannot give a precise date for her LMP or if the size of the uterus does not conform to the EDB as calculated by Nägele's rule. Ultrasound

FIG 8-8 Detecting fetal heartbeat. **A,** Father can listen to the fetal heart with a fetoscope (first detectable at 18 to 20 weeks with a fetoscope). **B,** Doppler ultrasound stethoscope (fetal heartbeat detectable at 12 weeks). **C,** Pinard stethoscope. **NOTE:** Hands should not touch stethoscope while nurse is listening. (*A,* Courtesy Shannon Perry, Phoenix, AZ. *B,* Courtesy Dee Lowdermilk, Chapel Hill, NC. *C,* Courtesy Julie Perry Nelson, Loveland, CO.)

also provides information about the well-being of the fetus (see Chapter 10).

Health Status. The assessment of fetal health status includes consideration of fetal movement. The mother is instructed to note the extent and timing of fetal movements and report immediately if the pattern changes or movement ceases. Regular movement is a reliable indicator of fetal health (Cunningham, Leveno, Bloom, et al., 2010).

The fetal heart rate (FHR) is checked on routine visits once it has been heard (see Fig. 8-8). Early in the second trimester, the heartbeat may be heard with the Doppler stethoscope (see Fig. 8-8, *B*). To detect the heartbeat before the fetal position can be palpated by Leopold maneuvers (see Box 16-6), the scope is moved around the abdomen until the heartbeat is audible. The heartbeat is counted for 1 minute, and the quality and rhythm are noted. Later in the second trimester, the FHR can be determined with the fetoscope or Pinard fetoscope (see Fig. 8-8, *A* and *C*). A normal rate and rhythm are other good indicators of fetal health. Once the heartbeat is noted, its absence is cause for immediate investigation.

Intensive investigation of fetal health status is initiated if any maternal or fetal complications arise (e.g., maternal hypertension, IUGR, premature rupture of membranes [PROM], irregular or absent FHR, absence of fetal movements after quickening). Careful, precise, and concise recording of patient responses and laboratory results contributes to the ongoing evaluation of maternal and fetal well-being.

Laboratory Tests. The number of routine laboratory tests done during follow-up visits in pregnancy is limited. A clean-catch urine specimen is obtained to test for levels of glucose, protein, nitrites, and leukocytes at each visit. When indicated, urine specimens for culture and sensitivity are obtained and cervical and vaginal smears and blood tests are repeated.

First-trimester screening for chromosomal abnormalities is offered as an option between 11 and 14 weeks. This multiple marker screen includes ultrasound evaluation of nuchal translucency (NT) and biochemical markers—pregnancy-associated placental protein (PAPP-A) and free beta-human chorionic gonadotropin (β-hCG). Between 15 and 20 weeks, maternal serum alpha-fetoprotein (MSAFP) screening, the QUAD test (alpha-fetoprotein, hCG, estriol, and inhibin A), or Penta Screen (components of QUAD test plus invasive trophoblast antigen [ITA]) can be done to screen for neural tube defects (NTDs) and other chromosomal abnormalities. Women who had first-trimester screening need MSAFP testing after 15 weeks for NTD screening (Gregory, Niebyl, and Johnson, 2012).

An ultrasound is often done at 18 to 24 weeks to survey fetal anatomy. At the same time, assessment of cervical length may be done as a screening tool for preterm labor risk. If cervical length is determined to be short, a transvaginal ultrasound should be done (Society for Maternal-Fetal Medicine Publications Committee, 2012). If the cervix is confirmed to be short, further assessment for preterm birth risk factors should occur and management options should be considered.

If not done earlier in pregnancy, a glucose screen is obtained between 24 and 28 weeks of gestation for women at high risk for gestational diabetes. Group B strep (GBS) testing is done between 35 and 37 weeks of gestation; cultures collected earlier will not

accurately predict GBS status at time of birth. Other cultures for STIs may be obtained in the last trimester, based on risk factors and geographic prevalence rates. Tests that are often repeated at 28 weeks include hemoglobin and hematocrit, serologic test for syphilis, and HIV testing. In addition, at 28 weeks, an Rh type and screen for antibodies is performed. If the woman is Rh negative and unsensitized, she should receive 300 mcg of Rh immune globulin (RhIG) (see Medication Guide, p. 503). Hematocrit testing may be repeated at 36 weeks in women with anemia and those at risk for peripartum hemorrhage (Gregory, Niebyl, and Johnson, 2012).

Other diagnostic tests, such as amniocentesis, are available to assess the health status of both the pregnant woman and the fetus (see Chapters 9 and 15 for further discussion).

Collaborative Care

After obtaining information through the assessment process, the data are analyzed to identify deviations from the norm and unique needs of the pregnant woman and her family. Care is optimized with a collaborative approach involving the physician or midwife, nurse, other relevant health care professionals, the woman, her partner, and her family.

The nurse-patient relationship is critical in setting the tone for further interaction. The techniques of listening with an attentive expression, touching, and using eye contact have their place, as does recognizing the woman's feelings and her right to express these feelings. The interaction may occur in various formal or informal settings. A clinical setting, home visits, or telephone conversations all provide opportunities for contact and can be used effectively.

Education About Maternal and Fetal Changes

Expectant parents typically are curious about the growth and development of the fetus and the consequent changes that occur in the mother's body. Mothers may be more tolerant of the discomforts related to the continuing pregnancy if they understand the underlying causes. Educational literature (printed, electronic, or web-based materials) that describes fetal and maternal changes is available and can be used to explain changes as they occur. Couples can track the development of their growing fetus through websites such as www.babycenter.com/fetal-development or www.parents.com/pregnancy/stages/fetal-development/. To be most effective, the material should be appropriate for the pregnant woman's or couple's ethnicity, culture, and literacy level and the agency's resources.

Education for Self-Management

The expectant mother needs information on many topics. The nurse who is observant, listens, and is familiar with typical concerns of expectant parents can anticipate the questions that will be asked and can encourage mothers and their partners to discuss what is on their minds. Printed literature can be given to supplement the individualized teaching the nurse provides; women often avidly read books, pamphlets, and web information related to their own experience. When nurses read the literature before they distribute it, they have an opportunity to point out areas that may not correspond with local health care practices. Nurses who work with expectant parents should be aware of popular web-based resources and programs related to pregnancy.

Pregnant women who receive conflicting advice or instruction are likely to grow increasingly frustrated with members of the health care team and the care provided. Several topics that may cause concern for pregnant women are discussed in the following sections.

Nutrition. Good nutrition is important in the maintenance of maternal health during pregnancy and in the provision of adequate nutrients for embryonic and fetal development. Assessing a woman's nutritional status and weight gain and providing information on nutrition are part of the nurse's responsibilities in providing prenatal care. Teaching may include discussion about foods high in iron, encouragement to take prenatal vitamins, and recommendations to limit caffeine intake. In some settings, a registered dietitian conducts classes for pregnant women about nutrition during pregnancy or interviews them to assess their knowledge of these topics. Nurses can refer women to a registered dietitian if a need is identified during the nursing assessment. (For detailed information concerning maternal and fetal nutritional needs and related nursing care, see Chapter 9.)

Personal Hygiene. During pregnancy, the sebaceous (sweat) glands are highly active because of hormonal influences and women often perspire freely. They may be reassured that the increase is normal and that their previous patterns of perspiration will return after the postpartum period. Baths and warm showers can be therapeutic because they relax tense, tired muscles; help counter insomnia; and make the pregnant woman feel fresh. Tub bathing is permitted even in late pregnancy because little water enters the vagina unless under pressure. However, late in pregnancy, when the woman's center of gravity lowers, she is at risk for falling. Tub bathing is contraindicated after rupture of the membranes.

Prevention of Urinary Tract Infection. Because of physiologic changes that occur in the renal system during pregnancy (see Chapter 7), infections of the lower urinary tract (acute urethritis, acute cystitis) are common. *Escherichia coli (E. coli)* is the most common causative organism for urinary tract infection (UTI) in pregnant women (Duff, 2012). Although UTIs can be asymptomatic, typical symptoms include frequency, urgency, dysuria, dribbling, and hesitancy; gross hematuria may occur. Women should be instructed to inform their health care provider promptly if they experience these symptoms. Urinary tract infections pose a risk to the mother and fetus; thus their prevention or early treatment is essential. Oral antibiotics are commonly prescribed.

The nurse can assess the woman's understanding of appropriate hand hygiene techniques to use before and after urinating and the importance of wiping the perineum from front to back. Soft, absorbent toilet tissue, preferably white and unscented, should be used; harsh, scented, or printed toilet paper may cause irritation. Bubble bath or other bath oils should be avoided because these can irritate the urethra. Women should wear underpants and panty hose with a cotton crotch and avoid wearing tight-fitting slacks or jeans for long periods. Anything that allows a buildup of heat and moisture in the genital area can foster the growth of bacteria.

Some women do not consume enough fluid. After exploring the woman's fluid preferences, the nurse should advise her to drink at least 2 liters (L) (eight glasses) of liquid a day to maintain an adequate fluid intake that ensures frequent urination. Pregnant women should not limit fluids in an effort to reduce the frequency of urination. Women need to know that if urine looks dark (concentrated), they must increase their fluid intake. The consumption of yogurt and acidophilus milk can help prevent urinary tract and vaginal infections. Although drinking cranberry juice is often recommended, there is conflicting evidence regarding its effectiveness and, in particular, the effective dose needed to prevent urinary tract infections.

The nurse should review healthy urination practices with the woman. Women should be told not to ignore the urge to urinate,

because holding urine lengthens the time bacteria are in the bladder and allows them to multiply. Women should plan ahead when faced with situations that may normally require them to delay urination (e.g., a long car ride). They should always urinate before going to bed at night. Bacteria also can be introduced during intercourse. It is helpful to wash the genital area with warm water before sex, to urinate before and after intercourse, and then to drink a large glass of water to promote additional urination.

Kegel Exercises. Kegel exercises—deliberate contraction and relaxation of the pubococcygeus muscle—strengthen the muscles around the reproductive organs and improve muscle tone. Many women are not aware of the muscles of the pelvic floor until it is pointed out that these are the muscles used during urination and sexual intercourse and that they can be consciously controlled. The pelvic floor muscles encircle the vaginal outlet, and they need to be exercised. An exercised muscle can stretch and contract readily at birth. Practice of pelvic muscle exercise during pregnancy also results in fewer complaints of urinary incontinence in late pregnancy and postpartum.

Preparation for Breastfeeding the Newborn. Pregnant women are usually eager to discuss their plans for feeding the newborn. The American Academy of Pediatrics (AAP) recommends exclusive breastfeeding for the first 6 months, continued breastfeeding as complementary feedings are introduced, and breastfeeding for at least 1 year and beyond as desired by the mother and infant (AAP Section on Breastfeeding, 2012). In the mother, medical contraindications to breastfeeding are uncommon and include untreated active tuberculosis (until treated for 2 weeks and deemed noninfectious), active herpes simplex lesions on the breast, human T-cell lymphotropic virus type I or II, and untreated brucellosis. Women on antimetabolite medications (chemotherapy) should not breastfeed, but they can pump and discard their milk temporarily; this is also true for radiopharmaceuticals and a few other medications (AAP Section on Breastfeeding, 2012; Lawrence and Lawrence, 2011). In developed countries, breastfeeding is discouraged in women who are HIV positive because of the risk for HIV transmission; however, in developing countries, breastfeeding is recommended because the advantages of breastfeeding for infants outweigh the risk for HIV transmission (Lawrence and Lawrence, 2011). Although hepatitis B antigen has not been shown to be transmitted through breast milk, as an added precaution it is recommended that infants born to hepatitis B antigen–positive women receive hepatitis B vaccine and hepatitis B immune globulin immediately after birth (Lawrence and Lawrence, 2011). Most women who choose to breastfeed do so because they are aware of the numerous benefits. Lack of knowledge about the benefits of breastfeeding and perceived personal and social disadvantages to breastfeeding can influence a woman not to breastfeed. Modesty issues, lack of support by the partner and family, incompatibility with lifestyle, and lack of confidence are among the reasons cited by women who decide to formula-feed their infants (Lawrence and Lawrence, 2011; Nelson, 2012).

A woman's decision about the method of infant feeding is usually made before pregnancy; thus it is essential to educate women of childbearing age about the benefits of breastfeeding. The woman and her partner are encouraged to decide what method of feeding is suitable for them; however, the benefits of breastfeeding should be emphasized. Once the couple has been given information about the advantages and disadvantages of breastfeeding and bottle-feeding, they can make an informed choice. Health care providers support these decisions and provide any needed assistance.

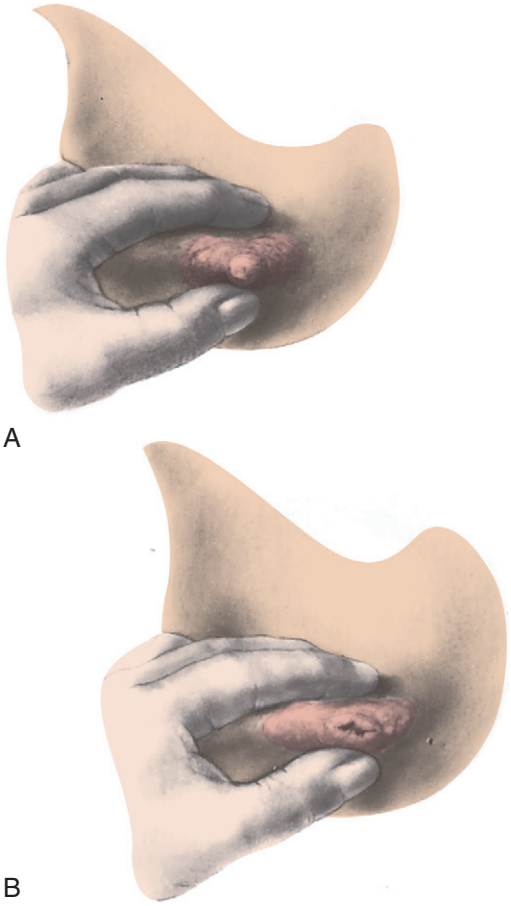

FIG 8-9 Test for inverted nipples **A,** Normal nipple everts with gentle pressure. **B,** Inverted nipple inverts with gentle pressure. (Adapted from Lawrence RA, Lawrence RM: *Breastfeeding: a guide for the medical profession,* ed 7, St Louis, 2011, Mosby.)

Assessment of breasts during the prenatal period may reveal potential concerns related to breastfeeding. Scars on the breast may indicate previous breast reduction surgery, which can impact milk production. The woman may have breast implants; this may or may not affect successful breastfeeding. Examination of the breasts may reveal flat or inverted nipples, which can affect the baby's ability to successfully latch on to the breast. To determine if nipples are inverted, a woman can perform a test on her nipples to determine freedom of protrusion (Fig. 8-9). The woman places her thumb and forefinger on her areola and presses inward gently. A normal nipple will evert or stand erect while an inverted nipple will appear to withdraw (Lawrence and Lawrence, 2011).

Exercises to break the adhesions that cause the nipple to invert do not work and may cause uterine contractions (Lawrence and Lawrence, 2011). Some clinicians recommend the prenatal use of breast shells (Fig. 8-10) during the last trimester for women with flat or inverted nipples, although evidence to support their effectiveness is lacking (Lawrence and Lawrence, 2011). They can be uncomfortable and cause irritation to the nipple or areola. Breast stimulation is contraindicated in women at risk for preterm labor; therefore the decision to suggest the use of breast shells to women with flat or inverted nipples must be made judiciously (Lawrence and Lawrence, 2011; Walker, 2010).

The woman is taught to cleanse the nipples with warm water to prevent blocking of the ducts with dried colostrum. Soap,

ointments, alcohol, and tinctures should not be applied because they remove protective oils that keep nipples supple. The use of these substances may cause the nipple to crack during early lactation (Lawrence and Lawrence, 2011).

The woman who plans to breastfeed should purchase a nursing bra that will accommodate her increased breast size during the last few months of pregnancy and during lactation. If her breasts are very heavy or if the woman feels uncomfortable with the weight unsupported, the bra can be worn day and night.

Dental Health. Dental care during pregnancy is especially important because nausea during pregnancy may lead to poor oral hygiene and allow dental caries to develop. Brushing at least twice daily and flossing once in the evening can reduce the potential for caries. Inflammation and infection of the gingival and periodontal tissues may occur. There is some evidence linking periodontal disease and preterm birth. While treatment may improve dental health, it does not prevent preterm birth (Cunningham, Leveno, Bloom, et al., 2010). Because calcium and phosphorus in the teeth are fixed in enamel, the old adage "for every child a tooth" is not true. Diagnosis and treatment of oral health problems, including necessary dental x-rays, are safe during pregnancy (Cunningham, Leveno, Bloom, et al., 2010; Kumar and Samelson, 2009). Dental care and nonemergent procedures are best scheduled during the second trimester when the woman is past the stage of feeling nauseous and can sit comfortably in the dental chair. To avoid supine hypotension during dental procedures, the pregnant woman in her second or third trimester is positioned in the dental chair with a small pillow under her right hip (Kumar and Samelson, 2009).

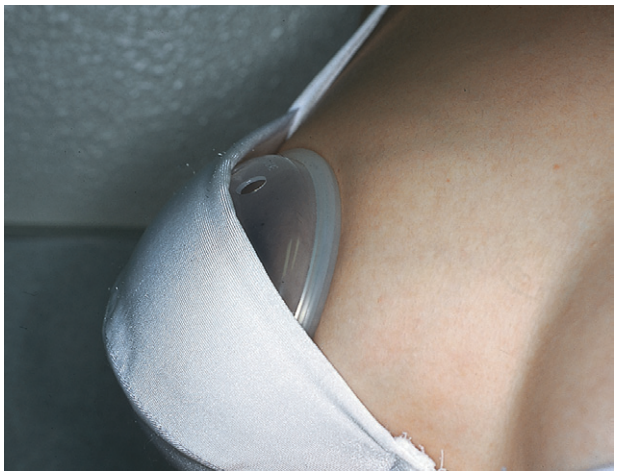

FIG 8-10 Breast shell in place inside bra; sometimes recommended for flat or inverted nipples. (Courtesy Michael S. Clement, MD, Mesa, AZ.)

Physical Activity. Physical activity promotes a feeling of well-being and can help reduce anxiety in the pregnant woman (see Evidence-Based Practice box). It improves circulation, promotes relaxation and rest, and counteracts boredom, as it does in the nonpregnant woman. The U.S. Department of Health and Human Services (USDHHS) recommends 150 minutes of moderate exercise each week during pregnancy for women who are not already active or engaging in moderate exercise. Women who are highly active or engage in vigorous aerobic exercise can continue during pregnancy if they remain healthy and discuss with their health care provider about adjusting activity over time as needed (USDHHS, 2008). Detailed exercise tips for pregnancy are presented in the Home Care box.

Exercises that help relieve the low back pain that often arises during the second trimester because of the increased weight of the fetus are demonstrated in Fig. 8-11.

Posture and Body Mechanics. Skeletal, musculature, and hormonal changes in pregnancy can predispose the woman to backache and possible injury. As pregnancy progresses, the pregnant woman's center of gravity changes, pelvic joints soften and relax, and stress is placed on abdominal musculature. Poor posture and body mechanics contribute to the discomfort and potential for injury (see Patient Teaching box). To minimize these problems, women can learn good body posture and body mechanics (Fig. 8-12). The activities described in the Home Care box can also promote greater physical comfort.

Rest and Relaxation. The pregnant woman is encouraged to plan regular rest periods, particularly as pregnancy advances. The side-lying position is recommended to promote uterine perfusion and fetoplacental oxygenation by eliminating pressure on the

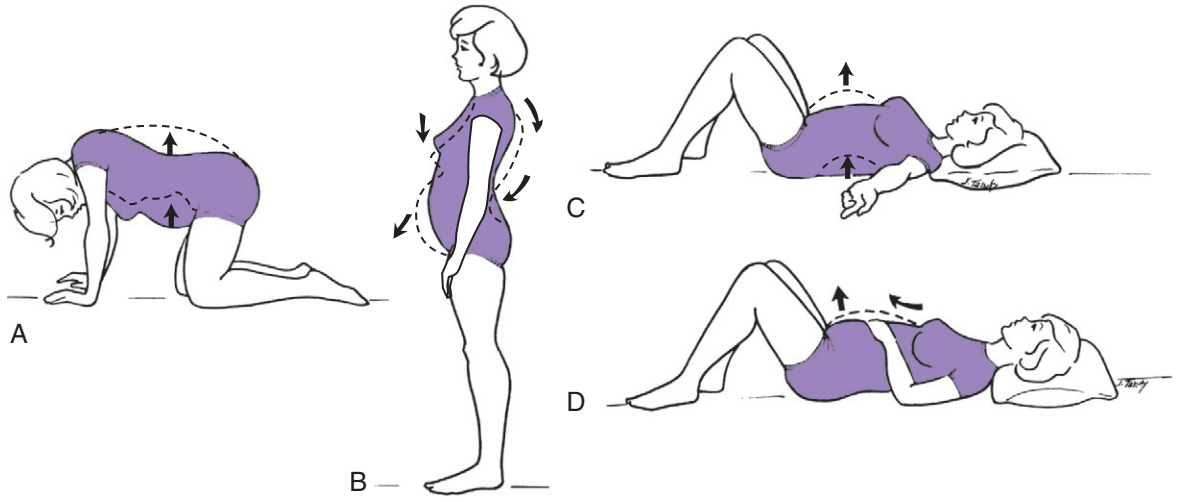

FIG 8-11 Exercises. **A, B,** and **C,** Pelvic rocking relieves low backache (excellent for relief of menstrual cramps as well). **D,** Abdominal breathing aids relaxation and lifts abdominal wall off uterus.

ascending vena cava and descending aorta, which can lead to supine hypotension (Fig. 8-13). The woman should also be shown the way to rise slowly from a side-lying position to prevent placing strain on the back and minimize the orthostatic hypotension caused by changes in position common in the latter part of pregnancy.

To stretch and rest back muscles at home or at work, the nurse can suggest that the woman do the following exercises:

- While standing behind a chair, the woman supports and balances herself using the back of the chair (Fig. 8-14). She squats for 30 seconds and then stands for 15 seconds. She should repeat 6 times, in several sets per day, as needed.

EVIDENCE-BASED PRACTICE

Nonpharmacologic Mind-Body Support Interventions for Healthy Pregnancy

Ask the Question

For pregnant women at risk for anxiety and depression, can antenatal support interventions improve health and birth outcomes?

Search for the Evidence

Search Strategies

English research–based publications on pregnancy support, anxiety, prenatal depression, and postpartum depression were included.

Databases Used

Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), PubMed, UpToDate, CINAHL, and the professional website for AWHONN.

Critically Analyze the Evidence

- A systematic review finds that pregnant women who were taught guided imagery and who practice relaxation techniques experience less anxiety during labor and decreased anxiety and depression in the immediate postpartum period (Marc, Toureche, Ernst, et al., 2011).
- For women with prenatal depression, being randomized to regular yoga or massage therapy improved scores for depression, anxiety, back and leg pain, and relationship over controls randomized to standard prenatal care. Additional benefits included greater gestational age and birth weight (Field, Diego, Hernandez-Reif, et al., 2012).
- Even brief antenatal group interventions focusing on stress management and coping skills for depressed women can reduce the risk of postpartum depression as much as 18%. In addition, the group intervention reduced depression in women with poor partner support and in women experiencing unplanned pregnancy (Kozinszky, Dudas, Devosa, et al., 2012).
- For women at risk for low-birth-weight babies, additional antenatal social support did not change the birth weights, but it did reduce admissions to hospitals for pregnancy complications and cesarean birth (Hodnett, Fredericks, and Weston, 2010).
- Exercise is a strongly recommended intervention for mental and physical well-being and weight control in pregnancy, especially for at-risk populations. Qualitative research finds that barriers to exercise for low-income African-Americans include poor motivation, misinformation, lack of affordable nearby facilities, and sociocultural barriers. Women exercised more when they were part of a group exercise class and when safe, low-cost facilities were present in their communities (Krans and Chang, 2011).

Apply the Evidence: Nursing Implications

- Women at risk for anxiety or depression may be especially vulnerable during pregnancy, when medication may not be advisable. Teaching stress management, guided imagery, and relaxation may help them cope with the changes of pregnancy and parenthood. Regular yoga and massage therapy may also provide additional benefits.
- All pregnant women benefit from social support. Some obstetric practices have adopted group prenatal appointments to try to facilitate group support. It is important that these not only include nurse-led patient education, but also allow time for social bonding and dialogue. Women at risk for depression and anxiety may benefit the most.
- The nurse can also assess the community for safe, low-cost exercise opportunities and make this information readily available to local pregnant women, along with information about the benefits of exercise. Initiating a regular walking club or encouraging daily walking partners provides a low-cost, safer, and social activity that can improve overall pregnancy well-being. In the bigger picture, advocating for safer communities decreases stress and improves health for all.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Describe EBP to include the components of research evidence, clinical expertise, and patient/family values.

Describe the strong evidence from systematic reviews, relevant information from single randomized controlled trials, and the ideas suggested by qualitative research.

Skills

Locate evidence reports related to clinical practice topics and guidelines.

Look for patterns and ideas that can be translated to nursing care.

Attitudes

Appreciate strengths and weaknesses of scientific bases for practice.

Value EBP that embraces both information that lends itself to randomized control trials, as well as qualitative research whose rich data may foster novel solutions.

HOME CARE

Exercise Tips for Pregnant Women

- *Consult your health care provider* when you know or suspect that you are pregnant. Discuss your medical and obstetric history, your current exercise regimen, and the exercises you would like to continue throughout pregnancy.
- *Seek help in determining an exercise routine* that is well within your limit of tolerance, especially if you have not been exercising regularly.
- *Consider decreasing weight-bearing exercises* (jogging, running) as pregnancy progresses and concentrating on non–weight bearing activities such as swimming, cycling, or stretching. If you are a runner, starting in your seventh month you may wish to walk instead.
- *Avoid risky activities* such as surfing, mountain climbing, skydiving, and racquetball because such activities that require precise balance and coordination may be dangerous. Avoid activities that require holding your breath and bearing down (Valsalva maneuver). Jerky, bouncy motions also should be avoided.
- *Exercise regularly* at least three times a week, as long as you are healthy, to improve muscle tone and increase or maintain your stamina. If you exercise sporadically, this may put undue strain on your muscles. Limit activity to shorter intervals. Exercise for 10 to 15 minutes, rest for 2 to 3 minutes, and then exercise for another 10 to 15 minutes.
- *Decrease your exercise level* as your pregnancy progresses. The normal alterations of advancing pregnancy such as decreased cardiac reserve and increased respiratory effort may produce physiologic stress if you exercise strenuously for a long time.
- *Take your pulse* every 10 to 15 minutes while you are exercising. If it is more than 140 beats/min, slow down until it returns to a maximum of 90 beats/min. You should be able to converse easily while exercising. If you cannot, you need to slow down.
- *Avoid becoming overheated* for extended periods. It is best not to exercise for more than 35 minutes, especially in hot, humid weather. As your body temperature rises, the heat is transmitted to your fetus. Prolonged or repeated elevation of fetal temperature may result in birth defects, especially during the first 3 months. Your temperature should not exceed 38° C (100° F).
- *Do not use hot tubs and saunas.*
- *Perform warm-up and stretching exercises* to prepare your joints for more strenuous exercise and lessen the likelihood of strain or injury to your joints. After the fourth month of gestation, you should not perform exercises flat on your back.
- *Include a cool-down period* of mild activity involving your legs after an exercise period to help bring your respiration, heart, and metabolic rates back to normal and prevent the pooling of blood in the exercised muscles.
- *Rest for 10 minutes after exercising,* lying on your side. As the uterus grows, it puts pressure on a major vein in your abdomen, which carries blood to your heart. Lying on your side removes the pressure and promotes return circulation from your extremities and muscles to your heart, thereby increasing blood flow to your placenta and fetus. You should rise gradually from the floor to prevent dizziness or fainting (orthostatic hypotension).
- *Stay hydrated. Drink two or three 8-oz glasses of water* after you exercise to replace the body fluids lost through perspiration. While exercising, drink water whenever you feel the need.
- *Increase your caloric intake* to replace the calories burned during exercise and provide the extra energy needs of pregnancy. Choose high-protein foods such as fish, milk, cheese, eggs, or meat.
- *Take your time.* This is not the time to be competitive or train for activities requiring speed or long endurance.
- *Wear a supportive bra.* Your increased breast weight may cause changes in posture and put pressure on the ulnar nerve.
- *Wear supportive shoes.* As your uterus grows, your center of gravity shifts and you compensate for this by arching your back. These natural changes may make you feel off balance and more likely to fall.
- *Stop exercising immediately* and consult your health care provider if you experience shortness of breath, dizziness, numbness, tingling, pain of any kind, more than four uterine contractions per hour, decreased fetal activity, or vaginal bleeding, and consult your health care provider.
- *Recognize signs of danger, including* vaginal bleeding*; blurred vision*; nausea; dizziness; fainting*; breathlessness; heart palpitations; increased swelling in your hands, feet, and ankles; sharp pain in the abdomen and chest*; and sudden change in body temperature.
- *Avoid the following exercises during pregnancy:* downhill snow skiing because the center of gravity changes and there is risk for falls; contact sports such as ice hockey, soccer, and basketball; and scuba diving because the pressure from the water could put the baby at risk for decompression sickness.

Riding recumbent bicycle provides exercise while supplying back support. Big brother becomes involved. (Courtesy Julie Perry Nelson, Loveland, CO.)

*If you experience any of these signs, contact your physician or midwife immediately.

PATIENT TEACHING

Safety During Pregnancy

Changes in the body caused by pregnancy include relaxation of joints, alteration to center of gravity, faintness, and discomforts. Problems with coordination and balance are common. Therefore the woman should follow these guidelines:

- Use good body mechanics.
- Use safety features on tools/vehicles (safety seat belts, shoulder harnesses, headrests, goggles, helmets) as specified.
- Avoid activities requiring coordination, balance, and concentration.
- Take rest periods; reschedule daily activities to meet rest and relaxation needs.

The developing embryo and fetus are vulnerable to environmental teratogens. Many potentially dangerous chemicals are present in the home, yard, and workplace: cleaning agents, paints, sprays, herbicides, and pesticides. The soil and water supply may be unsafe. Therefore the woman should follow these guidelines:

- Read all labels for ingredients and proper use of product.
- Ensure adequate ventilation with clean air.
- Dispose of wastes appropriately.
- Wear gloves when handling chemicals.
- Change job assignments or workplace as necessary.

HOME CARE

Posture and Body Mechanics

To Prevent or Relieve Backache

Do pelvic tilt:

- Pelvic tilt (rock) on hands and knees (see Fig. 8-11, *A*) and while sitting in straight-back chair.
- Pelvic tilt (rock) in standing position against a wall or lying on floor (see Fig. 8-11, *B* and *C*).
- Perform abdominal muscle contractions during pelvic tilt while standing, lying, or sitting to help strengthen rectus abdominis muscle (see Fig. 8-11, *D*).

Use good body mechanics.

- Use leg muscles to reach objects on or near floor. Bend at the knees, not the back. Knees are bent to lower body to squatting position. Feet are kept 12 to 18 inches apart to provide a solid base to maintain balance (see Fig. 8-12, *A*).
- Lift with the legs. To lift a heavy object (e.g., young child), one foot is placed slightly in front of the other and kept flat as the woman lowers herself onto one knee. She lifts the weight, holding it close to her body and never higher than the chest. To stand up or sit down, one leg is placed slightly behind the other as she raises or lowers herself (see Fig. 8-12, *B*).

To Restrict the Lumbar Curve

- For prolonged standing (e.g., ironing or because of employment), place one foot on low footstool or box; change positions often.
- Move car seat forward so that knees are bent and higher than hips. If needed, use a small pillow to support low back area.
- Sit in chairs low enough to allow both feet to be placed on floor, preferably with knees higher than hips.

FIG 8-12 Correct body mechanics. **A,** Squatting. **B,** Lifting. (Courtesy Julie Perry Nelson, Loveland, CO.)

FIG 8-13 Side-lying position for rest and relaxation. (Courtesy Julie Perry Nelson, Loveland, CO.)

- While sitting in a chair, the woman lowers her head to her knees for 30 seconds, then raises her head. She repeats this 6 times, several times per day, as needed.

Conscious relaxation is the process of releasing tension from the mind and body through deliberate effort and practice. The ability to relax consciously and intentionally can be beneficial for the following reasons:

- To relieve the normal discomforts related to pregnancy
- To reduce stress and diminish pain perception during the childbearing cycle
- To heighten self-awareness and trust in one's own ability to control responses and functions
- To help cope with stress in everyday life situations, whether or not the woman is pregnant

FIG 8-14 Squatting for muscle relaxation and strengthening and for keeping leg and hip joints flexible. (Courtesy Julie Perry Nelson, Loveland, CO.)

FIG 8-15 Position for resting legs and reducing edema and varicosities. Encourage the woman with vulvar varicosities to include a pillow under her hips. (Courtesy Julie Perry Nelson, Loveland, CO.)

BOX 8-3 CONSCIOUS RELAXATION TIPS

Preparation—Loosen clothing, assume a comfortable sitting or side-lying position with all parts of your body well supported with pillows. The use of soothing music is optional.

Beginning—Allow yourself to feel warm and comfortable. Inhale and exhale slowly and imagine peaceful relaxation coming over each part of your body, starting with the neck and working down to the toes. People who learn conscious relaxation often speak of feeling relaxed even if some discomfort is present.

Maintenance—Use imagery (fantasy or daydream) to maintain the state of relaxation. Using *active imagery,* imagine yourself moving or doing some activity and experiencing its sensations. Using *passive imagery,* imagine yourself watching a scene such as a lovely sunset.

Awakening—Return to the wakeful state gradually. Slowly begin to take in stimuli from the surrounding environment.

Further retention and development of the skill—Practice regularly for some periods each day (e.g., at the same hour for 10 to 15 minutes each day to feel refreshed, revitalized, and invigorated).

The techniques for conscious relaxation are numerous and varied. The guidelines given in Box 8-3 can be used by anyone.

Employment. Employment of pregnant women usually has no adverse effects on pregnancy outcomes. Unless complications occur, most women can continue working until the onset of labor (AAP Committee on Fetus and Newborn and ACOG Committee on Obstetric Practice, 2012). Pregnant women should not perform any job that subjects them to severe physical strain or exposes them to harmful substances (Cunningham, Leveno, Bloom, et al., 2010).

Job discrimination that is based solely on pregnancy is illegal. However, some job environments pose potential risk to the fetus (e.g., dry cleaning plants, chemical laboratories, and parking garages). Excessive fatigue is usually the deciding factor in the termination of employment. Strategies to improve safety during pregnancy are described in the Patient Teaching box on p. 205.

Women in sedentary jobs need to walk around at intervals to counter the sluggish circulation in the legs. They should neither sit nor stand in one position for long periods. They should avoid crossing their legs at the knees because all of these activities can foster the development of varices and thrombophlebitis. Standing for long periods also increases the risk for preterm labor. The pregnant woman's chair should provide adequate back support. Use of a footstool can prevent pressure on veins, relieve strain on varicosities, minimize swelling of feet, and prevent backache.

Clothing. Some women continue to wear their usual clothes during pregnancy as long as they fit and feel comfortable. If maternity clothing is needed, outfits may be purchased new or found in good condition at thrift shops or garage sales. Comfortable, loose clothing is best. Tight bras and belts, stretch pants, garters, tight-top knee socks, body shapers, and other constrictive clothing should be avoided, because tight clothing over the perineum encourages vaginitis and miliaria (heat rash) and impaired circulation in the legs can cause varicosities.

Maternity bras are constructed to accommodate the increased breast weight, chest circumference, and size of breast tail tissue (under the arm). These bras have drop-flaps over the nipples to facilitate breastfeeding. A good bra can help prevent neck ache and backache.

Maternity support (compression) hose give considerable comfort and promote greater venous emptying in women with large varicose veins. Ideally, support stockings should be put on before the woman gets out of bed in the morning. Fig. 8-15 demonstrates a position to rest the legs and reduce swelling.

Comfortable shoes that provide firm support and promote good posture and balance are advisable. Very high heels and platform shoes are not recommended because of the woman's changed center of gravity, which can cause her to lose her balance. In addition, the woman's pelvis tilts forward in the third trimester, increasing her lumbar curve. The resulting leg aches and cramps will be aggravated by shoes that do not provide good support. Fig. 8-16 shows exercises to relieve leg cramps.

Travel. Travel is not contraindicated for low risk pregnant women. Women with high risk pregnancies are advised to avoid long-distance travel after fetal viability has been reached to avert the economic and psychologic consequences of giving birth to a preterm infant far from home. Travel to areas where medical care is poor, water is untreated, or malaria is prevalent should be avoided if possible. Women who contemplate foreign travel should be aware that many health insurance carriers do not cover birth in a foreign setting

FIG 8-16 Relief of muscle spasm (leg cramps). **A,** Another person dorsiflexes foot with knee extended. **B,** Woman stands and leans forward, thereby dorsiflexing foot of affected leg. (Courtesy Shannon Perry, Phoenix, AZ.)

or even hospitalization for preterm labor. In addition, vaccinations for foreign travel may be contraindicated during pregnancy.

Pregnant women who travel long distances should schedule periods of activity and rest. While sitting, the woman can practice deep breathing, foot circling, and alternately contracting and relaxing different muscle groups. She should avoid becoming fatigued. Although travel in itself is not a cause of adverse outcomes such as miscarriage or preterm labor, certain precautions are recommended when traveling in a car. For example, women riding in a car should wear automobile restraints and stop to walk every hour.

Maternal death as a result of injury is the most common cause of fetal death. The next most common cause is placental separation **(abruptio placentae)** that occurs because body contours change in reaction to the force of a motor vehicle collision. The uterus as a muscular organ can adapt its shape to that of the body, but the placenta is not resilient. At the impact of collision, placental separation can occur. A combination lap belt and shoulder harness is the most effective automobile restraint, and both should be used. The

FIG 8-17 Proper use of seat belt and headrest. (Courtesy Brian and Mayannyn Sallee, Anchorage, AK.)

lap belt should be worn low across the hip bones and as snug as is comfortable (Fig. 8-17). The shoulder harness should be worn above the gravid uterus and below the neck to prevent chafing. The pregnant woman should sit upright. The headrest should be used to avoid whiplash injury. Airbags if present should remain engaged, but the steering wheel should be tilted upward away from the abdomen and the seat moved back away from the steering wheel as much as possible.

Air travel in large commercial jets usually poses little risk to the pregnant woman, but policies vary from airline to airline. The pregnant woman is advised to inquire about restrictions or recommendations from her carrier. Most health care providers allow air travel up to 36 weeks of gestation in women without medical or pregnancy complications. Air travel is not recommended for women with severe anemia, sickle cell disease or trait, history of thrombophlebitis, or placental abnormalities. Women at risk for preterm labor should avoid air travel (Sutton, 2012). Magnetometers (metal detectors) used at airport security checkpoints are not harmful to the fetus. The 8% humidity at which cabins are maintained in commercial airlines may result in some water loss; hydration (with water) should be maintained under these conditions. Sitting in the cramped seat of an airliner for prolonged periods may increase the risk for superficial and deep thrombophlebitis. A pregnant woman is encouraged to take a 15-minute walk around the aircraft during each hour of travel to minimize this risk.

Medications and Herbal Preparations. Although much has been learned in recent years about fetal drug toxicity, the possible teratogenicity of many prescription and OTC drugs is still unknown. This is especially true for new medications and combinations of medications. Moreover, certain subclinical errors or deficiencies in intermediate metabolism in the fetus may cause an otherwise harmless drug to be converted into a hazardous one. The greatest danger of drug-caused developmental defects in the fetus extends from the time of fertilization through the first trimester, a time when the woman may not realize she is pregnant. Self-treatment must be discouraged. The use of all drugs, including OTC medications, herbs, and vitamins, should be limited; and a careful record should be kept of all therapeutic and nontherapeutic agents used.

The use of complementary and alternative medicine by pregnant women is widespread and is based primarily on historical use and anecdotal information. There is limited research evidence about the

safety of herbal preparations, especially during pregnancy. While the use of complementary and alternative therapies is consistent with the holistic, woman-centered approach to care, caution is warranted in their use because of the lack of evidence (Hall, McKenna, and Griffiths, 2010).

SAFETY ALERT

Although some complementary and alternative medicine (CAM) may benefit the woman during pregnancy, some practices should be avoided because they may increase risk for complications. It is important to ask the woman about all medications she is taking, including OTC and herbal preparations.

Immunizations. Some concern has been raised over the safety of various immunization practices during pregnancy. Immunization with live or attenuated live virus or live bacterial vaccines is generally contraindicated during pregnancy (CDC, 2013). Live virus vaccines include those for measles (rubeola and rubella), chickenpox (varicella), and the Sabin (oral) poliomyelitis vaccine (no longer used in the United States). Human papilloma virus (HPV) vaccine is not recommended during pregnancy. Vaccines consisting of killed viruses that may be administered during pregnancy include tetanus, diphtheria, recombinant hepatitis B, and influenza vaccines (CDC, 2013).

The Centers for Disease Control and Prevention (CDC, 2013) recommends routine administration of the tetanus, diphtheria, and acellular pertussis (Tdap) vaccine during each pregnancy. The optimal timing for the vaccine is between 27 and 36 weeks of gestation.

SAFETY ALERT

Pregnant women who become ill with seasonal respiratory influenza (flu) are more likely than other persons to develop serious complications, such as pneumonia. All women whose pregnancy will take place from November through March should be offered an influenza vaccination.

Alcohol, Cigarette Smoke, Caffeine, and Drugs. Ethanol (alcohol) is a powerful teratogen that can have devastating effects on the developing fetus (e.g., fetal alcohol syndrome). Women who are pregnant or considering pregnancy should totally abstain from alcohol (Cunningham, Leveno, Bloom, et al., 2010). Cigarette smoking or continued exposure to secondhand smoke (even if the mother does not smoke) is associated with IUGR and an increase in perinatal and infant morbidity and mortality. Smoking can affect fertility and may lead to a greater risk for ectopic pregnancy. Smoking is associated with an increased incidence of spontaneous abortion, ectopic pregnancy, preterm birth, PROM, abruptio placentae, placenta previa, and fetal death (Cunningham, Leveno, Bloom, et al., 2010; Sidransky, Norman, McCarthy, et al., 2010). Smoking cessation activities should be incorporated into routine prenatal care. All women who smoke should be strongly encouraged to quit or at least reduce the number of cigarettes they smoke. In addition, pregnant women should be told about the negative effects of secondhand smoke on the fetus and encouraged to avoid such environments.

Research findings suggest that caffeine intake less than 200 mg per day during pregnancy does not appear to be a major contributing factor to miscarriage or preterm birth. The relationship between maternal caffeine intake and low birth weight has not been substantiated by research (ACOG, 2010). The March of Dimes (2010) recommends that pregnant women limit their daily caffeine to less than 200 mg per day. Women should be aware of the caffeine content of foods, drinks, and certain OTC medications and should intentionally limit their intake as recommended. Any drug or environmental agent that enters the pregnant woman's bloodstream has the potential to cross the placenta and harm the fetus. Marijuana, heroin, and cocaine are common examples of such substances. Although substance abuse in pregnancy is a major public health concern and comprehensive care of drug-addicted women improves maternal and neonatal outcomes, few facilities are available for treatment of these women (see Chapter 11).

Normal Discomforts. Pregnant women are confronted with symptoms that would be considered abnormal in the nonpregnant state. Women pregnant for the first time have an increased need for explanations of the causes of the discomforts and advice on ways to relieve the discomforts. The discomforts are fairly specific to each trimester of pregnancy. Table 8-3 provides information about the physiology, prevention, and self-management of discomforts experienced during the three trimesters. Box 8-4 lists alternative therapies used in pregnancy. Nurses can do much to allay a first-time mother's anxiety about such symptoms by telling her about them in advance, using terminology that the woman (or couple) can understand. Understanding the rationale for treatment promotes their participation in their care. Interventions should be individualized, with attention given to the woman's lifestyle and culture (see Nursing Care Plan).

Recognizing Potential Complications. One of the most important responsibilities of care providers is to alert the pregnant woman to signs and symptoms that indicate a potential complication of pregnancy. The woman needs to know how and to whom to report such warning signs (see Table 8-2). The woman and her family should receive a printed list of warning signs, written at the appropriate literacy level, that warrant a call to the health care provider (HCP) or clinic; phone numbers for the HCP or clinic should be listed. The nurse must answer questions honestly as they arise during pregnancy. Pregnant women often have difficulty deciding when to report signs and symptoms. The mother is encouraged to refer to the printed list of potential complications and to listen to her body. If she senses that something is wrong, she should call her care provider immediately. Several signs and symptoms must be discussed more extensively. These include vaginal bleeding,

Text continued on p. 213

BOX 8-4 ALTERNATIVE THERAPIES USED IN PREGNANCY

Touch and Energetic Therapies

- Massage
- Acupressure
- Therapeutic touch
- Healing touch
- Mind-body healing
- Imagery
- Meditation, prayer, reflection
- Biofeedback
- Aromatherapy
- Other modalities that may fall outside of nurse practice guidelines unless the nurse has completed additional training or certification:
  - Herbs
  - Homeopathy
  - Traditional Chinese medicine

TABLE 8-3 DISCOMFORTS RELATED TO PREGNANCY

DISCOMFORT	PHYSIOLOGY	EDUCATION FOR SELF-MANAGEMENT
First Trimester		
Breast changes, enlargement; pain, tingling, tenderness	Hypertrophy of mammary glandular tissue and increased vascularization, pigmentation, and size and prominence of nipples and areolae caused by hormonal stimulation	Wear supportive maternity bras with pads to absorb discharge (may be worn at night); wash with warm water and keep dry; breast tenderness may interfere with sexual expression/foreplay but is temporary
Urgency and frequency of urination	Vascular engorgement and altered bladder function caused by hormones; bladder capacity reduced by enlarging uterus and fetal presenting part	Empty bladder regularly; perform Kegel exercises; limit fluid intake before bedtime; wear perineal pad; report pain or burning sensation to primary health care provider
Languor and malaise; fatigue (early pregnancy, most commonly)	Unexplained; may be caused by increasing levels of estrogen, progesterone, and hCG or by elevated BBT; psychologic response to pregnancy and its required physical and psychologic adaptations	Rest as needed; eat well-balanced diet to prevent anemia
Nausea and vomiting, morning sickness—occurs in 50%-75% of pregnant women; starts between first and second missed periods and lasts until about fourth missed period; may occur any time during day; fathers also may have symptoms	Cause unknown; may result from hormonal changes, possibly hCG; may be partly emotional, related to ambivalence about or rejection of pregnant state	Avoid empty or overloaded stomach; maintain good posture—give stomach ample room; stop smoking; eat dry carbohydrate on awakening; remain in bed until feeling subsides or alternate dry carbohydrate 1 hr with fluids such as hot herbal decaffeinated tea, milk, or clear coffee the next hour until feeling subsides; eat five to six small meals per day; avoid fried, odorous, spicy, greasy, or gas-forming foods; acupressure, wristbands, ginger, vitamin B_6 alone or with doxylamine may be helpful; consult primary health care provider if intractable vomiting occurs
Ptyalism (excessive salivation) may occur starting 2-3 wk after first missed period	Possibly caused by elevated estrogen levels; may be related to reluctance to swallow because of nausea	Use astringent mouthwash, chew gum, eat hard candy as comfort measures
Gingivitis and epulis (hyperemia, hypertrophy, bleeding, tenderness); condition disappears spontaneously 1-2 mo after birth	Increased vascularity and proliferation of connective tissue from estrogen stimulation	Eat well-balanced diet, with adequate protein and fresh fruits and vegetables; brush teeth gently and observe good dental hygiene; avoid infection; see dentist
Nasal stuffiness; epistaxis (nosebleed)	Hyperemia of mucous membranes related to high estrogen levels	Use humidifier; avoid trauma; normal saline nose drops or spray may be used
Leukorrhea: often noted throughout pregnancy	Hormonally stimulated cervix becomes hypertrophic and hyperactive, producing abundant amount of mucus	Not preventable; do not douche; wear perineal pads; perform hygienic practices such as wiping front to back; report to primary health care provider if accompanied by pruritus, foul odor, or change in character or color
Psychosocial dynamics, mood swings, mixed feelings	Hormonal and metabolic adaptations; feelings about female role, sexuality, timing of pregnancy, and resultant changes in life and lifestyle	Participate in pregnancy support group; communicate concerns to partner, family, and others; request referral for supportive services if needed (financial assistance)
Second Trimester		
Pigmentation deepens, acne, oily skin	Melanocyte-stimulating hormone (from anterior pituitary)	Not preventable; it usually resolves during puerperium
Spider nevi (angiomas) appear over neck, thorax, face, and arms during second or third trimester	Focal networks of dilated arterioles (end-arteries) from increased concentration of estrogens	Not preventable; they fade slowly during late puerperium but rarely disappear completely
Palmar erythema occurs in 50% of pregnant women; may accompany spider nevi	Diffuse reddish mottling over palms and suffused skin over thenar eminences and fingertips; may be caused by genetic predisposition or hyperestrogenism	Not preventable; condition fades within 1 wk after giving birth

Continued

TABLE 8-3 DISCOMFORTS RELATED TO PREGNANCY—cont'd

DISCOMFORT	PHYSIOLOGY	EDUCATION FOR SELF-MANAGEMENT
Pruritus (noninflammatory)	Unknown cause; various types as follows: nonpapular; closely aggregated pruritic papules Increased excretory function of skin and stretching of skin possible factors	Keep fingernails short and clean; contact primary health care provider for diagnosis of cause Not preventable; symptomatic; can be managed with emollient baths, mild sedation, distraction, tepid baths with sodium bicarbonate or oatmeal added to water, lotions and oils, change of soaps or reduction in use of soap, loose clothing
Palpitations	Unknown; should not be accompanied by persistent cardiac irregularity	Not preventable; contact primary health care provider if accompanied by symptoms of cardiac decompensation
Supine hypotension (vena cava syndrome) and bradycardia	Induced by pressure of gravid uterus on ascending vena cava when woman is supine; reduces uteroplacental and renal perfusion	Assume side-lying position or semisitting posture, with knees slightly flexed (see also Emergency box, p. 197)
Faintness and, rarely, syncope (orthostatic hypotension); may persist throughout pregnancy	Vasomotor lability or postural hypotension from hormones; in late pregnancy, may be caused by venous stasis in lower extremities	Exercise moderately (deep breathing, vigorous leg movements); avoid sudden changes in position* and warm crowded areas; move slowly and deliberately; keep environment cool; avoid hypoglycemia by eating five or six small meals per day; wear compression hose; sit as necessary; if symptoms are serious, contact primary health care provider
Food cravings	Cause unknown; craving determined by culture or geographic area	Not preventable; satisfy craving unless it interferes with well-balanced diet; report unusual cravings to primary health care provider
Heartburn (pyrosis or acid indigestion): burning sensation, occasionally with burping and regurgitation of a little sour-tasting fluid	Progesterone slows GI tract motility and digestion, reverses peristalsis, relaxes cardiac sphincter, and delays emptying time of stomach; stomach displaced upward and compressed by enlarging uterus	Limit or avoid gas-producing or fatty foods and large meals; maintain good posture; sip milk for temporary relief; drink hot herbal tea; primary health care provider may prescribe antacid between meals; contact primary health care provider for persistent symptoms
Constipation	GI tract motility slowed because of progesterone, resulting in increased reabsorption of water and drying of stool; intestines compressed by enlarging uterus; predisposition to constipation because of oral iron supplementation	Drink six to eight glasses of water per day; include roughage in diet; exercise moderately; maintain regular schedule for bowel movements; use relaxation techniques and deep breathing; do not take stool softener, laxatives, mineral oil, other drugs, or enemas without first consulting primary health care provider
Flatulence with bloating and belching	Reduced GI motility because of hormones, allowing time for bacterial action that produces gas; swallowing air	Chew foods slowly and thoroughly; avoid gas-producing foods, fatty foods, large meals; exercise, maintain regular bowel habits
Varicose veins (varicosities): may be associated with aching legs and tenderness; may be present in legs and vulva; hemorrhoids are varicosities in perianal area	Hereditary predisposition; relaxation of smooth muscle walls of veins because of hormones, causing tortuous, dilated veins in legs and pelvic vasocongestion; condition aggravated by enlarging uterus, gravity, and bearing down for bowel movements; thrombi from leg varices rare but may be produced by hemorrhoids	Avoid lengthy standing or sitting, constrictive clothing, and constipation and bearing down with bowel movements; exercise moderately; rest with legs and hips elevated (see Fig. 8-15); wear compression hose; thrombosed hemorrhoid may be evacuated; relieve swelling and pain with warm sitz baths; apply astringent compresses locally
Leukorrhea: often noted throughout pregnancy	Hormonally stimulated cervix becomes hypertrophic and hyperactive, producing abundant amount of mucus	Not preventable; do not douche; maintain good hygiene; wear perineal pads; report to primary health care provider if accompanied by pruritus, foul odor, or change in character or color
Headaches (through wk 26)	Emotional tension (more common than vascular migraine headache); eye strain (refractory errors); vascular engorgement and congestion of sinuses resulting from hormone stimulation	Conscious relaxation; rest, massage, application of heat or cold; OTC analgesics (check with provider); contact primary health care provider for constant "splitting" headache to assess for preeclampsia

TABLE 8-3 DISCOMFORTS RELATED TO PREGNANCY—cont'd

DISCOMFORT	PHYSIOLOGY	EDUCATION FOR SELF-MANAGEMENT
Carpal tunnel syndrome (involves thumb, second and third fingers, lateral side of little finger)	Compression of median nerve resulting from changes in surrounding tissues; pain, numbness, tingling, burning; loss of skilled movements (typing); dropping of objects	Not preventable; elevate affected arms; splinting of affected hand may help; regressive after pregnancy; surgery is curative
Periodic numbness, tingling of fingers (acrodysesthesia) occurs in 5% of pregnant women	Brachial plexus traction syndrome resulting from drooping of shoulders during pregnancy (occurs especially at night and early morning)	Maintain good posture; wear supportive maternity bra; condition will disappear if lifting and carrying baby does not aggravate it
Round ligament pain (tenderness)	Stretching of ligament caused by enlarging uterus	Not preventable; rest, maintain good body mechanics to avoid overstretching ligament; relieve cramping by squatting or bringing knees to chest; sometimes heat helps
Joint pain, backache, and pelvic pressure; hypermobility of joints	Relaxation of symphyseal and sacroiliac joints because of hormones, resulting in unstable pelvis; exaggerated lumbar and cervicothoracic curves caused by change in center of gravity resulting from enlarging abdomen	Maintain good posture and body mechanics; avoid fatigue; wear low-heeled shoes; abdominal supports may be useful; practice conscious relaxation; sleep on firm mattress; apply local heat or ice; get back rubs; do pelvic rock exercise; rest; condition disappears 6-8 wk after birth
Third Trimester		
Shortness of breath and dyspnea: occur in 60% of pregnant women	Expansion of diaphragm limited by enlarging uterus; diaphragm elevated about 4 cm; some relief after lightening	Maintain good posture; sleep with extra pillows; avoid overloading stomach; stop smoking; contact health care provider if symptoms worsen to rule out anemia, emphysema, and asthma
Insomnia (later weeks of pregnancy)	Fetal movements, muscle cramping, urinary frequency, shortness of breath, or other discomforts	Reassurance, conscious relaxation, back massage or effleurage, support of body parts with pillows, and warm milk or warm shower before retiring are helpful
Psychosocial responses: mood swings, mixed feelings, increased anxiety	Hormonal and metabolic adaptations; feelings about impending labor, birth, and parenthood	Reassurance and support from significant other and nurse and improved communication with partner, family, and others are helpful
Gingivitis and epulis (hyperemia, hypertrophy, bleeding, tenderness): condition disappears spontaneously 1-2 mo after birth	Increased vascularity and proliferation of connective tissue from estrogen stimulation	Eat a well-balanced diet with adequate protein and fresh fruits and vegetables; gently brush teeth and practice good dental hygiene; avoid infection; see dentist for teeth cleaning
Urinary frequency and urgency return	Vascular engorgement and altered bladder function caused by hormones; bladder capacity reduced by enlarging uterus and fetal presenting part	Empty bladder regularly, do Kegel exercises; limit fluid intake before bedtime; reassurance is helpful; wear perineal pad; contact health care provider for pain or burning sensation
Perineal discomfort and pressure	Pressure from enlarging uterus, especially when standing or walking; multifetal gestation	Rest, conscious relaxation, and good posture are helpful; contact health care provider for assessment and treatment if pain is present
Leg cramps (gastrocnemius spasm), especially when reclining	Compression of nerves supplying lower extremities because of enlarging uterus; reduced level of diffusible serum calcium or elevation of serum phosphorus; aggravating factors: fatigue, poor peripheral circulation, pointing toes when stretching legs or when walking, drinking more than 1 L (1 qt) of milk per day	Dorsiflex foot until spasm relaxes (see Fig. 8-16, *A*); apply heat over affected muscle; stand on cold surface; supplement orally with magnesium lactate or citrate; aluminum hydroxide antacid removes phosphorus by absorbing it
Ankle edema (nonpitting) to lower extremities	Edema aggravated by prolonged standing, sitting, poor posture, lack of exercise, constrictive clothing (e.g., garters), or hot weather	Intake ample fluid for natural diuretic effect; put on support stockings before arising; rest periodically with legs and hips elevated (see Fig. 8-15); exercise moderately; contact health care provider if generalized edema develops; *diuretics are contraindicated*

BBT, Basal body temperature; *GI,* gastrointestinal; *hCG,* human chorionic gonadotropin; *OTC,* over-the-counter.
*Caution woman to rise slowly and sit on edge of bed or to assume hands-and-knees posture before rising and to get up slowly after sitting or squatting.

NURSING CARE PLAN

Discomforts of Pregnancy and Warning Signs

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
First Trimester			
Anxiety related to deficient knowledge about schedule of prenatal visits throughout pregnancy as evidenced by woman's questions and concerns	Woman will verbalize correct appointment schedule for duration of pregnancy and feelings of being "in control."	Provide information regarding schedule of visits, tests, and other assessments and interventions that will be provided throughout pregnancy	To empower woman to function in collaboration with caregiver and diminish anxiety
		Allow woman time to describe level of anxiety	To establish basis for care
		Provide information to woman regarding prenatal classes and labor area tours	To decrease feelings of anxiety about unknown
Imbalanced Nutrition: Less Than Body Requirements related to nausea and vomiting as evidenced by woman's report and weight loss	Woman will gain 1 to 2.5 kg during first trimester.	Verify prepregnant weight	To plan realistic diet according to individual woman's nutritional needs
		Obtain diet history	To identify current meal patterns and foods that may be implicated in nausea
		Advise woman to consume small, frequent meals and avoid having empty stomach	To avoid further nausea episodes
		Suggest that woman eat a simple carbohydrate such as dry crackers before arising in morning	To avoid empty stomach and decrease incidence of nausea and vomiting
		Advise woman to call health care provider if vomiting is persistent and severe	To identify possible incidence of hyperemesis gravidarum
Fatigue related to hormonal changes in first trimester as evidenced by woman's complaints	Woman will report decreased number of episodes of fatigue	Advise woman to rest as needed	To avoid increasing feeling of fatigue
		Advise woman to eat well-balanced diet	To meet increased metabolic demands and avoid anemia
		Discuss use of support systems to help with household responsibilities	To decrease workload at home and decrease fatigue
		Reinforce to woman the transitory nature of first trimester fatigue	To provide emotional support
		Explore with woman a variety of techniques to prioritize roles	To decrease family expectations
Second Trimester			
Constipation related to progesterone influence on gastrointestinal (GI) tract as evidenced by woman's report of altered patterns of elimination	Woman will report return to normal bowel elimination pattern after implementation of interventions.	Provide information to woman regarding pregnancy-related causes: progesterone slowing GI motility, growing uterus compressing intestines, and influence of iron supplementation	To provide basic information for self-management during pregnancy
		Assist woman to plan diet that will promote regular bowel movements, such as increasing amount of oral fluid intake to at least 6 to 8 glasses of water a day, increasing the amount of fiber in daily diet, and maintaining moderate exercise program	To promote self-management care
		Reinforce for woman that she should not take any laxatives, stool softeners, or enemas without first consulting the health care provider	To prevent any injuries to woman or fetus
Anxiety related to deficient knowledge about course of first pregnancy as evidenced by woman's questions regarding possible complications of second and third trimesters	Woman will correctly list signs of potential complications that can occur during second and third trimesters and exhibit no overt signs of stress.	Provide information concerning potential complications or warning signs that can occur during second and third trimesters, including possible causes of signs and importance of calling health care provider immediately	To ensure identification and treatment of problems in timely manner
		Provide a written list of complications	To have a reference list for emergencies

NURSING CARE PLAN

Discomforts of Pregnancy and Warning Signs—cont'd

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
Third Trimester			
Fear related to deficient knowledge regarding onset of labor and processes of labor related to inexperience as evidenced by woman's questions and statement of concerns	Woman will verbalize basic understanding of signs of labor onset and when to call health care provider, identify resources for childbirth education, and express increasing confidence in readiness to cope with labor.	Provide information regarding signs of labor onset and when to call health care provider; give written information regarding local childbirth education classes	To empower and promote self-management
		Promote ongoing effective communication with health care provider	To promote trust and decrease fear of unknown
		Provide woman with decision-making opportunities	To promote effective coping
		Provide opportunity for woman to verbalize fears regarding childbirth	To assist in decreasing fear through discussion
Disturbed Sleep Pattern related to discomforts or insomnia of third trimester as evidenced by woman's report of inadequate rest	Woman will report improvement of quality and quantity of rest and sleep.	Assess current sleep pattern, and review need for increased requirement during pregnancy	To identify need for change in sleep patterns
		Suggest change of position to side-lying with pillows between legs or to semi-Fowler's position	To increase support and decrease any problems with dyspnea or heartburn
		Reinforce possibility of use of various sleep aids such as relaxation techniques, reading, and decreased activity before bedtime	To decrease possibility of anxiety or physical discomforts before bedtime
Ineffective Sexuality Pattern related to changes in comfort level and fatigue	Woman will verbalize feelings regarding changes in sexual desire, and woman and her partner will express satisfaction with sexual activities.	Assess couple's usual sexuality patterns	To determine how patterns have been altered by pregnancy
		Provide information regarding expected changes in sexuality patterns during pregnancy	To correct any misconceptions
		Allow couple to express feelings in nonjudgmental atmosphere	To promote trust
		Refer couple for counseling as appropriate	To assist couple to cope with sexuality pattern changes
		Suggest alternative sexual positions	To decrease pressure on enlarging abdomen of woman and increase sexual comfort and satisfaction of couple

alteration in fetal movements, symptoms of preeclampsia, rupture of membranes, and preterm labor.

Recognizing Preterm Labor. Teaching each expectant mother to recognize preterm labor is necessary for early diagnosis and treatment. Preterm labor occurs after the twentieth week but before the thirty-seventh week of pregnancy. It consists of uterine contractions that, if untreated, cause the cervix to dilate and efface earlier than normal, resulting in preterm birth (see Chapter 17).

Warning signs and symptoms of preterm labor are listed in the Home Care box. Fig. 8-18 shows where in the body the signs and symptoms of preterm labor may be located.

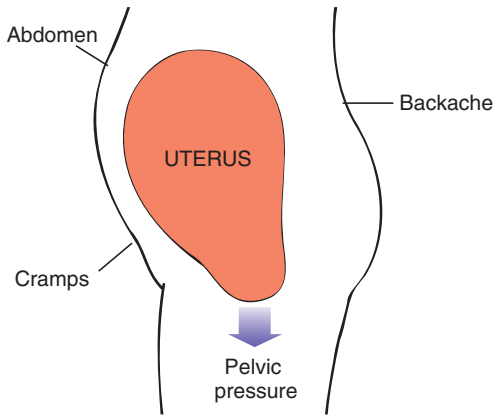

FIG 8-18 Symptoms of preterm labor.

Sexual Counseling

Sexual counseling of expectant couples includes countering misinformation, providing reassurance of normality, and suggesting alternative behaviors. The uniqueness of each couple is considered within a biopsychosocial framework (see Home Care box). Nurses can initiate discussion about sexual adaptations that must be made during pregnancy. They need a sound knowledge base about the

HOME CARE

How to Recognize Preterm Labor

- Because the onset of preterm labor is subtle and often hard to recognize, it is important to know how to feel your abdomen for uterine contractions. You can feel for contractions in the following way. While lying down, place your fingertips on the top of your uterus. A contraction is the periodic tightening or hardening of your uterus. If your uterus is contracting, you will actually feel your abdomen get tight or hard and then feel it relax or soften when the contraction is over.
- If you think you are having any of the other signs and symptoms of preterm labor, empty your bladder, drink three to four glasses of water for hydration, lie down tilted toward your side, and place a pillow at your back for support.
- Check for contractions for 1 hour. To tell how often contractions are occurring, check the minutes that elapse from the beginning of one contraction to the beginning of the next.
- It is *not normal* to have frequent uterine contractions (every 10 minutes or more often for 1 hour).
- Contractions of labor are regular, frequent, and hard. They also may be felt as a tightening of the abdomen or a backache. This type of contraction causes the cervix to efface and dilate.
- Call your doctor, nurse-midwife, clinic, or labor and birth unit or go to the hospital if any of the following signs occur:
  - You have uterine contractions every 10 minutes or more often for 1 hour *or*
  - You have any of the other signs and symptoms for 1 hour *or*
  - You have any bloody spotting or leaking of fluid from your vagina
- It is often difficult to identify preterm labor. Accurate diagnosis requires assessment by the health care provider, usually in the hospital or clinic.
- Post these instructions where they can be seen by everyone in the family.

HOME CARE

Sexuality in Pregnancy

- Be aware that maternal physiologic changes such as breast enlargement, nausea, fatigue, abdominal changes, perineal enlargement, leukorrhea, pelvic vasocongestion, and orgasmic responses may affect sexuality and sexual expression.
- Discuss responses to pregnancy with your partner.
- Keep in mind that cultural prescriptions (do's) and proscriptions (don'ts) may affect your responses.
- Although your libido may be depressed during the first trimester, it often increases during the second trimester.
- Discuss and explore the following with your partner:
  - Alternative behaviors (e.g., mutual masturbation, foot massage, cuddling).
  - Alternative positions (e.g., female superior, side-lying) for sexual intercourse.
- Intercourse is safe as long as it is not uncomfortable. There is no correlation between intercourse and miscarriage, but observe the following precautions:
  - Abstain from intercourse if you experience uterine cramping or vaginal bleeding; report event to your health care provider as soon as possible.
  - Abstain from intercourse (or any activity that results in orgasm) if you have a history of premature dilation of the cervix until the problem is corrected.
- Continue to use risk-reduction behaviors. Women at risk for acquiring or conveying sexually transmitted infections are encouraged to use condoms during sexual intercourse throughout pregnancy.

physical, social, and emotional responses to sex during pregnancy. Not all maternity nurses are comfortable dealing with the sexual concerns of their patients. Be aware of your personal strengths and limitations in dealing with sexual content, and be prepared to make referrals if necessary.

Many women merely need permission to be sexually active during pregnancy. Many other women, however, need to be given information about the physiologic changes that occur during pregnancy, have the myths that are associated with sex during pregnancy dispelled, and participate in open discussions of positions for intercourse that decrease pressure on the gravid abdomen. Such tasks are within the purview of the nurse and should be an integral component of the health care rendered.

Some couples need to be referred for sex therapy or family therapy. Couples whose long-standing problems with sexual dysfunction are intensified by pregnancy are good candidates for sex therapy. When a sexual problem is a symptom of a more serious relationship problem, the couple would benefit from family therapy.

Using the History. The couple's sexual history provides a basis for counseling, but history taking also is an ongoing process. The history reveals the woman's knowledge of female anatomy and physiology and her attitudes about sex during pregnancy, as well as her perceptions of the pregnancy, the health status of the couple, and the quality of their relationship.

Countering Misinformation. Many myths and much of the misinformation related to sex and pregnancy are masked by seemingly unrelated issues. For example, a discussion about the baby's ability to hear and see in utero may be prompted by questions about the baby being an "unseen observer" of sexual activities. The nurse must be extremely sensitive to the issues behind such questions when counseling in this highly charged emotional area.

Suggesting Alternative Behaviors. Research has not demonstrated that coitus and orgasm are contraindicated at any time during pregnancy for the obstetrically and medically healthy woman (Cunningham, Leveno, Bloom, et al., 2010). However, a history of more than one miscarriage; a threatened miscarriage in the first trimester; impending miscarriage in the second trimester; and PROM, bleeding, or abdominal pain during the third trimester warrant caution regarding coitus and orgasm.

Solitary and mutual masturbation and oral-genital intercourse may be used by couples as alternatives to penile-vaginal intercourse. Partners who enjoy cunnilingus (oral stimulation of the clitoris or vagina) may feel "turned off" by the normal increase in amount and odor of vaginal discharge during pregnancy. Couples who practice cunnilingus should be cautioned against the blowing of air into the vagina, particularly during the last few weeks of pregnancy when the cervix may be slightly open. An air embolism can occur if air is forced between the uterine wall and fetal membranes and enters the maternal vascular system through the placenta.

Showing the woman or couple illustrations of the possible variations of coital position is helpful (Fig. 8-19). The female-superior, side-by-side, rear-entry, and facing-each-other positions are alternatives to the traditional male-superior position. The woman astride (superior position) allows her to control the angle and depth of penile penetration, as well as protect her breasts and abdomen. During the third trimester, the side-by-side position or any position

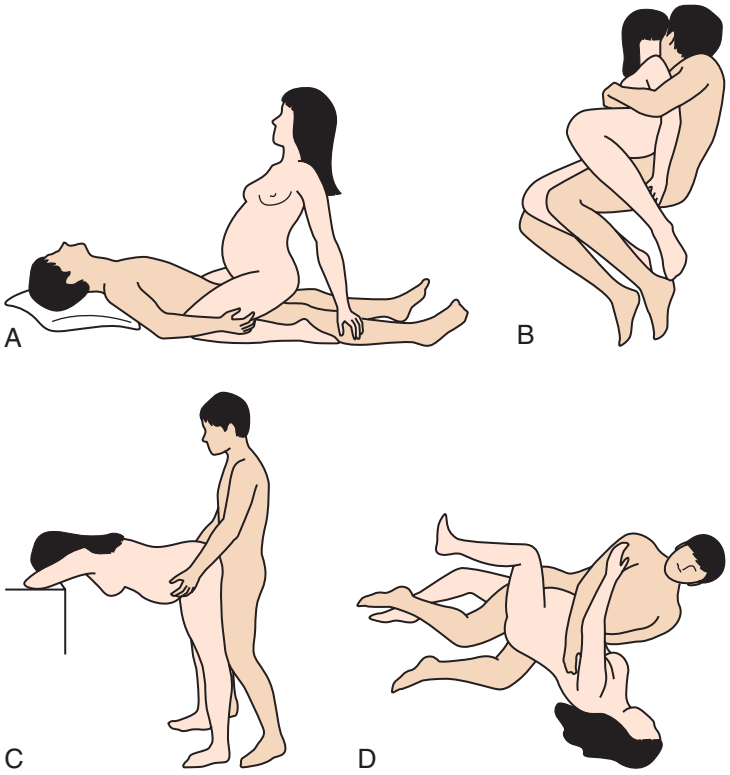

FIG 8-19 Positions for sexual intercourse during pregnancy. **A,** Female superior. **B,** Side by side. **C,** Rear entry. **D,** Facing each other.

that places less pressure on the pregnant abdomen and requires less energy may be preferred.

Multiparous women sometimes have significant breast tenderness in the first trimester. A coital position that avoids direct pressure on the woman's breasts and decreased breast fondling can be recommended to such couples. The woman should also be reassured that this condition is normal and temporary.

Some women complain of lower abdominal cramping and backache after orgasm during the first and third trimesters. A back rub can often relieve some of the discomfort and provide a pleasant experience. A tonic uterine contraction, often lasting up to a minute, replaces the rhythmic contractions of orgasm during the third trimester. Changes in FHR without fetal distress have also been reported.

The objective of risk reduction is to provide prophylaxis against the acquisition and transmission of sexually transmitted infections (STIs) (e.g., herpes simplex virus, human papilloma virus, and HIV). Because these diseases may be transmitted to the woman and her fetus, the use of condoms is recommended throughout pregnancy if the woman is at risk for acquiring an STI.

There is a lack of evidence regarding the safety of the use of sex toys during pregnancy. Popular pregnancy websites suggest that it is generally safe to use these devices in low-risk pregnancies (e.g., www.baby.com; www.parents.com). However, safety practices should be followed. Sex toys must be carefully cleaned. Sex toys inserted into the anus should never be inserted into the vagina. If a vibrator or other device is made of a material that is firmer than human flesh, force should not be used when inserting it into the vagina. The use of sex toys should be discontinued if pain occurs (Quilliam, 2010). Safer sex practices to reduce the risk of STIs include using condoms and avoiding the sharing of sex toys (ACOG Committee on Health Care for Underserved Women, 2012b).

Well-informed nurses who are comfortable with their own sexuality and the sex counseling needs of expectant couples can offer information and advice in this valuable but often neglected area. They can establish an open environment in which couples can feel free to introduce their concerns about sexual adjustment and seek support and guidance. This intervention is as important for lesbian women and their partners as it is for women partnered with men.

Psychosocial Support

Esteem, affection, trust, concern, consideration of cultural and religious responses, and listening are all components of the emotional support given to the pregnant woman and her family. The woman's satisfaction with her relationships and support, her feeling of competence, and her sense of being in control are important issues to be addressed in the third trimester. A discussion of fetal responses to stimuli such as sound, light, maternal posture, and tension, as well as patterns of sleeping and waking, can be helpful. Other issues of concern that can arise for the pregnant woman and couple include fear of pain, loss of control, and possible birth of the infant before reaching the hospital. Parental concerns about the responsibilities and tasks of parenthood; the safety of the mother and unborn child; siblings and their acceptance of the new baby; social and economic responsibilities; and possible conflicts in cultural, religious, or personal value systems are addressed. The father's or partner's commitment to the pregnancy, the couple's relationship, and their concerns about sexuality and sexual expression can emerge as issues for many expectant parents.

Providing the prospective mother and father with opportunities to discuss their concerns and validating the normality of their responses can meet their needs to some degree. Nurses must also recognize that men feel more vulnerable during their partner's pregnancy. Female partners may also have these feelings. Anticipatory guidance and health promotion strategies can help partners cope with their concerns. Nursing intervention may help them deal with such concerns either directly through counseling or indirectly through the education of the mothers. Health care providers can stimulate and encourage open dialog between the couple.

Variations in Prenatal Care

The course of prenatal care described thus far can seem to suggest that the experiences of childbearing women are similar and that nursing interventions are uniform across all populations. Although typical patterns of response to pregnancy are easily recognized and many aspects of prenatal care indeed are consistent, pregnant women enter the health care system with individual concerns and needs. The nurse's ability to assess unique needs and tailor interventions to the individual is the hallmark of expertise in providing care. Variations that influence prenatal care include culture, age, and number of fetuses.

Cultural Influences

Prenatal care as we know it is a phenomenon of Western medicine. In the U.S. biomedical model of care, women are encouraged to seek prenatal care as early as possible in their pregnancy by visiting a physician and/or a nurse-midwife. This model not only is unfamiliar but also seems strange to women of other cultures.

Many cultural variations are found in prenatal care. Even if the prenatal care described is familiar to a woman, some practices may conflict with the beliefs and practices of a subculture group to which she belongs. Because of these and other factors, such as lack of

money, lack of transportation, and language barriers, women from diverse cultures may not participate in the prenatal care system, for instance, by not keeping prenatal appointments. Such behavior may be misinterpreted by nurses as uncaring, lazy, or ignorant.

A concern for modesty is a deterrent to many women seeking prenatal care. For some women, exposing body parts, especially to a man, is considered a major violation of their modesty. For many women, invasive procedures, such as a vaginal examination, may be so threatening that they cannot be discussed even with their own husbands; therefore many women prefer a female health care provider. Too often, health care providers assume that women lose this modesty during pregnancy and labor, but most women value and appreciate efforts to maintain their modesty.

For many cultural groups, a physician is deemed appropriate only in times of illness. Because pregnancy is considered a normal process and the woman is in a state of health, the services of a physician are considered inappropriate. Western medicine's view of problems in pregnancy may differ from that of members of other cultural groups.

Although pregnancy is considered normal by many, certain practices are expected of women of all cultures to ensure a good outcome. *Cultural prescriptions* tell women what to do, and *cultural proscriptions* establish taboos. The purposes of these practices are to prevent maternal illness caused by a pregnancy-induced imbalanced state and to protect the vulnerable fetus. Prescriptions and proscriptions regulate the woman's emotional response, clothing, physical activity and rest, sexual activity, and dietary practices. Exploration of the woman's beliefs, perceptions of the meaning of childbearing, and health care practices may help health care providers foster her self-actualization, promote attainment of the maternal role, and positively influence her relationship with her spouse.

To provide culturally sensitive care, the nurse must be knowledgeable about practices and customs. Although it is not possible to know everything about every culture and subculture or the many lifestyles that exist, it is important to learn about the varied cultures in the setting in which a nurse practices. When exploring cultural beliefs and practices related to childbearing, the nurse can support and nurture the beliefs that promote physical or emotional adaptation (Fig. 8-20). However, if potentially harmful beliefs or activities are identified, the nurse should sensitively provide education and propose modifications.

Emotional Response. Virtually all cultures emphasize the importance of maintaining a socially harmonious and agreeable environment for the pregnant woman (see Community Focus box). A lifestyle with minimal stress is important in ensuring a successful outcome for the mother and baby. Harmony with other people must be fostered, and visits from extended family members may be required to demonstrate pleasant and noncontroversial relationships. If discord exists in a relationship, it is usually dealt with in culturally prescribed ways.

Besides proscriptions regarding food, other proscriptions involve forms of magic. For example, some Mexicans believe pregnant women should not be allowed to witness an eclipse of the moon because it may cause a cleft palate in the infant. They also believe that exposure to an earthquake may precipitate preterm birth, miscarriage, or a breech presentation. In some cultures, a pregnant woman must not ridicule someone with an affliction for fear her child might be born with the same handicap. A mother should not hate a person lest her child resemble that person. Dental work should not be done during pregnancy because it may cause a baby to have a cleft lip. A folk belief widely held in many cultures is that the pregnant woman should refrain from raising her arms above her head and from tying knots because such movements tie knots in the umbilical cord and may cause it to wrap around the baby's neck. Another belief is that placing a knife under the bed of a laboring woman will "cut" her pain.

Clothing. Although most cultural groups do not prescribe specific clothing for pregnancy, modesty is an expectation for many. Some Mexican women of the Southwest wear a cord beneath the breasts and knotted over the umbilicus. This cord, called a *muñeco,* is thought to prevent morning sickness and ensure a safe birth. Amulets, medals, and beads also may be worn to ward off evil spirits.

Physical Activity and Rest. Norms that regulate physical activity of mothers during pregnancy vary tremendously. Many groups, including Native Americans and some Asian groups, encourage women to be active, to walk, and to engage in normal although not strenuous activities to ensure that the baby is healthy and not too large. Other groups such as Filipinos believe that any activity is dangerous, and others willingly take over the work of the pregnant woman. Some Filipinos believe that this inactivity protects the mother and child. The mother is encouraged simply to produce the succeeding generation. If health care providers do not know of this belief, they could misinterpret this behavior as laziness or noncompliance with the desired prenatal health care regimen. It is important for the nurse to find out the way each pregnant woman views activity and rest.

Sexual Activity. In most cultures, sexual activity is not prohibited until the end of pregnancy. Some Latinos view sexual activity as necessary to keep the birth canal lubricated. Conversely, some Vietnamese have definite proscriptions about sexual intercourse,

FIG 8-20 Umbilical amulet. Northern Plains tribes of Native Americans made amulets to hold the umbilical cord of a newborn child. The parents protected the child by ensuring that it was carried or worn by the child. (Courtesy Shannon Perry, Phoenix, AZ.)

COMMUNITY FOCUS

Culture and Childbirth Beliefs and Practices

Select an immigrant or other minority group in your community and identify childbirth-related beliefs and practices that are unique to that group. Are there stores in the area that sell items that meet the needs of that group? Does the community center have activities or classes that are directed toward that group? Are childbirth education programs available that provide essential information while incorporating cultural patterns? Are childbirth classes available in languages other than English? What could you, as a nurse, contribute to the community that would help meet the needs of that group?

requiring abstinence throughout the pregnancy because it is thought that sexual intercourse may harm the mother and the fetus.

Nutrition. Nutritional information given by Western health care providers may be a source of conflict for many cultural groups. Such a conflict commonly is not known by health care providers unless they understand the dietary beliefs and practices of the particular people for whom they are caring. For example, Muslims have strict regulations regarding preparation of food, and if meat cannot be prepared as prescribed, they may omit it from their diets. Many cultures permit pregnant women to eat only warm foods.

Age Differences

The age of the childbearing couple may have a significant influence on their physical and psychosocial adaptation to pregnancy. Normal developmental processes that occur in both very young and older mothers are interrupted by pregnancy and require a different type of adaptation to pregnancy from that of the woman of typical childbearing age. Although the individuality of each pregnant woman is recognized, special needs of expectant mothers 15 years of age or younger or those 35 years of age or older are summarized here.

Adolescents. Teenage pregnancy is a worldwide problem. The United States has one of the highest teen birth rates among industrialized nations. However, the rate of teen births has declined in the United States since the 1950s. From 2009 to 2010, the teen birth rate decreased 9% to the historic low of 34.3%. In 2010, there were 367,752 births to teens from ages 15 to 19 years, which is 43% lower than the highest number recorded in 1970 (644,708) (Hamilton and Ventura, 2012). Hispanic adolescents have the highest birth rate, although the rate for African-American adolescents also is high. Most of these young women are unmarried, and many are not ready for the emotional, psychosocial, and financial responsibilities of parenthood.

Numerous adolescent pregnancy-prevention programs have had varying degrees of success. Characteristics of programs that make a difference are those that have sustained commitment to adolescents over a long period, involve the parents and other adults in the community, promote abstinence and personal responsibility, and assist adolescents to develop a clear strategy for reaching future goals such as a college education or a career.

When adolescents become pregnant and decide to give birth, they are much less likely than older women to receive adequate prenatal care, with many receiving no care at all. These young women also are more likely to smoke and less likely to gain adequate weight during pregnancy. As a result of these and other factors, babies born to adolescents are at greatly increased risk for LBW, neglect and abuse, serious and long-term disability, and dying during the first year of life.

Delayed entry into prenatal care may be the result of late recognition of pregnancy, denial of pregnancy, or confusion about the services that are available. Such a delay in care may leave inadequate time before birth to attend to correctable problems. The very young pregnant adolescent is at higher risk for each of the confounding variables associated with poor pregnancy outcomes (e.g., socioeconomic factors) and for the conditions associated with a first pregnancy, regardless of age (e.g., gestational hypertension). However, when prenatal care is initiated early and consistently and confounding variables are controlled, very young pregnant adolescents are at no greater risk (nor are their infants) for an adverse outcome than older pregnant women. Thus the role of the nurse in reducing the risks and consequences of adolescent pregnancy is to encourage early and continued prenatal care; to provide early and ongoing education about pregnancy, birth, and parenting (Fig. 8-21); and to refer the adolescent, if necessary, for appropriate social support services, which can help reverse the effects of a negative socioeconomic environment (see Nursing Care Plan).

FIG 8-21 Pregnant adolescents review fetal development. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA).

Women Older Than 35 Years. Two groups of older parents have emerged in the population of women having a child late in their childbearing years. One group consists of women who have many children or who have an additional child during the menopausal period. The other group consists of women who have deliberately delayed childbearing until their late 30s or early 40s.

The U.S. birth rate for women who are 40 to 44 years of age was 10.2 births per 1000 women, which is the highest rate since 1967. The birth rate for women 45 to 49 years of age is stable at 0.7 births per 1000 women (Hamilton, Martin, and Ventura, 2011).

Multiparous Women. Multiparous women may have never used contraceptives because of personal choice or a lack of knowledge concerning contraceptives. They also may be women who have used contraceptives successfully during the childbearing years but, as menopause approaches, cease menstruating regularly or stop using contraception and subsequently become pregnant. The older multiparous woman may believe that pregnancy separates her from her peer group and that her age is a hindrance to close associations with young mothers. Other parents welcome the unexpected infant as evidence of continuing maternal and paternal roles.

Primiparous Women. The number of first-time pregnancies in U.S. women between ages 35 and 40 years has increased significantly over the past three decades (Heron, Sutton, Xu, et al., 2010) to 10.5 per 1000 births (Hamilton, Martin, and Ventura, 2011). Seeing women in their late 30s or 40s during their first pregnancy is no longer unusual for health care providers. Reasons for delaying pregnancy include a desire to obtain advanced education, career priorities, and use of better contraceptive measures. Women who are infertile do not delay pregnancy deliberately but may become pregnant at a later age as a result of fertility studies and therapies.

These women choose parenthood. They often are established in a career and a lifestyle with a partner that includes time for self-attention, the establishment of a home with accumulated possessions, and freedom to travel. When asked the reason they chose pregnancy later in life, many reply, "Because time is running out."

The dilemma of choice includes recognition that being a parent will have both positive and negative consequences. Couples need to discuss the consequences of childbearing and childrearing before

NURSING CARE PLAN

Adolescent Pregnancy

NURSING DIAGNOSIS	EXPECTED OUTCOMES	INTERVENTIONS	RATIONALES
Imbalanced Nutrition: Less Than Body Requirements related to intake insufficient to meet metabolic needs of fetus and adolescent patient	Adolescent will gain weight as prescribed by age, take prenatal vitamins/ iron as prescribed, and maintain normal hematocrit and hemoglobin.	Assess current diet history/intake	To determine prescriptions for additions or changes in present dietary pattern
		Compare prepregnancy weight with current weight	To determine if pattern of weight gain is consistent with appropriate fetal growth and development
		Provide information concerning food prescriptions for appropriate weight gain, considering preferences for "fast food" and peer influences	To correct any misconceptions and increase chances for compliance with diet
		Include adolescent's immediate family or support system during instruction	To ensure that person preparing family meals receives information
Risk for Injury, maternal or fetal, related to inadequate prenatal care and screening	Adolescent will experience uncomplicated pregnancy and give birth to healthy fetus at term.	Provide information, using therapeutic communication and confidentiality	To establish relationship and build trust
		Discuss importance of ongoing prenatal care and possible risks to adolescent patient and fetus	To reinforce that ongoing assessment is crucial to health and well-being of patient and fetus, even if patient feels well. The adolescent patient is more at risk for certain complications that may be avoided or managed early if prenatal visits are maintained
		Discuss risks of alcohol, tobacco, and recreational drug use during pregnancy	To minimize risks to patient and fetus because adolescent patients have higher abuse rate than rest of pregnant population
		Assess for evidence of sexually transmitted infection (STI), and provide information regarding sexual practices	To minimize risk to patient and fetus because adolescent is more at risk for STIs
		Screen for preeclampsia on an ongoing basis	To minimize risk because adolescent population is more at risk for preeclampsia
Social Isolation related to body image changes of pregnant adolescent as evidenced by patient statements and concerns	Adolescent will identify support systems and report decreased feelings of social isolation.	Establish a therapeutic relationship	To listen objectively and establish trust
		Discuss with patient changes in relationships that have occurred as result of pregnancy	To determine extent of isolation from family, peers, and father of baby
		Provide referrals and resources appropriate for developmental stage of patient	To give information for patient support
		Provide information regarding parenting classes, breastfeeding classes, and childbirth preparation classes	To give further information and group support, which lessens social isolation
Interrupted Family Processes related to adolescent pregnancy	Adolescent will reestablish relationship with her mother and father of baby.	Encourage communication with mother	To clarify roles and relationships related to birth of infant
		Encourage communication with father of baby (if she desires continued contact)	To ascertain level of support to be expected of father of baby
		Refer to support group	To learn more effective problem-solving methods and reduce conflict within the family
Disturbed Body Image related to situational crisis of pregnancy	Adolescent will verbalize positive comments regarding her body image during pregnancy.	Assess pregnant adolescent's perception of self related to pregnancy	To provide basis for further interventions
		Give information regarding expected body changes occurring during pregnancy	To provide a realistic view of these temporary changes
		Provide opportunity to discuss personal feelings and concerns	To promote trust and support

NURSING CARE PLAN

Adolescent Pregnancy—cont'd

NURSING DIAGNOSIS	EXPECTED OUTCOMES	INTERVENTIONS	RATIONALES
Risk for Impaired Parenting related to immaturity and lack of experience in new role of adolescent mother	Parents will demonstrate parenting roles with confidence.	Provide information on growth and development	To enhance knowledge so that adolescent mother can have basis for caring for her infant
		Refer to parenting classes	To enhance knowledge and obtain support for providing appropriate care to newborn and infant
		Initiate discussion of child care	To assist adolescent in problem solving for future needs
		Assess parenting abilities of adolescent mother and father	To provide baseline for education
		Provide information on parenting classes that are appropriate for parents' developmental stage	To give opportunity to share common feelings and concerns
		Assist parents to identify pertinent support systems	To give assistance with parenting as needed

committing themselves to this lifelong venture. Partners in this group seem to share the preparation for parenthood, the planning for a family-centered birth, and the desire to be loving and competent parents. However, the reality of child care may prove difficult for them.

First-time mothers older than 35 years select the "right time" for pregnancy; this time is influenced by their awareness of the increasing possibility of infertility or of genetic defects in the infants of older women. Such women seek information about pregnancy from books, friends, and electronic resources. They actively try to prevent fetal disorders and are careful in searching for the best possible maternity care. They identify sources of stress in their lives. They have concerns about having enough energy and stamina to meet the demands of parenting and their new roles and relationships.

If older women become pregnant after treatment for infertility, they may suddenly have negative or ambivalent feelings about the pregnancy. They may experience a multifetal pregnancy that may create emotional and physical problems. Adjusting to parenting two or more infants requires adaptability and additional resources.

During pregnancy, parents explore the possibilities and responsibilities of changing identities and new roles. They must prepare a safe and nurturing environment during pregnancy and after birth. They must integrate the child into an established family system and negotiate new roles (parent, sibling, and grandparent roles) for family members.

Adverse perinatal outcomes are more common in older primiparas than in younger women, even when they receive good prenatal care. Women 35 years of age and older are more likely than younger primiparas to have infants with chromosomal abnormalities, LBW infants, preterm birth, abruptio placentae, and multiple gestation (Johnson and Tough, 2012). The incidence of malpresentation also is more common in older primiparas, and they are more likely to have a cesarean birth. In addition, in women ages 35 years or older, there is an increased risk for maternal mortality from hemorrhage, infection, embolisms, hypertensive disorders of pregnancy, cardiomyopathy, and strokes.

Multifetal Pregnancy

A multifetal pregnancy, or pregnancy with more than one fetus, places the mother and fetuses at increased risk for adverse outcomes. The maternal blood volume is increased, resulting in an increased strain on the maternal cardiovascular system. Anemia often develops because of a greater demand for iron by the fetuses. Marked uterine distention, increased pressure on the adjacent viscera and pelvic vasculature, and diastasis of the two rectus abdominis muscles may occur (see Fig. 7-13). Placenta previa develops more commonly in multifetal pregnancies because of the large size or placement of the placentas. Premature separation of the placenta may occur before the second and any subsequent fetuses are born.

Twin pregnancies often end prematurely. Spontaneous rupture of membranes before term is common. Congenital malformations are twice as common in monozygotic twins as in singletons, although there is no increase in the incidence of congenital anomalies in dizygotic twins. Two-vessel cords (i.e., cords with a single umbilical artery) occur more often in twins than in singletons; this abnormality is most common in monozygotic twins. The most serious problem for the fetus is the local shunting of blood between placentas (twin-to-twin transfusion); this causes the recipient twin to be larger and the donor twin to be small, pallid, dehydrated, malnourished, and hypovolemic. However, the larger twin may develop congenital heart failure during the first 24 hours after birth.

The clinical diagnosis of multifetal pregnancy is accurate in about 90% of cases. The likelihood of a multifetal pregnancy is increased if any one or a combination of the following factors is noted during a careful assessment:

- History of dizygotic twins in the female lineage
- Use of fertility drugs
- More rapid uterine growth for the number of weeks of gestation
- Polyhydramnios
- Palpation of more than the expected number of small or large parts
- Asynchronous fetal heartbeats or more than one fetal electrocardiographic tracing
- Ultrasonographic evidence of more than one fetus

The diagnosis of multifetal pregnancy is a shock to many expectant parents, and they may need additional support and education to help them cope with the changes they face. The mother needs nutrition counseling so that she gains more weight than that needed for a singleton birth. She should also be counseled that maternal

adaptations will probably be more uncomfortable, and she should be provided with information about the possibility of a preterm birth.

If the presence of more than three fetuses is diagnosed, the parents may face decisions regarding selective reduction of the fetuses to reduce the incidence of premature birth and improve the opportunities for the remaining fetuses to grow to term gestation (Cunningham, Leveno, Bloom, et al., 2010). This situation poses an ethical dilemma for many couples, especially those who have worked hard to overcome problems with infertility and those who harbor strong values regarding the right to life. Nurses can initiate discussions with couples to help them identify resources (e.g., a minister, priest, rabbi, or mental health counselor) to aide in the decision-making process.

Prenatal care for women with multifetal pregnancies includes changes in the pattern of care and modifications in other aspects such as the amount of weight gained and the nutritional intake necessary. For example, the prenatal visits of these mothers are scheduled at least every 2 weeks in the second trimester and weekly thereafter. Fetal growth is carefully monitored throughout pregnancy using regular ultrasound evaluations. The recommended weight gain is increased with twin gestation; women with normal prepregnancy weight should gain 17 to 25 kg (37.4 to 55 lb) (Rasmussen and Yaktine, 2009). Iron and vitamin supplements are desirable.

The considerable uterine distention involved in a multifetal pregnancy can worsen the backache commonly experienced by pregnant women. Maternity support hose may be worn to control leg varicosities. Every multifetal pregnancy is at risk for preterm labor; thus the women receive frequent ultrasound examinations, FHR monitoring, and nonstress tests. Routine bedrest is not recommended in twin pregnancies at low risk for preterm labor. Some practitioners recommend bedrest beginning at 20 weeks for women carrying triplets or more to prevent preterm labor (Newman and Unal, 2012). If bedrest is recommended, the mother needs to assume the lateral position to promote increased placental perfusion. If birth is delayed until after the thirty-sixth week, the risk for morbidity and mortality decreases for the neonates.

Multiple newborns will likely place a strain on finances, space, workload, and the mother's and family's coping abilities. Lifestyle changes may be necessary. Parents will need assistance in making realistic plans for the care of the babies (e.g., whether to breastfeed and whether to raise them as "alike" or as separate individuals). Parents can be referred to national organizations such as Mother of Twins (www.nomotc.org) and the La Leche League (www.lalecheleague.org) for further support.

CHILDBIRTH AND PERINATAL EDUCATION

The goal of childbirth and perinatal education is to assist individuals and their family members to make informed, safe decisions about pregnancy, birth, and early parenthood. It also is to assist them to comprehend the long-lasting effects that empowering birth experiences have in the lives of women and the impact of early experiences on the development of children and the family. Perinatal education ideally begins in the preconception period when women are considering pregnancy and continues throughout the prenatal period as nurses and other health care providers provide ongoing education for pregnant women and their partners during regular prenatal visits.

Contemporary perinatal education programs are an expansion of the earlier childbirth education movement that originally offered a set of classes in the third trimester of pregnancy to prepare parents for birth. Today perinatal education programs consist of a menu of class series and activities from preconception through the early months of parenting.

Health-promoting education should be provided in a context that emphasizes how a healthy body is best able to adapt to the changes that accompany pregnancy. Without this context of health, routine care and testing for risks may contribute to a mindset of families that pregnancy is a pathologic as opposed to a healthy mind-body-spirit event.

Some of the decisions the childbearing family must consider are whether to have a baby, followed by choices of a care provider and type of care (a midwifery model [natural oriented] versus a medical [intervention oriented] model); the place for birth (hospital, birthing center, home); and the type of infant feeding (breast or bottle) and infant care. If a woman previously had a cesarean birth, she may consider a trial of labor after cesarean (TOLAC) to attempt a vaginal birth. Perinatal education can provide information to help childbearing families make informed decisions about these issues.

Previous pregnancy and childbirth experiences are important elements that influence current learning needs. Other important factors include the age of the woman and her support person, their cultural background, personal philosophy with regard to childbirth, socioeconomic status, spiritual beliefs, and learning styles. The nurse considers all of these in helping the woman and her partner develop the best plan to meet their needs.

Typically, the pregnant woman is accompanied by her partner when attending childbirth education classes, although sometimes a friend, teenage daughter, or parent is the designated support person. There are also classes for grandparents and siblings to prepare them for their attendance at birth and/or the arrival of the baby. Siblings often see a film about birth and learn ways they can help welcome the baby. They also learn to cope with changes that include a reduction in parental time and attention. Grandparents learn about current child care practices and how to help their adult children adapt to parenting in a supportive way.

Perinatal Education Programs

Childbearing, when one is prepared and well supported, presents to women a unique and powerful opportunity to find their core strength in a manner that forever changes their self-perception. Expectant parents and their families have different interests and information needs as the pregnancy progresses.

A variety of approaches to childbirth education have evolved as childbirth educators attempt to meet learning needs of expectant parents. In addition to classes designed specifically for pregnant adolescents, their partners, and/or parents, classes exist for other groups with special learning needs. These include classes for first-time mothers older than 35 years, single women, adoptive parents, parents of multiples, or women with disabilities such as those who are visually impaired or deaf. Refresher classes for parents with children not only review coping techniques for labor and birth but also help couples prepare for sibling reactions and adjustments to a new baby. Cesarean birth classes are available for couples who have this kind of birth scheduled because of breech presentation or other risk factors. Other classes focus on vaginal birth after cesarean (VBAC) because many women can successfully give birth vaginally after previous cesarean birth.

Throughout the series of classes, support systems that people can use during pregnancy and after birth are discussed. Such support systems help parents function independently and effectively. During

all the classes, the open expression of feelings and concerns about any aspect of pregnancy, birth, and parenting is welcomed.

Early pregnancy ("early bird") classes provide fundamental information. Classes are developed around the following areas: (1) early fetal development, (2) physiologic and emotional changes of pregnancy, (3) human sexuality, and (4) the nutritional needs of the mother and fetus. The classes often address environmental and workplace hazards. Exercises, nutrition, warning signs, drugs, and self-medication also are topics of interest and concern.

Mid-pregnancy classes emphasize the woman's participation in self-management. Classes provide information on preparation for breastfeeding and formula-feeding, infant care, basic hygiene, common complaints and simple safe remedies, infant health, parenting, and updating and refining the birth plans.

Late pregnancy classes emphasize labor and birth. There are different methods of coping with labor and birth, and these are often the basis for various prenatal classes. These include Lamaze, Bradley, and Dick-Read. These classes usually include a tour of the birthing facility. Because fear of pain in labor is a key issue for many women, preparation for childbirth classes provide information on management of discomfort during labor and birth. Topics include relaxation and breathing techniques, imagery and visualization, biofeedback, and pharmacologic interventions such as intravenous medications and epidural analgesia. Couples need information about the advantages and disadvantages of pain medication and about other techniques for coping with labor. An emphasis on nonpharmacologic pain management strategies helps couples manage the labor and birth with dignity and increased comfort. Most instructors teach a flexible approach, which helps couples learn and master many techniques to use during labor (see Chapter 14 for further discussion).

Perinatal Care Choices

Often the first decision the woman makes is who will be her primary health care provider for the pregnancy and birth. This decision is doubly important because it usually affects where the birth will take place. The nurse can provide information about the different types of health care providers and what kind of care to expect from each type. Women are encouraged to ask potential care providers a series of pertinent questions (Box 8-5).

Physicians

Physicians (obstetricians, family medicine physicians, osteopathic physicians) attended 92% of hospital births and 5% of home births in the United States in 2009 (MacDorman, Mathews, and Declercq, 2012). Family practice physicians and osteopathic physicians provide care for primarily low risk pregnant women and refer high risk patients to obstetricians. Obstetricians see low risk and high risk patients. Care often includes pharmacologic and medical management of problems as well as use of technologic procedures.

Nurse-Midwives

Certified nurse-midwives are registered nurses with education in the two disciplines of nursing and midwifery. Throughout history, midwives have held a holistic view of childbirth. In 2009, certified nurse midwives attended 7.4% of hospital births and 19% of home births (MacDorman, Mathews, and Declercq, 2012). Nurse-midwives practice with physicians or independently with an arrangement for physician backup. They usually see low risk obstetric patients. Care is often noninterventionist, and the woman and her family are encouraged to be active participants in the care. Nurse-midwives refer patients with complications to physicians.

BOX 8-5 QUESTIONS TO ASK POTENTIAL MATERNITY CARE PROVIDERS

The Coalition to Improve Maternity Services (CIMS), a group of more than 50 nursing and maternity care–oriented organizations, produced a document to assist women in selecting their perinatal care. After some explanation of choices, women are encouraged to ask potential care providers the following questions:

- Who can be with me during labor and birth?
- What happens during a normal labor and birth in your setting?
- How do you allow for differences in culture and beliefs?
- Can I walk and move around during labor? What position do you suggest for birth?
- How do you make sure everything goes smoothly when my nurse, doctor, midwife, or agency works with each other?
- What things do you normally do to a woman in labor?
- How do you help mothers stay as comfortable as they can be? Besides drugs, how do you help mothers relieve the pain of labor?
- What if my baby is born early or has special problems?
- Do you circumcise babies?
- How do you help mothers who want to breastfeed?

Adapted from Coalition to Improve Maternity Services (CIMS): *Having a baby? 10 questions to ask,* 2000, www.motherfriendly.org/Resources/Documents/Having_a_Baby-English.pdf.

Direct-Entry Midwives

Direct-entry midwives (also called *certified professional midwives*) are trained in midwifery schools or universities as a profession distinct from nursing. In the United States, their certification process is administered by the American College of Nurse-Midwives. They also refer the patients in whom problems develop to physicians. Increasing numbers of midwives in the United Kingdom and Ireland are in this category.

Independent Midwives

Independent midwives, who also may be called *lay midwives,* are nonprofessional caregivers. Their training varies greatly, from self-teaching to formal training. They manage about 1% of births in the United States. Patients who develop problems are referred to a physician. A majority of births are managed in the home setting. In many international settings, lay midwives are called *traditional birth attendants.* Births are in the home.

Doulas

A doula is professionally trained to provide labor support, including physical, emotional, and informational support, to women and their partners during labor and birth. The doula does not become involved with clinical tasks (Doulas of North America [DONA], 2008). Today many couples, no matter which type of childbirth classes they take, also employ a doula for labor support.

A doula typically meets with the woman and her partner before labor. At this meeting, the doula assesses the woman's expectations and desires for the birth experience. With this information as a guide during labor and birth, the doula focuses efforts on assisting the woman to achieve her goals. Doulas work collaboratively with other health care providers and the partner or other support persons, but their primary goal is to assist the woman. Doulas who are also trained medical interpreters can enhance the care of women with limited English proficiency (Maher, Crawford-Carr, and Neidigh, 2012).

BOX 8-6 QUESTIONS TO ASK WHEN CHOOSING A DOULA

To discover the specific training, experience, and services offered by anyone who provides labor support, potential patients, nursing supervisors, physicians, midwives, and others should ask the following questions of that person:

- What training have you had?
- Tell me about your experience with birth, both personally and as a doula.
- What is your philosophy about childbirth and supporting women and their partners through labor?
- May we meet to discuss our birth plans and the role you will play in supporting me through childbirth?
- May we call you with questions or concerns before and after the birth?
- When do you try to join women in labor? Do you come to our home or meet us at the hospital?
- Do you meet with us after the birth to review the labor and answer questions?
- Do you work with one or more backup doulas for times when you are not available? May we meet them?
- What is your fee?

Adapted from Doulas of North America: *Doulas of North America position paper: the birth doula's contribution to modern maternity care,* 2008, www.dona.org/pdfs/position_papers/BIRTH%20Paper–%204%20page.pdf.

Doulas may be found through community contacts, other health care providers, or childbirth educators; a number of organizations offer information or referral services. It is important that the expectant mother be comfortable with the doula who will be attending her. See Box 8-6 for a list of questions to ask when arranging for a doula. Doulas of North America (DONA) is an organization that certifies doulas (www.dona.org). Although the doula role originally developed as an assistant during labor, some women and their families benefit from assistance during the postpartum period. Postpartum doulas provide assistance to the new mother as she develops competence with infant care, feeding, and other maternal tasks and to the family as they adjust to life with a new baby.

Birth Plans

The **birth plan** is a natural evolution of a contemporary wellness-oriented lifestyle in which patients assume a level of responsibility for their own health. The birth plan is a tool with which parents can explore their childbirth options and choose those that are most important to them. The plan must be viewed as tentative since the realities of what is feasible may change as the actual labor and birth unfold. It is understood to be a preference list based on a best-case scenario.

It is useful for the nurse in a prenatal practice setting to initiate a discussion of choices and birth planning during the first and second prenatal visits. Some maternity practices provide printed material describing available options and giving answers to commonly asked questions, and tours of the birth setting are offered by almost all birthing facilities. The nurse can provide couples with pertinent information and make them aware of the various options for care and the advantages and consequences of each so they can begin making informed decisions. Early plans can be modified as the couple learn more details in their childbirth class. Topics for the expectant parents to consider when creating a birth plan are listed in the Family-Centered Care box.

FAMILY-CENTERED CARE

Creating a Birth Plan

Topics for birth plan discussion and decision making may include any or all of the following:

Partner's participation: Attend prenatal visits? Childbirth and parent education classes? Present during labor? During birth? During cesarean birth?

Birth setting: Hospital delivery room or birthing room (if available)? A birthing center? Home?

Labor management: Walk around during labor? Use a rocking chair? Use a shower? Use a Jacuzzi, if available? Intermittent versus continuous use of an electronic fetal monitor? Have music or dimmed lighting? Have older children or other people present? Is telemetry monitoring available? Consider stimulation of labor? Consider medication—what kind?

Birth: Positions—Side-lying? On hands and knees, kneeling, or squatting? Use a birthing bed or delivery table? Will you be photographing, videotaping, or recording any of the labor or birth? Who would you like to be present—partner, older siblings, other family members, or friends? What do you know about the use of forceps? Episiotomy? Will your partner want to cut the umbilical cord? Emergency considerations/contingencies (e.g., cesarean)?

Immediately after birth: Do you want to hold the baby skin-to-skin right away? Breastfeed immediately?

Postpartum care: What kind of care do you anticipate—labor, delivery, recovery, postpartum room; mother-baby couplet care? How long does your insurance company provide coverage for you to stay? Would you like to attend self-management classes, or do you prefer to get such information from media sources? On which subjects?

The birth plan can serve as a means of open communication between the pregnant woman and her partner and also between the couple and health care providers. An early introduction to the idea of a birth plan allows the couple time to think about events or situations that could make their childbearing experience more meaningful and those they would prefer to avoid (Anderson and Kilpatrick, 2012).

Traditionally, birth plans are created prenatally and implemented upon admission to the labor and birth unit. However, when women without predesigned birth plans are admitted, nurses can use a template with simple questions about preferences for care to help them develop a simple birth plan (Anderson and Kilpatrick, 2012; Kuo, Lin, Hsu, et al., 2010). This is in accordance with the Association of Women's Health, Obstetrics and Neonatal Nurses's (AWHONN's) position statement on nursing support of laboring women, specifically creating individualized care plans for laboring women based on their needs, desires, and expectations (AWHONN, 2011).

Birth Setting Choices

With careful thought, the concept of natural, family, or woman-centered maternity care can be implemented in any setting. The three primary options for birth settings today are the hospital, birth center, and home. Women consider several factors in choosing a setting for childbirth, including the preference of their health care provider, characteristics of the birthing unit, and preference of their third-party payer. Approximately 99% of all births in the United States take place in a hospital setting (MacDorman, Mathews, and Declercq, 2012). However, the types of labor and birth services vary greatly, from the traditional labor and delivery rooms with separate

FIG 8-22 Labor, delivery, recovery, and postpartum (LDRP) units. (*A,* Courtesy Dee Lowdermilk, Chapel Hill, NC. *B,* Courtesy Mercy Hospital, St Louis, MO.)

postpartum and newborn units to in-hospital birthing centers where all or almost all care takes place in a single unit.

Labor, Delivery, Recovery, Postpartum (Birthing) Rooms

Labor, delivery, and recovery (LDR) and labor, delivery, recovery, and postpartum (LDRP) rooms offer families a comfortable, private space for childbirth (Fig. 8-22). Women are admitted to LDR units, labor and give birth, and spend the first 1 to 2 hours postpartum there for immediate recovery and to have time with their families to bond with their newborns. After this period of recovery, the mothers and newborns are transferred to a postpartum unit and nursery or mother-baby unit for the duration of their stay. Care is provided by different nursing staff (e.g., labor and delivery nurses, postpartum nurses, nursery nurses). In some hospitals, the same nurse provides care for both mothers and newborns (mother-baby or couplet care).

In LDRP units, total care is provided from admission for labor through postpartum discharge in the same room and usually by the same nursing staff. The woman and her family may stay in this unit for 6 to 48 hours after giving birth. The units are furnished in a homelike atmosphere, similar to LDR units but have accommodations for family members to stay overnight (see Fig. 8-22, *A*).

Both units are equipped with fetal monitors, emergency resuscitation equipment for both mother and newborn, and heated cribs or warming units for the newborn. Often this equipment is

FIG 8-23 Birth center. **A,** Note double bed, baby crib, and birthing stool. **B,** Lounge and kitchen. (*A,* Courtesy Dee Lowdermilk, Chapel Hill, NC. *B,* Courtesy Michael S. Clement, MD, Mesa, AZ. Photo location: Bethany Birth Center, Phoenix, AZ.)

out of sight in cabinets or closets when it is not being used (see Fig. 8-22, *B*).

Birth Centers

Free-standing birth centers are usually built in locations separate from the hospital but may be located nearby in case transfer of the woman or newborn is needed. These birth centers are intended to offer families an alternative to hospital or home birth, providing a third choice that is a safe and cost-effective compromise. The centers are usually staffed by nurse-midwives or physicians who also have privileges at the local hospital. Only women at low risk for complications are included for care.

Birth centers typically have homelike accommodations, including a double bed for the couple and a crib for the newborn (Fig. 8-23, *A*). Emergency equipment and drugs are available but stored out of view. Private bathroom facilities are incorporated into each birth unit. There may be an early labor lounge or a living room and small kitchen (see Fig. 8-23, *B*). The family is admitted to the birth center for labor and birth and will remain there until discharge, which often takes place within 6 hours of the birth.

Other services provided by the free-standing birth centers include those necessary for safe management during the childbearing cycle. Attendance at childbirth and parenting classes is required of all patients. Expectant families develop birth plans (i.e., the practices and procedures they would like to either include or exclude from their childbirth experience). Patients must understand that some situations require transfer to a hospital, and they must agree to abide by those guidelines.

Birth centers and hospitals with a comprehensive birthing program may have resources for parents such as a lending library that includes books and videotapes; reference files on related topics; recycled maternity clothes, baby clothes, and equipment; and supplies and reference materials for childbirth educators. The centers may also have referral files for community resources that offer services relating to childbirth and early parenting, including support groups (e.g., for single parents, postbirth support, and parents of twins), genetic counseling, women's issues, and consumer action.

When births occur in a birth center or a home setting, they should be located close to a major hospital so that quick transfer to that institution is possible when necessary. Ambulance service and emergency procedures must be readily available. Fees vary with the services provided but typically are less than or equal to those charged by local hospitals. Some base fees on the ability of the family to pay (a reduced-fee sliding scale). Several third-party payers, as well as Medicaid and the Civilian Health and Medical Programs of the Uniformed Services (TRICARE/CHAMPUS), recognize and reimburse these centers.

Home Birth

Home birth has always been popular in certain countries such as Sweden and The Netherlands. In developing countries, hospitals or adequate lying-in facilities often are unavailable to most pregnant women and home birth is a necessity. In the United States, 0.72% of births occurred in a home setting in 2009. This is a 29% increase from 0.56% in 2004 (MacDorman, Mathews, and Declercq, 2012).

Home birth remains a controversial topic in American health care (Lowe, 2009). Organizations such as the American College of Obstetricians and Gynecologists (ACOG) and the American Medical Association agree that the safest setting for birth is a hospital or birthing center that meets standards set forth by AAP and ACOG or a freestanding birth center that meets standards of the Accreditation Association for Ambulatory Health Care (ACOG Committee on Obstetric Practice, 2011b; American Medical Association, 2008). ACOG emphasizes the need to inform women considering planned home birth about risks and benefits; while they note that absolute risk may be low, they cite a twofold to threefold increased risk for neonatal death with home birth compared with planned hospital birth (ACOG Committee on Obstetric Practice, 2011b). Research findings based on cohort and observational studies do not support this stance. Large-scale studies have documented the safety of planned home birth for healthy, low risk women who are attended by registered midwives and when there is a system in place for transfer to a hospital facility (de Jonge, van der Goes, Ravelli, et al., 2009; Hutton, Reitsma, and Kaufman, 2009; Janssen, Saxell, Page, et al., 2009; McIntyre, 2012). The National Perinatal Association (2008) and the American College of Nurse Midwives (2011) support planned home birth for carefully selected low risk women within a system that provides hospitalization as needed.

With a home birth, the family is in control of the experience and the birth may be more physiologically natural in familiar surroundings (see Critical Thinking Case Study). The mother may be more relaxed than she would be in the hospital environment. Home births are typically unmedicated (no pharmacologic analgesia). The family can assist in and be a part of the birth, and the mother-father/partner-infant (and sibling-infant) contact is immediate and sustained. Home birth may be less expensive than a hospital confinement. Serious infection may be less likely (assuming strict aseptic principles are followed) because it is usual for people to be relatively immune to the bacteria in their own home.

CRITICAL THINKING CASE STUDY

Deciding About a Home Birth

Maxine, 37 years old and gravida 1, para 0, is interested in having a home birth. She has insulin-dependent diabetes. She is currently 14 weeks pregnant, and her pregnancy is progressing normally. According to an ultrasound examination, she has one fetus of appropriate size for gestational age with no detectable anomalies. She asks a nurse on the obstetric clinic about how to find a midwife who will attend a home birth.

1. Evidence—Is there sufficient evidence to draw conclusions about the safety of a home birth for Maxine?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Assessments that are necessary to identify whether it is feasible and safe for Maxine to have a home birth
   b. Supports necessary for a home birth
   c. How to identify providers who are willing to attend a home birth
   d. Ethics of the nurse assisting Maxine to find a midwife who will attend a home birth
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

KEY POINTS

- The prenatal period is a preparatory one, both physically and psychologically.
- Psychosocial aspects of care may affect pregnancy, childbirth, and the adjustment of the new family.
- The pregnant woman's readiness to learn is at a high level, making this an excellent time to help her expand her self-management skills.
- Maternal physical and familial adaptations to pregnancy generate needs that the nurse can anticipate and meet.
- Even with a normal pregnancy, the nurse must remain alert to hazards such as supine hypotension, warning signs and symptoms, and signs of family maladaptations.
- Each pregnant woman needs to know how to recognize and report preterm labor.
- Parent-child, sibling-child, and grandparent-child relationships are affected by pregnancy.
- Cultural prescriptions and proscriptions influence responses to pregnancy and to the health care delivery system.
- Childbirth education teaches tuning in to the body's inner wisdom and coping strategies that enhance women's ability to know how to give birth.
- Childbirth education is a process designed to help parents make the transition from the role of expectant parents to the role and responsibilities of parents of a new baby.
- Nurses provide information that enables expectant parents to make informed choices about their health care provider and birth setting.

CHAPTER

9

Maternal and Fetal Nutrition

Shannon E. Perry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Explain recommended maternal weight gain during pregnancy.
- Compare the recommended level of intake of energy sources, protein, and key vitamins and minerals during pregnancy and lactation.
- Give examples of the food sources that provide the nutrients required for optimal maternal nutrition during pregnancy and lactation.
- Examine the role of nutrition supplements during pregnancy.
- List five nutritional risk factors during pregnancy.
- Compare the dietary needs of adolescent and mature pregnant women.
- Analyze examples of eating patterns of women from two different ethnic or cultural backgrounds and identify potential dietary problems.
- Assess nutritional status during pregnancy.

Nutrition is one of the many factors that influence the outcome of pregnancy (Fig. 9-1). However, maternal nutritional status is an especially significant factor, both because it is potentially alterable and because good nutrition before and during pregnancy is an important preventive measure for a variety of problems. These problems include birth of low-birth-weight (LBW) (birth weight of 2500 g or less) and preterm infants. Evidence is growing that a mother's nutrition and lifestyle affect the long-term health of her children. Thus the importance of good nutrition must be emphasized to all women of childbearing potential. Key components of nutrition care during the preconception period and pregnancy include (Harnisch, Harnisch, and Harnisch, 2012):

- Nutrition assessment that includes appropriate weight for height and adequacy and quality of dietary intake and habits
- Diagnosis of nutrition-related problems or risk factors such as diabetes, phenylketonuria (PKU), and obesity
- Intervention based on an individual's dietary goals and plan to promote appropriate weight gain, ingestion of a variety of foods, appropriate use of dietary supplements, and physical activity
- Evaluation as an integral part of the nursing care provided to women during the preconception period and pregnancy, with referral to a nutritionist or dietitian as necessary

NUTRIENT NEEDS BEFORE CONCEPTION

The first trimester of pregnancy is a crucial one in terms of embryonic and fetal organ development. A healthful diet before conception is the best way to ensure that adequate nutrients are available for the developing fetus. Folate or folic acid intake is of particular concern in the periconception period. Folate is the form in which this vitamin is found naturally in foods, and folic acid is the form used in fortification of grain products and other foods and in vitamin supplements. Neural tube defects (failure in closure of the neural tube) are more common in infants of women with poor folic acid intake. Proper closure of the neural tube is required for normal formation of the spinal cord, and the neural tube begins to close within the first month of gestation, often before the woman realizes that she is pregnant (Box 9-1).

Maternal and fetal risks in pregnancy are increased when the mother is significantly underweight or overweight when pregnancy begins. Ideally, all women would achieve their desirable body weights before conception.

NUTRIENT NEEDS DURING PREGNANCY

Nutrient needs are determined, at least in part, by the stage of gestation. The amount of fetal growth varies during the different stages

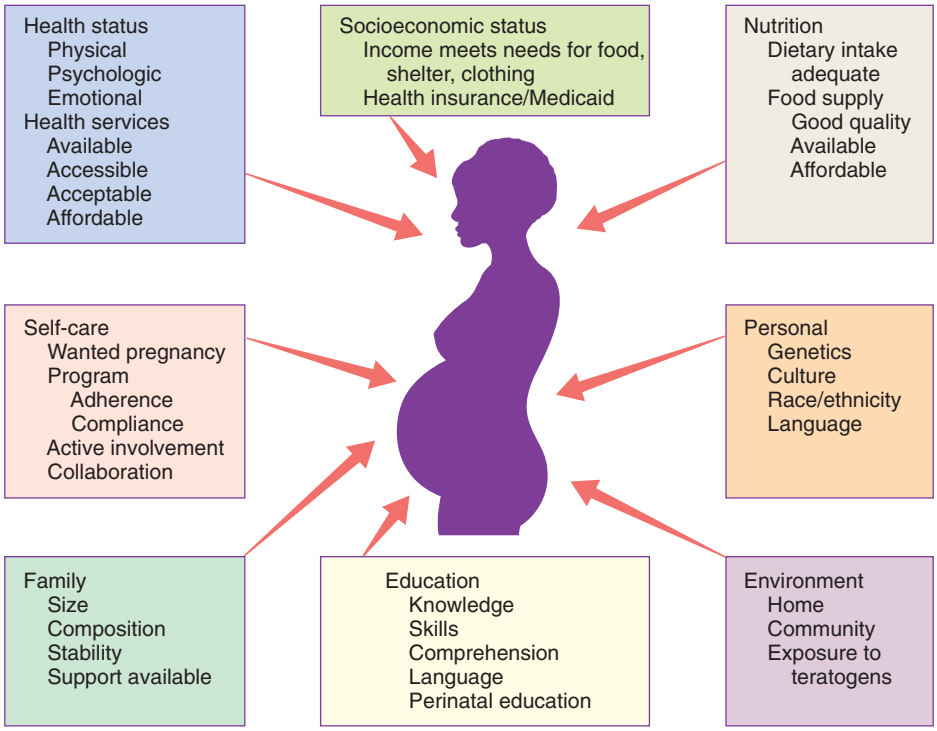

FIG 9-1 Factors that influence the outcome of pregnancy.

BOX 9-1 FOOD SOURCES OF FOLATE

Foods Providing 500 mcg or More per Serving
- Liver: chicken, turkey, goose (100 g [3.5 oz])

Foods Providing 200 mcg or More per Serving
- Liver: lamb, beef, veal (100 g [3.5 oz])

Foods Providing 100 mcg or More per Serving
- Legumes, cooked (½ cup)
  - Peas: black-eyed, chickpea (garbanzo)
  - Beans: black, kidney, pinto, red, navy
  - Lentils
- Vegetables (½ cup)
  - Asparagus
  - Spinach, cooked
- Papaya (1 medium)
- Breakfast cereal, ready-to-eat ½ to 1 cup)
- Wheat germ (¼ cup)

Foods Providing 50 mcg or More per Serving
- Vegetables (½ cup)
  - Broccoli
  - Beans: lima beans, baked beans, or pork and beans
  - Greens: collards or mustard, cooked
  - Spinach, raw
- Fruits (½ cup)
  - Avocado
  - Orange or orange juice
- Pasta, cooked (1 cup)
- Rice, cooked (1 cup)

Foods Providing 20 mcg or More per Serving
- Bread (1 slice)
- Egg (1 large)
- Corn (½ cup)

of pregnancy. During the first trimester, the synthesis of fetal tissues places relatively few demands on maternal nutrition. Therefore during the first trimester, when the embryo or fetus is very small, the needs are only slightly increased over those before pregnancy. In contrast, the last trimester is a period of noticeable fetal growth when most of the fetal stores of energy sources and minerals are deposited. Thus as fetal growth progresses during the second and third trimesters, the pregnant woman's need for some nutrients increases greatly. Factors that contribute to the increase in nutrient needs include the following factors:

- The uterine-placental-fetal unit.
- Maternal blood volume and constituents: During pregnancy the total blood volume increases by about 40% to 50% over normal. The plasma volume increases by 50% in women in their first pregnancies and more than this in multifetal pregnancies. Although red blood cell (RBC) production also is stimulated, the expansion of RBC mass is not as great as that of plasma volume.
- Maternal mammary development.

Dietary Reference Intakes (DRIs) (www.iom.edu) have been established for the people of the United States and Canada and are updated regularly. The DRIs include recommendations for daily nutritional intakes that meet the needs of almost all (97% to 98%) of the healthy members of the population. They are divided into age, sex, and life-stage categories (e.g., infancy, pregnancy, and lactation), and they can be used as goals in planning the diets of individuals (Table 9-1).

Energy Needs

Energy (**kilocalories** [kcal]) needs are met by carbohydrate, fat, and protein in the diet. No specific recommendations exist for the amount of carbohydrate and fat in the diet of the pregnant women, but the intake of these nutrients should be adequate to support the recommended weight gain. Although protein can be used to supply energy, its primary role is to provide amino acids for the synthesis of new tissues (see discussion later in this chapter). Longitudinal assessment of weight gain during pregnancy is the best way to determine whether the kcal intake is

TABLE 9-1 RECOMMENDATIONS FOR DAILY INTAKES OF SELECTED NUTRIENTS DURING PREGNANCY AND LACTATION

NUTRIENT (UNITS)	RECOMMENDATION FOR NONPREGNANT WOMAN*	RECOMMENDATION FOR PREGNANCY*	RECOMMENDATION FOR LACTATION*	ROLE IN RELATION TO PREGNANCY AND LACTATION	FOOD SOURCES
Energy (kilocalories [kcal] or kilojoules [kJ]†)	Variable	First trimester, same as nonpregnant; second trimester, nonpregnant needs + 340 kcal (1424 kJ); third trimester, nonpregnant needs + 452 kcal (1892 kJ)	First 6 months, nonpregnant needs + 330 kcal (1382 kJ); second 6 months, nonpregnant needs + 400 kcal (1675 kJ)	Growth of fetal and maternal tissues; milk production	Carbohydrate, fat, and protein
Protein (g)	46	First trimester, same as nonpregnant; second and third trimesters, nonpregnant needs + 25 g‡	Nonpregnant needs + 25 g	Synthesis of the products of conception; growth of maternal tissue and expansion of blood volume; secretion of milk protein during lactation	Meats, eggs, cheese, yogurt, legumes (dry beans and peas, peanuts), nuts, grains
Water (L) in food and beverages	2.7	3	3.8	Expansion of blood volume, excretion of wastes; milk secretion	Water and beverages made with water, milk, juices; all foods, especially frozen desserts, fruits, lettuce and other fresh vegetables
Fiber (g)	25	28	29	Promotes regular bowel elimination; reduces long-term risk for heart disease, diverticulosis, and diabetes	Whole grains, bran, vegetables, fruits, nuts and seeds
Minerals					
Calcium (mg)	1300/1000	1300/1000	1300/1000	Fetal skeleton and tooth formation; maintenance of maternal bone and tooth mineralization	Milk, cheese, yogurt, sardines or other fish eaten with bones left in, deep green leafy vegetables except spinach or Swiss chard, calcium-set tofu, baked beans, tortillas
Iron (mg)	15/18	30	10/9	Maternal hemoglobin formation, fetal liver iron storage	Liver, meats, whole grain or enriched breads and cereals, deep green leafy vegetables, legumes, dried fruits
Zinc (mg)	9/8	12/11	13/12	Component of numerous enzyme systems, possibly important in preventing congenital malformations	Liver, shellfish, meats, whole grains, milk

Continued

TABLE 9-1 RECOMMENDATIONS FOR DAILY INTAKES OF SELECTED NUTRIENTS DURING PREGNANCY AND LACTATION—cont'd

NUTRIENT (UNITS)	RECOMMENDATION FOR NONPREGNANT WOMAN*	RECOMMENDATION FOR PREGNANCY*	RECOMMENDATION FOR LACTATION*	ROLE IN RELATION TO PREGNANCY AND LACTATION	FOOD SOURCES
Iodine (mcg)	150	220	290	Increased maternal metabolic rate	Iodized salt, seafood, milk and milk products, commercial yeast breads, rolls, and donuts
Magnesium (mg)	360/310-320	400/350-360	360/310-320	Involved in energy and protein metabolism, tissue growth, muscle action	Nuts, legumes, cocoa, meats, whole grains
Fat-Soluble Vitamins					
A (mcg)	700	750/770	1200/1300	Essential for cell development, tooth bud formation, bone growth	Dark green leafy vegetables, dark yellow vegetables and fruits, liver, fortified margarine and butter
D (mcg)	5	5	5	Involved in absorption of calcium and phosphorus, improves mineralization	Fortified milk and breakfast cereals; salmon, tuna, and other oily fish; butter, liver
E (mg)	15	15	19	Antioxidant (protects cell membranes from damage), especially important for preventing breakdown of red blood cells (RBCs)	Vegetable oils, green leafy vegetables, whole grains, liver, nuts and seeds, cheese, fish
Water-Soluble Vitamins					
C (mg)	65/75	80/85	115/120	Tissue formation and integrity, formation of connective tissue, enhancement of iron absorption	Citrus fruits, strawberries, melons, broccoli, tomatoes, peppers, raw dark green leafy vegetables
Folate (mcg)	400	600	500	Prevention of neural tube defects, increased maternal RBC formation	Fortified ready-to-eat cereals and other grain products, green leafy vegetables, oranges, broccoli, asparagus, artichokes, liver
B_6 or pyridoxine (mg)	1.2/1.3	1.9	2	Involved in protein metabolism	Meats, liver, dark green vegetables, whole grains
B_{12} (mcg)	2.4	2.6	2.8	Production of nucleic acids and proteins, especially important in formation of RBCs and neural functioning	Milk and milk products, eggs, meats, liver, fortified soy milk

Data from Otten JJ, Helwig JP, Meyers LD, editors: *Dietary reference intakes: the essential guide to nutrient requirements,* Washington, DC, 2006, National Academies Press.

*When two values appear, separated by a diagonal slash, the first is for females younger than 19 years and the second is for those 19 to 50 years of age.

†The international metric unit of energy measurement is the joule (J). 1 kcal = 4.184 kJ.

‡Add an additional 25 g in twin pregnancies.

adequate; very underweight or active women may require more than the recommended increase in kcal to sustain the desired rate of weight gain.

Weight Gain

The desirable weight gain during pregnancy varies among women. The primary factor to consider in making a weight-gain recommendation is the appropriateness of the prepregnancy weight for the woman's height—that is, whether the woman's weight was normal before pregnancy or whether she was underweight or overweight. Whenever possible, the woman should achieve a weight in the normal range for her height before pregnancy. Maternal and fetal risks in pregnancy are increased when the mother is significantly underweight or overweight before pregnancy and when weight gain during pregnancy is either too low or too high. Severely underweight women are more likely to have preterm labor and to give birth to LBW infants. Both normal-weight and underweight women with inadequate weight gain have an increased risk for giving birth to an infant with **intrauterine growth restriction (IUGR).** Greater-than-expected weight gain during pregnancy may occur for many reasons, including multiple gestation, edema, gestational hypertension, and overeating. When obesity is present (either preexisting obesity or obesity that develops during pregnancy), there is an increased likelihood of macrosomia and feto-pelvic disproportion; operative vaginal birth; emergency cesarean birth; postpartum hemorrhage; wound, genital tract, or urinary tract infection; birth trauma; and late fetal death. Obese women are more likely than normal-weight women to have preeclampsia and gestational diabetes.

A commonly used method of evaluating the appropriateness of weight for height is the **body mass index (BMI),** which is calculated by the following formula:

$$\text{BMI} = \text{Weight} \div \text{Height}^2$$

in which the weight is in kilograms and height is in meters. Thus for a woman who weighed 51 kg before pregnancy and is 1.57 m tall:

$$\text{BMI} = 51\ \text{kg} \div (1.57\ \text{m})^2, \text{ or } 20.7$$

Prepregnant BMI can be classified into the following categories: less than 18.5, underweight or low; 18.5 to 24.9, normal; 25 to 29.9, overweight or high; and greater than 30, obese (www.nhlbisupport.com/bmi). The BMI can be calculated on this website (see also Box 3-6).

At the first health care visit, the pregnant woman should be helped to establish a weight-gain goal for pregnancy that is suited to her prepregnancy weight. Progress toward this goal should be monitored at each visit.

For women with single fetuses, current recommendations are that women with normal BMI should gain 11.5 to 16 kg (25 to 35 lbs) during pregnancy (Fig. 9-2). Box 9-2 lists recommended weight gain for pregnancies with single fetuses, twin gestations, and multifetal (more than 2) gestations for women who are normal weight, underweight, and overweight.

Pattern of Weight Gain

The optimal rate of weight gain depends on the stage of pregnancy. During the first and second trimesters, growth takes place primarily in maternal tissues; during the third trimester, growth occurs primarily in fetal tissues. During the first trimester of singleton pregnancy, the average total weight gain is only 1 to 2 kg. Thereafter the recommended weight gain increases to approximately 0.5 kg per

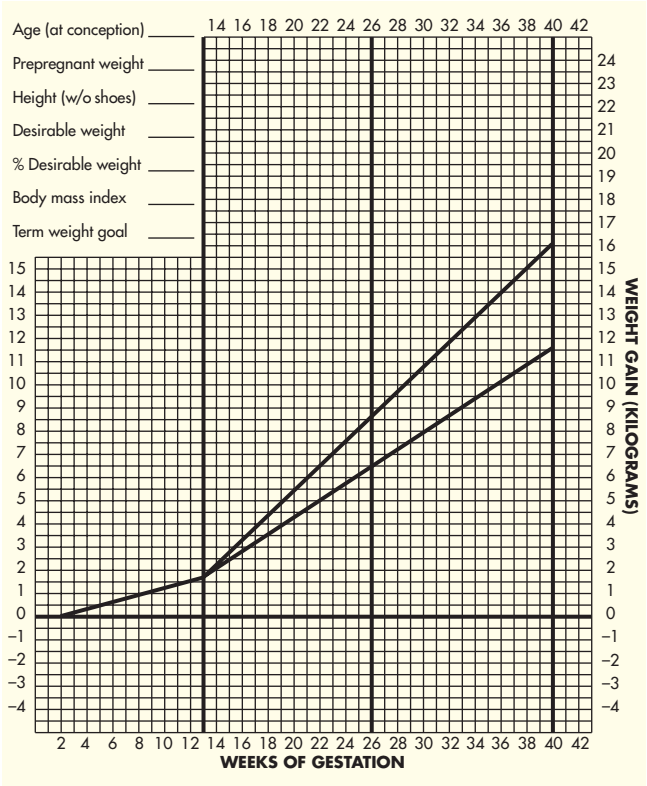

FIG 9-2 Prenatal weight-gain chart for plotting weight gain for normal-weight women.

BOX 9-2 WEIGHT GAIN DURING PREGNANCY

- Progressive weight gain during pregnancy is essential to ensure normal fetal growth and development and the deposition of maternal stores that promote successful lactation.
- Recommended weight gain during pregnancy is determined largely by prepregnancy weight for height. The recommended total weight gain is as follows: underweight women, 12.5 to 18 kg (28 to 40 lbs); normal-weight women, 11.5 to 16 kg (25 to 35 lbs); overweight women, 7 to 11.5 kg (15 to 25 lbs); and obese women 5 to 9 kg (11 to 20 lbs). For twin gestations, the recommended total weight gain is 21 to 28 kg (46 to 62 lbs) for women who are underweight before conception, 17 to 25 kg (37 to 54 lbs) for normal-weight women, 14 to 23 kg (31 to 50 lbs) for overweight women, and 11 to 19 kg (25 to 42 lbs) for obese women.
- There is not enough information available to make firm recommendations about optimal weight gain for women with more than 2 fetuses, but provisional recommendations have been made for all prepregnancy body mass index (BMI) categories except the underweight category (Institute of Medicine [IOM], 2009). The provisional recommendations for a gestation with more than 2 fetuses suggest that normal-weight women gain 17 to 25 kg, overweight women gain 14 to 23 kg, and obese women gain 11 to 19 kg.
- Weight gain should be achieved through a balanced diet of regular foods chosen from all the different food groups (see Table 9-3).
- The pattern of weight gain is important: approximately 0.5 kg per week during the second and third trimesters for underweight women, 0.4 kg per week for normal-weight women, 0.3 kg per week for overweight women, and 0.2 kg per week for obese women.

week for an underweight woman and 0.4 kg per week for a woman of normal weight. The recommended weekly weight gain for overweight women during the second and third trimesters is 0.3 kg, and for obese women, 0.2 kg.

The recommended energy (kcal) intake corresponds to the recommended pattern of gain (see Table 9-1). There is no increment for the first trimester; an additional 340 kcal per day and 462 kcal per day over the prepregnant intake is recommended during the second and third trimester, respectively. These recommendations are most appropriate for singleton pregnancy and may need to be adjusted in multiple gestation. The amount of food providing the needed increase in energy is not large. The 340 additional kcal needed during the second trimester can be provided by one additional serving from any one of the following groups: milk, yogurt, or cheese (all skim milk products); fruits; vegetables; and bread, cereal, rice, or pasta. In the third trimester, an additional one third of a serving will provide the needed kcal.

The reasons for an inadequate weight gain (less than 1 kg per month for normal-weight women or less than 0.5 kg per month for obese women during the last two trimesters) or excessive weight gain (more than 3 kg per month) should be evaluated thoroughly. Possible reasons for deviations from the expected rate of weight gain, besides inadequate or excessive dietary intake, include measurement or recording errors or differences in weight of clothing or time of day. An exceptionally high gain is likely to be caused by an accumulation of fluids, and a gain of more than 3 kg in a month, especially after the twentieth week of gestation, often indicates the development of preeclampsia.

Hazards of Restricting Adequate Weight Gain

An obsession with thinness and dieting pervades the North American culture. Figure-conscious women may find it difficult to make the transition from guarding against weight gain before pregnancy to valuing weight gain during pregnancy. In counseling these women, the nurse can emphasize the positive effects of good nutrition as well as the adverse effects of maternal malnutrition (manifested by poor weight gain) on infant growth and development. This counseling includes information on the components of weight gain during pregnancy (Table 9-2) and the amount of this weight that will be lost at birth. Because lactation can help reduce maternal energy stores gradually, this also provides an opportunity to promote breastfeeding.

TABLE 9-2 TISSUES CONTRIBUTING TO MATERNAL WEIGHT GAIN AT 40 WEEKS OF GESTATION

TISSUE	KILOGRAMS	POUNDS
Fetus	3.2-3.9	7-8.5
Placenta	0.9-1.1	2-2.5
Amniotic fluid	0.9	2
Increase in uterine tissue	0.9	2
Breast tissue	0.5-1.8	1-4
Increased blood volume	1.8-2.3	4-5
Increased tissue fluid	1.4-2.3	3-5
Increased stores (fat)	1.8-2.7	4-6

In the United States, 20% of women who give birth are obese (www.cdc.gov/reproductivehealth/MaternalInfantHealth/PregComplications.htm). Pregnancy is not a time for a weight-reduction diet. Even overweight or obese pregnant women need to gain at least enough weight to equal the weight of the products of conception (fetus, placenta, and amniotic fluid). If they limit their energy intake to prevent weight gain, they may also excessively limit their intake of important nutrients. Moreover, dietary restriction results in catabolism of fat stores, which in turn augments the production of ketones. The long-term effects of mild ketonemia during pregnancy are not known, but ketonuria is associated with the occurrence of preterm labor. It should be stressed to obese women (and to all pregnant women) that the quality of the weight gain is important, with emphasis placed on the consumption of nutrient-dense foods and the avoidance of empty-calorie foods (see Critical Thinking Case Study).

Excessive Weight Gain

Weight gain is important, but pregnancy is not an excuse for uncontrolled dietary indulgence. The woman should place an emphasis on the quality of her food intake as she considers her needs and those of her fetus. Excessive weight gained during pregnancy may be difficult to lose after pregnancy, thus contributing to chronic overweight or obesity—an etiologic factor in a host of chronic diseases, including hypertension, diabetes mellitus, and arteriosclerotic heart disease. The woman who gains 18 kg or more is especially at risk (Box 9-3). Food energy intake and particularly intake of fat is likely to be high among pregnant women, especially low-income women (see Evidence-Based Practice box).

Protein

Protein, with its essential constituent *nitrogen*, is the nutritional element basic to growth. Adequate protein intake is essential to meet increasing demands in pregnancy.

CRITICAL THINKING CASE STUDY

Nutrition and the Overweight Pregnant Woman

Tamara, age 27, of African-American and Asian heritage, is 3 months pregnant and comes to her initial appointment for diagnosis and care. She appears to be overweight for her height (5′ 6″ tall, 172 lbs [78 kg]). To provide optimal care for her, you plan to calculate her prepregnancy body mass index (BMI). When her pregnancy is confirmed, you are asked to plan a diet with Tamara that meets the minimum daily requirements and allows for growth of the pregnancy. You know that it is important to include consideration of personal preferences and cultural factors in your plan. With Tamara, identify barriers to implementing the plan.

1. Evidence—Is there sufficient evidence to draw conclusions about an appropriate nutrition plan, considering personal preferences and cultural factors?
2. Assumptions—Describe underlying assumptions about each of the following issues:
   a. Dietary Reference Intakes for pregnancy and lactation
   b. Indicators of nutritional risk in pregnancy; possibility of lactose intolerance
   c. Daily food guide for pregnancy and lactation
   d. Sources of calcium for women who do not drink milk
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your conclusion?

BOX 9-3 BARIATRIC OBSTETRIC CARE

Obstetricians today are seeing more morbidly obese pregnant women—those who weigh 400, 500, and even 600 pounds. Obesity creates many risks for pregnant women, including hypertension, diabetes, and prematurity. To manage their conditions and to meet their logistical needs, a new medical subspecialty—bariatric obstetrics—has arisen. Extra-wide blood pressure cuffs, scales that can accommodate up to 880 pounds, and extra-wide surgical tables designed to hold the weight of these women are used. Special techniques for ultrasound examination and longer surgical instruments for cesarean birth are required. In the bariatric obstetric clinic at St. Louis University in St. Louis, Missouri, women are counseled to avoid gaining weight and even to lose weight during pregnancy. New evidence indicates that when obese women maintain or lose weight during pregnancy, they have fewer complications and give birth to healthier babies.

From Paul AM: Too fat and pregnant, *New York Times*, July 13, 2008.

EVIDENCE-BASED PRACTICE

Weight Management in Pregnancy

Ask the Question

For obese and overweight pregnant women, are weight-management interventions safe and beneficial to mother and baby?

Search for the Evidence

Search Strategies

- English language research-based publications on pregnancy, obesity, weight gain, diet, exercise were included.
- Exclusions included trials in developing countries with food shortages.

Databases Used

- Cochrane Collaborative Database, National Guideline Clearinghouse (Agency for Healthcare Research and Quality [AHRQ]), CINAHL, PubMed, UpToDate, and the professional website for the Association of Women's Health, Obstetric and Neonatal Nurses (AWHONN).

Critically Analyze the Evidence

- Obesity in pregnancy is associated with offspring with attention deficit hyperactivity disorder (ADHD) in childhood, eating disorders in adolescence, and psychotic disorders in adulthood (Van Lieshout, Taylor, and Boyle, 2011).
- Weight-management interventions for obese pregnant women result in significantly decreased weight gain and in significantly less preeclampsia and shoulder dystocia (Thangaratinam, Rogozinska, Jolly, et al., 2012).
- The most effective interventions were dietary resulting in decreased risk for preeclampsia, gestational hypertension, and preterm birth, with no harm to the fetus (Thangaratinam, Rogozinska, Jolly, et al., 2012).
- In a systematic review, researchers found that goal setting was a useful technique for achieving optimal weight gain. Obese women may require further counseling (Brown, Sinclair, Liddle, et al., 2012).
- Regular activity improved maternal glycemic control and fetal outcomes. Caregivers should recommend physical activity to most pregnant women as safe and beneficial (Ferraro, Gaudet, and Adamo, 2012).

Apply the Evidence: Nursing Implications

- Preconceptional counseling should include prevention of obesity, ideally from childhood. Obese women are at risk for cardiac and pulmonary diseases, gestational hypertension and diabetes, and obstructive sleep apnea. Obesity in pregnancy may result in higher risk for congenital anomalies, operative birth, and surgical complications (Davies, Maxwell, McLeod, et al., SOGC, 2010).
- Nurses are frequently the main educators for their pregnant patients. Counseling obese pregnant women about nutrition and food choices and using collaborative goal setting for weight gain can prevent pregnancy risks and avoid weight gain that may persist beyond pregnancy.
- Activity needs to be frequent, fun, and affordable. An excellent idea is encouraging the woman to walk with other pregnant women, which provides social support and increased safety. In addition, the nurse can advocate for low-cost indoor facilities in the community.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

- Explain the role of evidence in determining best clinical practice.
- Both nutrition counseling and motivation work best for weight management in pregnancy.

Skills

- Locate evidence reports related to clinical practice topics and guidelines.
- Dietary and activity interventions are safe and beneficial in pregnancy for obese women.

Attitudes

- Appreciate the importance of regularly reading relevant professional journals.
- Systematic reviews and professional guidelines highlight interventions that have evidence of success, such as motivational goal setting for weight management.

*Adapted from Quality and Safety Education for Nurses (QSEN) at www.qsen.org/.

These demands arise from:

- The rapid growth of the fetus
- The enlargement of the uterus and its supporting structures, the mammary glands, and the placenta
- The increase in the maternal circulating blood volume and the subsequent demand for increased amounts of plasma protein to maintain colloidal osmotic pressure
- The formation of amniotic fluid

Milk, meat, eggs, and cheese are **complete protein foods** with a high biologic value. Legumes (dried beans and peas), whole grains, and nuts are also valuable sources of protein. In addition, these protein-rich foods are a source of other nutrients such as calcium, iron, and B vitamins. Plant sources of protein often provide needed dietary fiber. The recommended daily food plan (Table 9-3) is a guide to the amounts of these foods that would supply the quantities of protein needed. The recommendations provide for only a modest increase in protein intake (25 g daily) over the prepregnant levels in adult women.

Protein intake in many people in the United States is relatively high; thus many women may not need to increase their protein intake at all during pregnancy. Three servings of milk, yogurt, or cheese (four for adolescents) and two servings (5 to 6 oz [140 to 168 g]) of meat, poultry, or fish would supply most of the recommended protein for a pregnant woman. Additional protein is provided by vegetables and breads, cereals, rice, or pasta. Pregnant adolescents, women from impoverished backgrounds, and women

TABLE 9-3 DAILY FOOD GUIDE FOR PREGNANCY AND LACTATION

FOOD GROUP	DAILY AMOUNT OF FOOD RECOMMENDED FOR WOMEN*	SERVING SIZE
Grains	6- to 8-ounce equivalents At least half of grain servings should be whole grains. *Whole grains* are those that contain the entire grain kernel (bran, germ, endosperm) (e.g., whole wheat or cornmeal, oatmeal, and brown rice). Refined grains have been milled to remove the bran and germ (e.g., white flour, white bread, degermed cornmeal, white rice, and corn or flour tortillas).	1-ounce equivalent = 1 slice bread, 1 cup ready-to-eat cereal, or ½ cup cooked rice or pasta or cooked cereal
Vegetables Vary the vegetables consumed to take advantage of the different nutrients they offer	2½ to 3 cups Weekly intake should include at least the following: 3 cups dark green vegetables (e.g., spinach or greens, broccoli, bok choy, romaine lettuce); 2 cups orange vegetables (e.g., carrots; acorn, butternut, or Hubbard squash; sweet potatoes); 3 cups dry beans or peas (e.g., black, navy, or kidney beans; chickpeas; black-eyed peas; split peas; lentils; soybeans; tofu); 3 cups starchy vegetables (corn, green peas, potatoes); and 6½ cups of other vegetables (e.g., artichokes, asparagus, bean sprouts, green beans, cauliflower, cucumber, tomatoes, iceberg or head lettuce).	1 cup = 2 cups raw leafy greens; 1 cup of other vegetables, raw or cooked; or 1 cup of vegetable juice
Fruits	2 cups	1 cup = 1 cup raw, frozen, or canned fruit; 1 cup 100% juice; or ½ cup dried fruit
Milk, yogurt, and cheese (milk group)	3 cups Most milk group choices should be fat free or low fat.	1 cup = 1 cup milk or yogurt; 1½ ounces natural cheese; 2 ounces processed cheese (e.g., American); 2 cups cottage cheese; 1½ cups ice cream (choose fat-free or low-fat most often)
Meat, poultry, fish, dry beans, eggs, and nuts (meat and beans† groups)	5½- to 6½-ounce equivalents Most meat and poultry choices should be lean or low fat. Fish, nuts, and seeds contain healthy oils, so choose these foods frequently instead of meat or poultry.	1 ounce-equivalent = 1 ounce (30 g) meat, poultry, or fish; ¼ cup cooked dried beans†; 1 egg; 1 tablespoon (15 mL) peanut butter; ½ ounce nuts or seeds
Oils	6 teaspoons (30 mL) Choose oils rather than solid fats. Solid fats are fats that are solid at room temperature, such as butter, shortening, stick margarine, and pork, chicken, or beef fat. Read the label: choose products with no *trans* fats, limit intake of saturated fats, and choose oils high in monounsaturated and polyunsaturated fats.	1 teaspoon = 1 teaspoon liquid oil (e.g., olive, canola, sunflower, safflower, peanut, soybean, cottonseed) or soft margarine (tub or squeeze bottle); 1 tablespoon mayonnaise or Italian salad dressing; ¾ tablespoon Thousand Island salad dressing; 8 large olives; ⅙ medium avocado; ⅓ ounce dry roasted peanuts, mixed nuts, cashews, sunflower seeds†

*These are approximate amounts based on a relatively sedentary lifestyle and should be individualized. Intake may have to be increased for women with a more active lifestyle or multiple gestation, those who are underweight before pregnancy, or those exhibiting poor gestational weight gain. Needs during lactation may also be greater than these recommendations.
†Beans are also part of the vegetable group; avocados are also part of the fruit group, and nuts and seeds are part of the meat and beans group.

adhering to unusual diets such as a macrobiotic (highly restricted vegetarian) diet are those whose protein intake is most likely to be inadequate. High-protein supplements are not recommended because they have been associated with an increased incidence of preterm births.

Pregnant and nursing women should be especially careful when choosing fish to select those that are low in mercury.

SAFETY ALERT

High levels of mercury can harm the developing nervous system of the fetus or young child, and certain fish are especially high in mercury. Women who may become pregnant, women who are pregnant or nursing, and young children need to follow some precautions: (1) avoid eating shark, swordfish, king mackerel, and tilefish; (2) check local advisories about the safety of fish caught by family and friends in local bodies of water, but if no advisory is available, limit intake of these fish to 6 ounces and eat no other fish that week; and (3) eat as much as 12 ounces a week of a variety of commercially caught fish and shellfish low in mercury, such as shrimp, salmon, pollock, catfish, and canned light tuna (but limit intake of albacore or "white" tuna and tuna steaks, which contain more mercury, to 6 ounces per week). Additional information about mercury levels in a variety of commercial fish is available at www.cfsan.fda.gov/~frf/sea-mehg.html.

Fluids

Water is the main substance of cells, blood, lymph, amniotic fluid, and other vital body fluids. It is essential during the exchange of nutrients and waste products across cell membranes. It also aids in maintaining body temperature. A good fluid intake promotes regular bowel function, which is sometimes a problem during pregnancy. The recommended daily intake is about 8 to 10 glasses (2.3 L) of fluid. Water, milk, and decaffeinated tea are good sources. Foods in the diet should supply an additional 700 mL or more of fluid. Dehydration may increase the risk for cramping, contractions, and preterm labor.

The safety of caffeine use in pregnancy is an important consideration. Some investigators (e.g., Weng, Odouli, and Li, 2008) but not others (e.g., Pollack, Louis, Sundaram, et al., 2010) found that women who consume more than 200 mg of caffeine daily (equivalent to about 12 oz of coffee) may be at increased risk for miscarriage. Data also suggest that excess caffeine intake may contribute to IUGR. In their review, Jahanfar and Sharifah (2009) found that there is insufficient evidence to determine whether caffeine has any effect on pregnancy outcome. Although the evidence about caffeine is far from conclusive, the March of Dimes recommends a daily intake of no more than 200 mg of caffeine (March of Dimes, 2010). Caffeine is found not only in coffee but also in tea, some soft drinks, and chocolate (Table 9-4).

Aspartame (NutraSweet, Equal), acesulfame potassium (Sunett), and sucralose (Splenda)—artificial sweeteners commonly used in low- or no-calorie beverages and low-calorie food products—have not been found to have adverse effects on the normal mother or fetus and therefore are approved by the U.S. Food and Drug Administration (FDA) for use during pregnancy. Aspartame, which contains phenylalanine, should be avoided by pregnant women with PKU (Box 9-4). Stevia (stevioside) is a sweetener sold as a dietary supplement; no acceptable daily intake has been established for stevia.

Minerals and Vitamins

In general, the nutrient needs of pregnant women, with perhaps the exception of folate and iron, can be met through dietary sources. Counseling about the need for a varied diet rich in vitamins and minerals should be a part of early prenatal care of every pregnant woman and should be reinforced throughout pregnancy (see Community Focus box). It has been suggested that taking a micronutrient supplement (including vitamins and trace minerals) before and during pregnancy reduces the risk for congenital defects, LBW, and preterm birth, as well as preeclampsia. There is no conclusive evidence to support this suggestion, but further research is needed on maternal and fetal benefits of micronutrient supplementation. Supplements are especially advisable for women with known nutritional risk factors (Box 9-5). It is important that the pregnant woman understand that the use of a vitamin-mineral supplement does not lessen the need to consume a nutritious, well-balanced diet.

TABLE 9-4 CAFFEINE CONTENT OF COMMON BEVERAGES AND FOODS

BEVERAGE OR FOOD	CAFFEINE (MG)
Coffee (8 oz [240 mL])	95
Espresso (1 oz [30 mL])	64
Tea, black, brewed (8 oz [240 mL])	47
Tea, ready-to-drink, with lemon (12 oz [360 mL])	7
Tea, green, brewed (8 oz [240 mL])	50
Tea, white, brewed (8 oz [240 mL])	35
Energy drink, Rockstar (8 oz [240 mL])	79
Energy drink, Red Bull (8.4 oz [250 mL])	77
Energy drink, Vault (8 oz [250 mL])	68
Energy drink, AMP (8 oz [240 mL])	74
Cola beverage, regular (12 oz [360 mL])	29
Hot chocolate, homemade or from mix (8 oz [240 mL])	5
Dark chocolate bar (1 oz [30 g])	23
Candy bar, milk chocolate with almonds (1.5 oz [45 g])	7

COMMUNITY FOCUS

Nutrition Education in the Prenatal Clinic

Visit a prenatal clinic. Identify sources of nutrition education that are evident in the waiting room. Does the clinic employ a nutritionist/dietitian? Who provides nutrition counseling in the clinic? Are print materials available in multiple languages? Are interpreters available? Are there sources for free materials on nutrition that could be placed in the clinic? Identify strengths and weaknesses of nutrition education in that setting. Develop a feasible plan for improving nutrition education in the clinic.

BOX 9-4 USE OF ARTIFICIAL SWEETENERS DURING PREGNANCY

All of the following sweeteners are approved for use in all age-groups, including pregnant women, in the United States:

Acesulfame K
- Brand names: Sunett, Sweet One
- Primary uses: baked goods, frozen desserts, candies, beverages
- Sweetness: 200 times sweeter than sugar
- Shelf life: long
- Suitability for cooking: good; does not break down when heated
- Health concerns: none known

Aspartame
- Brand names: Equal, NutraSweet, NatraTaste
- Primary uses: beverages, frozen desserts, dairy products, chewing gum, breakfast cereals, tabletop sweetener
- Sweetness: 180 times sweeter than sugar
- Shelf life: relatively short (approximately 5 months in a soft drink)
- Suitability for cooking: breaks down and loses sweetness if cooked at high temperatures or for long periods
- Health concerns: contains phenylalanine, a consideration in the diets of people with phenylketonuria

Saccharin
- Brand name: Sweet'N Low
- Primary uses: fountain drinks, chewable vitamins and medications, tabletop sweetener
- Sweetness: 300 times sweeter than sugar
- Shelf life: long
- Suitability for cooking: good; does not lose sweetness during cooking
- Health concerns: linked to bladder cancer in rats

Sucralose
- Brand name: Splenda
- Primary uses: baked goods, beverages, frozen desserts, gelatins, tabletop sweetener
- Sweetness: 600 times sweeter than sugar
- Shelf life: long
- Suitability for cooking: very good; does not break down during cooking (maltodextrin is added to give products better bulk and texture)
- Health concerns: none known

Sugar Alcohols (not technically artificial sweeteners; contain almost as many calories as sugar)
- Types: sorbitol, xylitol, lactitol, mannitol, and maltitol
- Primary uses: sugar-free candy, cookies, and chewing gum
- Sweetness: most are approximately 70% as sweet as sugar; xylitol equals sugar in sweetness
- Shelf life: long
- Suitability for cooking: good
- Advantages over sugar: do not promote tooth decay and are more slowly metabolized, thus do not create a rapid peak in blood glucose
- Health concerns: diarrhea can occur with large intakes

Sugar is important for the volume and moisture of baked goods. Artificial sweeteners may produce a good-tasting product, but some sugar is necessary in many recipes to yield normal volume and texture.

BOX 9-5 INDICATORS OF NUTRITIONAL RISK IN PREGNANCY

- Adolescence or less than 2 years postmenarche
- Frequent pregnancies: three within 2 years
- Poor fetal outcome in a previous pregnancy
- Poverty/food insecurity
- Poor diet habits with resistance to change
- Use of tobacco, alcohol, or drugs
- Weight at conception under or over normal weight
- Problems with weight gain
  - Any weight loss
  - Weight gain of less than 1 kg/month after the first trimester
  - Weight gain of more than 3 kg/month after the first trimester
- Multifetal pregnancy
- Low hemoglobin and/or hematocrit values
- Diabetes
- Chronic illness, including an eating disorder, that affects intake, absorption, or metabolism of nutrients

Iron

Iron is needed to allow transfer of adequate iron to the fetus and to permit expansion of the maternal RBC mass. Beginning in the latter part of the first trimester, the blood volume of the mother increases steadily, peaking at about 1500 mL more than that in the nonpregnant state. In twin gestations, the increase is at least 500 mL greater than that in pregnancies with single fetuses. Plasma volume increases more than RBC mass, with the difference between plasma and RBCs being greatest during the second trimester. The relative excess of plasma causes a modest decrease in the hemoglobin concentration and hematocrit, known as **physiologic anemia of pregnancy.** This is a normal adaptation during pregnancy.

Poor iron status, which can result in iron deficiency anemia, is relatively common among women in the childbearing years. Iron deficiency (not necessarily anemia) is estimated to affect approximately 10% of nonpregnant women in the childbearing years in the United States. Anemic women are poorly prepared to tolerate hemorrhage at the time of birth. In addition, women who have iron deficiency anemia during early pregnancy are at increased risk for preterm birth. Iron deficiency during the third trimester apparently does not carry the same risk. In the United States, anemia is most

common among adolescents, African-American women, and women of lower socioeconomic status.

A supplement of 30 mg of ferrous iron daily starting by 12 weeks of gestation helps ensure an adequate iron intake. Iron supplements may be poorly tolerated during the nausea prevalent in the first trimester, and starting the supplement after this point may improve tolerance. If maternal iron deficiency anemia is present (preferably diagnosed by measurement of serum ferritin, a storage form of iron), increased dosages (60 to 120 mg daily) may be required. Certain foods taken with an iron supplement can promote or inhibit absorption of iron from the supplement. See the Patient Teaching box later in the chapter regarding iron supplementation. Even when a woman is taking an iron supplement, she should also include good food sources of iron in her daily diet (see Table 9-1).

Calcium

There is no increase in the DRI of calcium during pregnancy and lactation compared with the recommendation for the nonpregnant woman (see Table 9-1). The DRI (1000 mg daily for women 19 years and older and 1300 mg for those younger than 19 years) appears to provide sufficient calcium for fetal bone and tooth development to proceed while maintaining maternal bone mass. Milk and yogurt are especially rich sources of calcium, providing approximately 300 mg per cup (240 mL). Nevertheless, many women do not consume these foods or do not consume adequate amounts to provide the recommended intakes of calcium. One problem that can interfere with milk consumption is **lactose intolerance,** the inability to digest milk sugar (lactose) caused by the lack of the lactase enzyme in the small intestine. It is relatively common in adults, particularly African-Americans, Asians, Native Americans, and Inuits (Alaska Natives). Milk consumption can cause abdominal cramping, bloating, and diarrhea in such people, although many lactose-intolerant individuals can tolerate small amounts of milk without symptoms. Yogurt, sweet acidophilus milk, buttermilk, cheese, chocolate milk, and cocoa may be tolerated even when fresh fluid milk is not. Commercial lactase supplements (e.g., Lactaid) are widely available to consume with milk, and many supermarkets stock lactase-treated milk. The lactase in these products hydrolyzes, or digests, the lactose in milk, making it possible for lactose-intolerant people to drink milk.

In some cultures it is uncommon for adults to drink milk. For example, Puerto Ricans and other Hispanic people may use milk only as an additive in coffee. Pregnant women from these cultures may need to consume nondairy sources of calcium (Box 9-6). If calcium intake appears low and the woman does not change her dietary habits despite counseling, a supplement containing 600 mg of elemental calcium may be needed daily. Calcium supplements may also be recommended when a pregnant woman experiences leg cramps caused by an imbalance in the calcium-to-phosphorus ratio.

SAFETY ALERT

Bone meal, which is sometimes used as a calcium source by pregnant women, is frequently contaminated with lead. Lead freely crosses the placenta; thus regular maternal intake of bone meal may result in high levels of lead in the fetus (Shannon, 2003).

Other Minerals and Electrolytes

Magnesium. Diets of women in the childbearing years are likely to be low in magnesium, and as many as half of pregnant and lactating women may have inadequate intakes. Adolescents and low-income women are especially at risk. Dairy products, nuts, whole grains, and green leafy vegetables are good sources of magnesium.

Sodium. During pregnancy the need for sodium increases slightly, primarily because the body water is expanding (e.g., the expanding blood volume). Sodium is essential for maintaining body water balance. In the past, dietary sodium was routinely restricted in an effort to control the peripheral edema that commonly occurs during pregnancy. It is now recognized that moderate peripheral edema is normal in pregnancy, occurring as a response to the fluid-retaining effects of elevated levels of estrogen. Sodium is not routinely restricted in pregnancy, and restriction has not proved effective in reducing the rates of preeclampsia. Severe sodium restriction may make it difficult for pregnant women to achieve an adequate diet. Grain, milk, and meat products, which are good sources of nutrients needed during pregnancy, are significant sources of sodium. In addition, sodium restriction may stress the adrenal glands and the kidneys as they attempt to retain adequate sodium. In general, sodium restriction is necessary only if the woman has a medical condition such as renal or liver failure or hypertension that warrants such a restriction.

Excessive intake of sodium is discouraged during pregnancy because it may contribute to development of hypertension in salt-sensitive individuals. An adequate sodium intake for pregnant and lactating women, as well as for nonpregnant women in the childbearing years, is estimated to be 1.5 g/day, with a recommended upper limit of intake of 2.3 g/day. Table salt (sodium chloride) is the richest source of sodium, with approximately 2.3 g of sodium contained in 1 teaspoon (5 g) of salt. Most canned foods contain added salt unless the label states otherwise. Large amounts of sodium are also found in many processed foods, including meats (e.g., smoked or cured meats, cold cuts, and corned beef), frozen entrees and meals, baked goods, mixes for casseroles or grain products, soups, and condiments. Products low in nutritive value and excessively high

BOX 9-6 CALCIUM SOURCES FOR WOMEN WHO DO NOT DRINK MILK

Each of the following provides approximately the same amount of calcium as 1 cup of milk:

Fish
- 3-oz can of sardines
- 4½-oz can of salmon (if bones are eaten)

Beans and Legumes
- 3 cups of cooked dried beans
- 2½ cups of refried beans
- 2 cups of baked beans with molasses
- 1 cup of tofu (calcium added in processing)

Greens
- 1 cup of collards
- 1½ cups of kale or turnip greens

Baked Products
- 3 pieces of cornbread
- 3 English muffins
- 4 slices of French toast
- 2 (7-inch diameter) waffles

Fruits
- 11 dried figs
- 1⅛ cups of orange juice with calcium added

Sauces
- 3 oz of creamy pesto sauce
- 5 oz of cheese sauce

in sodium include pretzels, potato and other chips (except salt free), pickles, catsup, prepared mustard, steak and Worcestershire sauces, some soft drinks, and bouillon. A moderate sodium intake can usually be achieved by salting food lightly during cooking; adding no additional salt at the table; and avoiding low-nutrient, high-sodium foods.

Potassium. Diets including adequate intakes of potassium are associated with reduced risk for hypertension. Potassium has been identified as one of the nutrients most likely to be lacking in the diets of women of childbearing years. A diet including 8 to 10 servings of unprocessed fruits and vegetables daily, along with moderate amounts of low-fat meats and dairy products, has been effective in reducing sodium intake while providing adequate amounts of potassium.

Zinc. Zinc is a constituent of numerous enzymes involved in major metabolic pathways. Zinc deficiency is associated with malformations of the central nervous system in infants. When large amounts of iron and folic acid are consumed, the absorption of zinc is inhibited and the serum zinc levels are reduced as a result. Because iron and folic acid supplements are commonly prescribed during pregnancy, pregnant women should be encouraged to consume good sources of zinc daily (see Table 9-1). Women with anemia who receive high-dose iron supplements also need supplements of zinc and copper.

Fluoride. There is no evidence that prenatal fluoride supplementation reduces the child's likelihood of tooth decay during the preschool years. No increase in fluoride intake over the nonpregnant DRI is recommended during pregnancy.

Fat-Soluble Vitamins

The fat-soluble vitamins include vitamins A, D, E, and K. These are of special concern during pregnancy because vitamin E intake is among the nutrients most likely to be lacking in the diets of women of childbearing age; intake of vitamins A and D is also low in the diets of some women. Fat-soluble vitamins are stored in the body tissues; in the event of prolonged overdoses, these vitamins can reach toxic levels. Because of the high potential for toxicity, pregnant women are advised to take fat-soluble vitamin supplements only as prescribed. However, toxicity from dietary sources is very unlikely.

Vitamin E is needed for protection against oxidative stress, and pregnancy is associated with increased oxidative stress. Oxidative stress above that usually associated with pregnancy has been proposed as an explanation for the etiology of preeclampsia, although supplementation with vitamin E has not been effective in reducing rates of preeclampsia. Vegetable oils and nuts are especially good sources of vitamin E, and whole grains and green leafy vegetables are moderate sources.

Adequate intake of vitamin A is needed so that sufficient amounts of the vitamin can be stored in the fetus. A well-chosen diet, including adequate amounts of deep yellow and deep green vegetables and fruits such as leafy greens, broccoli, carrots, cantaloupe, and apricots, provides sufficient amounts of carotenes that can be converted in the body to vitamin A. Congenital malformations have occurred in infants of mothers who took excessive amounts of preformed vitamin A (from supplements) during pregnancy; thus supplements are not recommended routinely for pregnant women. Vitamin A analogs (e.g., isotretinoin [Accutane]), which are prescribed for the treatment of cystic acne, are a special concern. Isotretinoin use during early pregnancy has been associated with an increased incidence of heart malformations, facial abnormalities, cleft palate, hydrocephalus, and deafness and blindness in the infant, as well as an increased risk for miscarriage. Topical agents such as tretinoin (Retin-A) do not appear to enter the circulation in substantial amounts, but their safety in pregnancy has not been confirmed.

Vitamin D plays an important role in absorption and metabolism of calcium. The main food sources of this vitamin are enriched or fortified foods such as milk and ready-to-eat cereals. Vitamin D is also produced in the skin by the action of ultraviolet light (in sunlight). A severe deficiency may lead to neonatal hypocalcemia and tetany, as well as to hypoplasia of the tooth enamel. Women with lactose intolerance and those who do not include milk in their diet for any reason are at risk for vitamin D deficiency. Other risk factors for deficiency are dark skin, with African-American women being at high risk for deficiency; habitual use of clothing that covers most of the skin (e.g., Moslem women with extensive body covering); and living in northern latitudes where sunlight exposure is limited, especially during the winter. Use of recommended amounts of sunscreen with a sun protection factor (SPF) rating of 15 or greater reduces skin vitamin D production by as much as 99%, thus bringing about a need for regular intake of fortified foods or a supplement.

Water-Soluble Vitamins

Body stores of water-soluble vitamins are much smaller than those of fat-soluble vitamins, and the water-soluble vitamins, in contrast to fat-soluble vitamins, are readily excreted in the urine. Therefore good sources of these vitamins must be consumed frequently. Toxicity with overdose is less likely than it is in people taking fat-soluble vitamins.

Folate/Folic Acid. Because of the increase in RBC production during pregnancy, as well as the nutritional requirements of the rapidly growing cells in the fetus and placenta, pregnant women should consume about 50% more folic acid than nonpregnant women, or about 0.6 mg (600 mcg) daily. In the United States, all enriched grain products (which include most white breads, flour, and pasta) must contain folic acid at a level of 1.4 mg/kg of flour. This level of fortification is designed to supply approximately 0.1 mg of folic acid daily in the average American diet and has significantly increased folic acid consumption in the population as a whole. All women of childbearing potential need careful counseling about including good sources of folate in their diets (see Box 9-1). Supplemental folic acid is usually prescribed to ensure that intake is adequate. Women who have borne a child with a neural tube defect are advised to consume 4 mg (4000 mcg) of folic acid daily, and a supplement is required for them to achieve this level of intake.

Pyridoxine. Pyridoxine, or vitamin B_6, is involved in protein metabolism. Although levels of a pyridoxine-containing enzyme have been reported to be low in women with preeclampsia, there is no evidence that supplementation prevents or eradicates the condition. Pyridoxine has been effective in reducing the nausea and vomiting of early pregnancy in some trials.

Vitamin C. Vitamin C, or ascorbic acid, plays an important role in tissue formation and enhances the absorption of iron. The vitamin C needs of most women are readily met by a diet that includes at least one or two daily servings of citrus fruit or juice or another good source of the vitamin (see Table 9-1), but women who smoke need more.

Vitamin B_{12}. Vitamin B_{12} is involved in production of nucleic acids and protein; it is especially important in formation of RBCs and neural functioning. It is found in milk and milk products, eggs, meats, liver, and fortified soy milk.

FIG 9-3 Nonfood substances consumed in pica: red clay from Georgia, nzu from East Nigeria, baking powder, cornstarch, baking soda, laundry starch, and ice. Some individuals practice *poly-pica,* consuming more than one of these or other nonfood substances. (Courtesy Shannon Perry, Phoenix, AZ.)

Other Nutritional Issues During Pregnancy

Pica and Food Cravings

Pica, which is the practice of consuming nonfood substances (e.g., clay, dirt, and laundry starch) or excessive amounts of foodstuffs low in nutritional value (e.g., cornstarch, ice or freezer frost, baking powder, or baking soda), is often influenced by the woman's cultural background (Fig. 9-3). In the United States, it appears to be most common among African-American and Hispanic women, women from rural areas, and women with a family history of pica. One problem with pica is that regular and heavy consumption of low-nutrient products may cause more nutritious foods to be displaced from the diet. As an example, cornstarch ingestion is popular among African-American women. It is a source of "empty" calories; half a cup (64 g) provides 240 kcal but almost no vitamins, minerals, or protein. Overuse of cornstarch can contribute to development of gestational diabetes. In addition, the pica items consumed may interfere with the absorption of nutrients, especially minerals. Women with pica have been found to have lower hemoglobin levels than do those without pica.

Moreover, there is a risk that nonfood items are contaminated with heavy metals or other toxic substances. Among Mexican-American women, consumption of "tierra" includes both soil and pulverized Mexican pottery. Lead contamination of soils and soil-based products has caused high levels of lead in pregnant women and their newborns. Regular household use of Mexican pottery in cooking or serving food or ingestion of ground pottery must be included in interviews or questionnaires regarding nutrition intake of pregnant women. The possibility of pica must be considered when pregnant women are found to be anemic, and the nurse should provide counseling about the health risks associated with pica.

The existence of picas, as well as details of the types and amounts of products ingested, is likely to be discovered only by the sensitive interviewer who has developed a relationship of trust with the woman. It has been proposed that pica and food cravings (e.g., the urge to have ice cream, pickles, or pizza) during pregnancy are caused by an innate drive to consume nutrients missing from the diet. However, research has not supported this hypothesis.

Adolescent Pregnancy Needs

Many adolescent females have diets that provide less than the recommended intakes of key nutrients, including calcium and iron. Pregnant adolescents and their infants are at increased risk for complications during pregnancy and parturition. Growth of the pelvis is delayed in comparison with growth in stature, and this helps explain why cephalopelvic disproportion and other mechanical problems associated with labor are common among young adolescents. Competition for nutrients between the growing adolescent and the fetus may also contribute to some of the poor outcomes apparent in teen pregnancies. Recommended weight-gain goals are not different from those of adult women. Pregnant adolescents are encouraged to choose a weight-gain goal at the upper end of the range for their BMI. BMI is calculated as for adult women (Institute of Medicine [IOM], 2009) rather than by using the adolescent BMI growth charts available from the Centers for Disease Control and Prevention (CDC) (www.cdc.gov). Adolescent females who have given birth have greater percentages of total fat and visceral fat (associated with the metabolic syndrome and cardiovascular disease) than those who have never given birth (Gunderson, Striegel-Moore, Schreiber, et al., 2009); thus the adolescent mother needs careful teaching regarding nutritional intake and physical activity to control body weight in the postpartum period.

Efforts to improve the nutritional health of pregnant adolescents focus on:

- Improving the nutrition knowledge, meal planning, and selection and food preparation skills of young women
- Promoting access to prenatal care
- Developing nutrition interventions and educational programs that are effective with adolescents
- Striving to understand the factors that create barriers to change in the adolescent population

Preeclampsia

There has been speculation that the poor intake of various nutrients might contribute to development of preeclampsia, but no definitive evidence exists. At present, a diet adequate in the recommended nutrients (see Table 9-1), along with use of a supplement that provides micronutrients both before and during pregnancy, appears to be the best means of reducing the risk for preeclampsia.

Physical Activity During Pregnancy

Moderate exercise during pregnancy yields numerous benefits, including improving muscle tone, potentially shortening the course of labor, and promoting a sense of well-being. If no medical or obstetric problems contraindicate physical activity, pregnant women should engage in a minimum of 30 minutes of moderate physical exercise on most, if not all, days of the week. Two nutritional concepts are especially important for women who choose to exercise during pregnancy. First, a liberal amount of fluid should be consumed before, during, and after exercise because dehydration can trigger premature labor. Second, the calorie intake should be sufficient to meet the increased needs of pregnancy and the demands of exercise.

NUTRIENT NEEDS DURING LACTATION

Nutritional needs during lactation are similar in many ways to those during pregnancy. Needs for energy (calories), protein, calcium,

iodine, zinc, the B vitamins (thiamine, riboflavin, niacin, pyridoxine, and vitamin B_{12}), and vitamin C remain greater than nonpregnant needs. The recommendations for some of these (e.g., vitamin C, zinc, and protein) are slightly to moderately higher than during pregnancy (see Table 9-1). This allowance covers the amount of the nutrients released in the milk, as well as the needs of the mother for tissue maintenance. In the case of iron and folic acid, the recommendation during lactation is lower than that during pregnancy. Both of these nutrients are essential for RBC formation and thus for maintaining the increase in the blood volume that occurs during pregnancy. With the decrease in maternal blood volume to nonpregnant levels after birth, maternal iron and folic acid needs also decrease. Many lactating women have a delay in the return of menses, which also conserves blood cells and reduces iron and folic acid needs. It is especially important that the calcium intake be adequate; if it is not, a supplement of 600 mg of calcium per day may be needed.

The recommended energy intake for the first 6 months is an increase of 330 kcal more than the woman's nonpregnant intake. It becomes difficult to obtain adequate nutrients for maintenance of lactation if total caloric intake is less than 1800 kcal. Because of the deposition of energy stores, the woman who has gained the optimal amount of weight during pregnancy is heavier after birth than at the beginning of pregnancy. As a result of the caloric demands of lactation, the lactating mother usually experiences a gradual but steady weight loss. Most women rapidly lose several kilograms during the first month after birth, whether or not they breastfeed. After the first month, the average loss during lactation is 0.5 to 1 kg a month, and a woman who is overweight may be able to lose up to 2 kg without decreasing her milk supply.

Fluid intake must be adequate to maintain milk production, but the mother's level of thirst is the best guide to the right amount. There is no need to consume more fluids than those needed to satisfy thirst.

Smoking, alcohol intake, and excessive caffeine intake should be avoided during lactation. Smoking not only may impair milk production but also exposes the infant to the risk of passive smoking. It is speculated that the infant's psychomotor development may be affected by maternal alcohol use, and alcohol use may impair the milk-ejection reflex. Caffeine intake can lead to a reduced iron concentration in milk and consequently contribute to the development of anemia in the infant. The caffeine concentration in milk is only approximately 1% of the mother's plasma level, but caffeine levels build up in the infant. Breastfed infants of mothers who drink large amounts of coffee or caffeine-containing soft drinks may be unusually active and wakeful.

CARE MANAGEMENT

During pregnancy, nutrition plays a key role in achieving an optimal outcome for the mother and her unborn baby. The motivation to learn about nutrition is usually greater during pregnancy because parents strive to "do what's right for the baby." Optimal nutrition cannot eliminate all problems that may arise during pregnancy, but it does establish a good foundation for supporting the needs of the mother and her unborn baby.

Assessment

Ideally a nutritional assessment is performed before conception so that any recommended changes in diet, lifestyle, and weight can be undertaken before the woman becomes pregnant.

Information on nutrition and diet is obtained from an interview and review of the woman's health records, physical examination, and laboratory results.

Obstetric and Gynecologic Effects on Nutrition

Nutrition reserves may be depleted in the multiparous woman or one who has had frequent pregnancies (especially three pregnancies within 2 years). A history of preterm birth or the birth of an LBW or small-for-gestational-age (SGA) infant may indicate inadequate dietary intake. Birth of a large-for-gestational-age (LGA) infant often indicates the existence of maternal diabetes mellitus. Contraceptive methods also may affect reproductive health. Increased menstrual blood loss often occurs during the first 3 to 6 months after placement of an intrauterine contraceptive device; consequently the user may have low iron stores or even iron deficiency anemia. Oral contraceptive agents are associated with decreased menstrual losses and increased iron stores; however, oral contraceptives may interfere with folic acid metabolism.

Health History

Chronic maternal illnesses such as diabetes mellitus, renal disease, liver disease, cystic fibrosis or other malabsorptive disorders, seizure disorders and the use of anticonvulsant agents, hypertension, and PKU may affect a woman's nutritional status and dietary needs. In women with illnesses that have resulted in nutrition deficits or that require dietary treatment (e.g., diabetes mellitus, PKU), it is extremely important for nutritional care to be started and for the condition to be optimally controlled before conception. A registered dietitian can provide in-depth counseling for the woman who requires medical nutrition therapy during pregnancy and lactation.

Usual Maternal Diet

The woman's usual food and beverage intake, the adequacy of her income and other resources to meet her nutrition needs, any dietary modifications, food allergies and intolerances, and all medications and nutrition supplements being taken, as well as pica and cultural dietary requirements, should be ascertained. In addition, the presence and severity of nutrition-related discomforts of pregnancy such as morning sickness, constipation, and pyrosis (heartburn) should be determined. The nurse should be alert to any evidence of eating disorders such as anorexia nervosa, bulimia, or frequent and rigorous dieting before or during pregnancy.

The effect of food allergies and intolerances on nutritional status ranges from very important to almost nil. Lactose intolerance is of special concern in pregnant and lactating women because no other food group equals milk and milk products in terms of calcium content. If a woman has lactose intolerance, the interviewer should explore her intake of other calcium sources (see Box 9-6).

The assessment must include an evaluation of the woman's financial status and her knowledge of sound dietary practices. The quality of the diet improves with increasing socioeconomic status and educational level. Poor women may not have access to adequate refrigeration and cooking facilities and may find it difficult to obtain adequate nutritious food. Food-borne illnesses may cause adverse effects in pregnancy, and the woman's understanding of safe food-handling practices such as the following should be assessed:

- Cleansing hands, food preparation surfaces, and utensils frequently
- Avoiding contact between raw meat, fish, or poultry and other foods that will not be cooked before consumption
- Storing foods properly
- Cooking foods to a safe temperature

SAFETY ALERT

Pregnant women who contract listeriosis, a disease resulting from infection with the bacteria *Listeria,* are at increased risk for miscarriage, premature birth, and stillbirth. During pregnancy, women should not consume unpasteurized milk or products made with unpasteurized milk, including soft cheeses such as Brie, Camembert, and the soft Mexican cheeses queso blanco, queso fresco, panela, and asadero. Hot dogs, luncheon meats, bologna, and deli meats should be eaten only if they have been reheated to be steaming hot. Deli-made and other store-bought salads such as egg, chicken, ham, and seafood should not be eaten.

Box 9-7 provides a simple tool for obtaining diet history information. When potential problems are identified, they should be followed up with a careful interview.

Physical Examination

Anthropometric (body) measurements provide short-term and long-term information on a woman's nutritional status and are thus essential to the assessment. At a minimum, the woman's height and weight must be determined at the time of her first prenatal visit, and her weight should be measured at each subsequent visit (see earlier discussion of BMI).

A careful physical examination can reveal objective signs of malnutrition (Table 9-5). It is important to note, however, that some of these signs are nonspecific and that the physiologic changes of pregnancy may complicate the interpretation of physical findings. For example, lower extremity edema often occurs when calorie and protein deficiencies are present but it may also be a normal finding in the third trimester of pregnancy. The interpretation of physical findings is made easier by a thorough health history and by laboratory testing if indicated.

Laboratory Testing

The only nutrition-related laboratory testing needed by most pregnant women is a hematocrit or hemoglobin measurement to screen for the presence of anemia. Because of the physiologic anemia of pregnancy, the reference values for hemoglobin and hematocrit must be adjusted during pregnancy. The lower limit of the normal range for hemoglobin during pregnancy is 11 g/dL in the first and third trimesters and 10.5 g/dL in the second trimester (compared with 12 g/dL in the nonpregnant state). The lower limit of the normal range for hematocrit is 33% during the first and third trimesters and 32% in the second trimester (compared with 36% in the nonpregnant state). Cutoff values for anemia are higher in women who smoke or live at high altitudes because the decreased oxygen-carrying capacity of their RBCs causes them to produce more RBCs than other women produce.

A woman's history or physical findings may indicate the need for additional testing. These tests might include a complete blood cell count with a differential to identify megaloblastic or macrocytic anemia and measurement of levels of specific vitamins or minerals believed to be lacking in the diet.

Nutrition Care and Teaching

For many women with uncomplicated pregnancies, the nurse can serve as the primary source of nutrition education. The registered dietitian, who has specialized training in diet evaluation and planning, nutritional needs during illness, ethnic and cultural food patterns, as well as translating nutrient needs into food patterns, frequently serves as a consultant. Pregnant women with serious nutritional problems, those with intervening illnesses such as diabetes (either preexisting or gestational), and any others requiring in-depth dietary counseling should be referred to the dietitian. The nurse, dietitian, physician, and nurse-midwife collaborate in helping the woman achieve nutrition-related expected outcomes. Nutritional care and teaching generally involve:

- Acquainting the woman with nutritional needs during pregnancy and the characteristics of an adequate diet, if necessary
- Helping her individualize her diet so that she achieves an adequate intake while conforming to her personal, cultural, financial, and health circumstances
- Acquainting her with strategies for coping with the nutrition-related discomforts of pregnancy
- Helping her use nutrition supplements appropriately
- Consulting with and making referrals to other professionals or services as indicated

Two programs that provide nutrition services are the food stamp program and the Special Supplemental Nutrition Program for Women, Infants and Children (WIC), which provides vouchers for selected foods for pregnant and lactating women as well as for infants and children at nutritional risk (see the Nursing Care Plan). WIC foods include items such as eggs, cheese, milk, juice, and fortified cereals—foods chosen because they provide iron, protein, vitamin C, and other vitamins.

Adequate Dietary Intake

Nutrition teaching can take place in a one-on-one interview or in a group setting. In either case, teaching should emphasize the importance of choosing a varied diet composed of readily available foods (rather than specialized diet supplements). Good nutrition practices (and avoidance of poor practices such as smoking and alcohol or drug use) are essential content for prenatal classes designed for women in early pregnancy.

MyPlate (www.choosemyplate.gov) can be used as a guide to making daily food choices during pregnancy and lactation, just as it is during other stages of the life cycle. Additional individualized information and resources for professionals are available from the website. The importance of consuming adequate amounts from the milk, yogurt, and cheese group must be emphasized, especially for adolescents and women younger than 25 years, who are still actively adding calcium to their skeletons; adolescents need at least three or four servings from the milk group daily.

Pregnancy. The pregnant woman must understand what adequate weight gain during pregnancy means, recognize the reasons for its importance, and be able to evaluate her own gain in terms of the desirable pattern. Many women, particularly those who have worked hard to control their weight before pregnancy, may find it difficult to understand why the weight-gain goal is so high when a newborn infant is so small. The nurse can explain that maternal weight gain consists of increments in the weight of many tissues, not just the growing fetus (see Table 9-2).

Dietary overindulgence, which may result in excessive fat stores that persist after giving birth, should be discouraged. Nevertheless, it is best not to focus unduly on weight gain because this could result in feelings of stress and guilt in the woman who does not follow the preferred pattern of gain. Teaching regarding weight gain during pregnancy is summarized in Box 9-2.

Postpartum. An important goal of postpartum nutrition is for the woman to lose the weight gained during pregnancy. Retention of this weight can contribute to overweight/obesity and the

BOX 9-7 FOOD INTAKE QUESTIONNAIRE

Which of the following did you eat or drink yesterday? If the way you ate yesterday wasn't the way you usually eat, choose a recent day that was typical for you.

FOOD OR DRINK	NUMBER OF SERVINGS	FOOD OR DRINK	NUMBER OF SERVINGS
Beer, wine, other alcoholic drinks	_____	Orange or grapefruit juice	_____
Tea	_____	Fruit juice other than orange or grapefruit	_____
Coffee	_____	Soft drinks	_____
Caffeinated	_____	Milk	_____
Decaffeinated	_____	Cereal with milk	_____
Fruit drink	_____	Yogurt	_____
Water	_____	Pizza	_____
Cheese	_____	Melon (e.g., watermelon, cantaloupe, honeydew)	_____
Macaroni and cheese	_____	Berries (kind)	_____
Other foods with cheese (e.g., lasagna, enchiladas, cheeseburgers)	_____	Apples	_____
Orange or grapefruit	_____	Other fruit	_____
Bananas	_____	Broccoli	_____
Peaches or apricots	_____	Green beans	_____
Green salad	_____	Potatoes (other than fried)	_____
Spinach or greens	_____	Corn	_____
Green peas	_____	Other vegetables	_____
Sweet potatoes	_____	Chicken or turkey	_____
Carrots	_____	Egg	_____
Meat	_____	Nuts	_____
Fish	_____	Hot dog	_____
Peanut butter	_____	Cold cuts (e.g., bologna)	_____
Dried beans or peas	_____	Roll/bagel	_____
Bacon or sausage	_____	Noodles	_____
Bread	_____	Chips	_____
Rice	_____	Cake	_____
Spaghetti or other pasta	_____	Donut or pastry	_____
Tortillas	_____	Cookie	_____
French fries	_____	Pie	_____

Are you often bothered by any of the following? (Circle all that apply)
Nausea Vomiting Heartburn Constipation

Are you on a special diet? No _____ Yes _____
If yes, what kind?
_____

Do you try to limit the amount or kind of food you eat to control your weight?
No _____ Yes _____

Do you avoid any foods for health or religious reasons? No _____ Yes _____
If yes, what foods?
_____

Do you take any prescribed drugs or medications? No _____ Yes _____
If yes, what are they?
_____

Do you take any over-the-counter medications (e.g., aspirin, cold medicines, acetaminophen [Tylenol])? No _____ Yes _____
If yes, what are they?
_____

Do you take any herbal supplements? No _____ Yes _____
If yes, what are they?
_____

Do you ever have trouble affording the food you need? No _____ Yes _____

Do you have any help getting the food you need? No _____ Yes _____
If yes, what kind? Food stamps ____ WIC ____ School lunch or breakfast ____
Food from a food pantry, soup kitchen, or food bank _____ Other _____

TABLE 9-5 PHYSICAL ASSESSMENT OF NUTRITIONAL STATUS

SIGNS OF GOOD NUTRITION	SIGNS OF POOR NUTRITION
General Appearance	
Alert, responsive, energetic, good endurance	Listless, apathetic, cachectic, easily fatigued, looks tired
Muscles	
Well developed, firm, good tone, some fat under skin	Flaccid, poor tone, tender, "wasted" appearance
Gastrointestinal Function	
Good appetite and digestion, normal regular elimination, no palpable organs or masses	Anorexia, indigestion, constipation or diarrhea, liver or spleen enlargement
Cardiovascular Function	
Normal heart rate and rhythm, no murmurs, normal blood pressure for age	Rapid heart rate, enlarged heart, abnormal rhythm, elevated blood pressure
Hair	
Shiny, lustrous, firm, not easily plucked, healthy scalp	Stringy, dull, brittle, dry, thin and sparse, depigmented, can be easily plucked
Skin (General)	
Smooth, slightly moist, good color	Rough, dry, scaly, pale, pigmented, irritated, easily bruised, petechiae
Face and Neck	
Skin color uniform, smooth, pink, healthy appearance; no enlargement of thyroid gland; lips not chapped or swollen	Scaly, swollen, skin dark over cheeks and under eyes, lumpiness or flakiness of skin around nose and mouth; thyroid enlarged; lips swollen, angular lesions or fissures at corners of mouth
Oral Cavity	
Reddish pink mucous membranes and gums; no swelling or bleeding of gums; tongue healthy pink or deep reddish in appearance, not swollen or smooth, surface papillae present; teeth bright and clean, no cavities, no pain, no discoloration	Gums spongy, bleed easily, inflamed or receding; tongue swollen, scarlet and raw, magenta color, beefy, hyperemic and hypertrophic papillae, atrophic papillae; teeth with unfilled caries, absent teeth, worn surfaces, mottled
Eyes	
Bright, clear, shiny, no sores at corners of eyelids, membranes moist and healthy pink color, no prominent blood vessels or mound of tissue (Bitot spots) on sclera, no fatigue circles beneath	Eye membranes pale, redness of membrane, dryness, signs of infection, redness and fissuring of eyelid corners, dryness of eye membrane, dull appearance of cornea, blue sclerae
Extremities	
No tenderness, weakness, or swelling; nails firm and pink	Edema, tender calves, tingling, weakness; nails spoon-shaped, brittle
Skeleton	
No malformations	Bowlegs, knock-knees, chest deformity at diaphragm, beaded ribs, prominent scapulae

development of later health problems including the metabolic syndrome, cardiovascular disease, and diabetes.

The need for a varied diet with food from all the food groups continues throughout lactation. The lactating woman should be advised to consume at least 1800 kcal daily, and she should receive counseling if her diet appears to be inadequate in any nutrients. Special attention should be given to her zinc, vitamin B_6, and folic acid intake because the recommendations for these remain higher than for nonpregnant women (see Table 9-1). Sufficient calcium is needed to allow for both milk formation and maintenance of maternal bone mass. It may be difficult for lactating women to consume enough of these nutrients without careful meal planning.

Obese women and normal-weight women who gain more than the recommended amount of weight during pregnancy are less likely to breastfeed than normal-weight women with appropriate weight gain. Obese women who do choose to breastfeed have a statistically shorter period of lactation than normal-weight women. The woman who does not breastfeed can lose weight gradually if she consumes a balanced diet that provides slightly less than her daily energy expenditure, although overweight and obese women with excessive weight gain during pregnancy have an increased likelihood of failing to return to their prepregnancy weights (Siega-Riz, Viswanathan, Moos, et al., 2009). A reasonable weight-loss goal for nonlactating women is 0.5 to 0.9 kg per week; a loss of 1 kg per month is recommended for most lactating women. Those at risk for obesity and overweight need follow-up to ensure that they know how to make wise food choices, primarily from fruits, vegetables, whole grains, lean meats, and low-fat dairy products. An hour of moderately vigorous physical activity (e.g., walking, jogging, swimming, cycling, aerobic dance) most days of the week will improve the ability of the woman to lose weight gradually and maintain the weight loss.

NURSING CARE PLAN

Nutrition During Pregnancy

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
Deficient Knowledge related to nutritional requirements during pregnancy	Woman will describe nutritional requirements and exhibit evidence of incorporating requirements into diet.	Review basic nutritional requirements for healthy diet by using recommended dietary guidelines and MyPlate	To provide knowledge baseline for discussion
		Discuss increased nutrient needs (calories, protein, minerals, vitamins) that occur as result of being pregnant	To increase knowledge needed for altered dietary requirements
		Discuss relation between weight gain and fetal growth	To reinforce interdependence of fetus and mother
		Calculate appropriate total weight gain range during pregnancy using woman's body mass index as guide, and discuss recommended rates of weight gain during various trimesters of pregnancy	To provide concrete measures of dietary success
		Review food preferences, cultural eating patterns or beliefs, and prepregnancy eating patterns	To enhance integration of new dietary needs
		Discuss how to fit nutritional needs into usual dietary patterns and how to alter any identified nutritional deficits or excesses	To increase chances of success with dietary alterations
		Discuss food aversions or cravings that may occur during pregnancy and strategies to deal with these if they are detrimental to fetus (e.g., pica)	To ensure well-being of fetus
		Have woman keep food diary delineating eating habits, dietary alterations, aversions, and cravings	To track eating habits and potential problem areas
Imbalanced Nutrition: Less Than Body Requirements related to inadequate intake of needed nutrients	Woman's weekly weight gain will be increased to appropriate rate using her body mass index (BMI) and recommended weight gain ranges as guidelines.	Review recent diet history (including food aversions) using food diary, 24-hour recall, or food frequency approach	To ascertain dietary inadequacies contributing to insufficient weight gain
		Review normal activity and exercise routines and discuss eating patterns and reasons that lead to decreased food intake (e.g., morning sickness, pica, fear of becoming fat, stress, boredom)	To determine level of energy expenditure and to identify habits that contribute to inadequate weight gain
		Review optimal weight gain guidelines and their rationale	To ensure that woman is knowledgeable about healthful weight gain rates
		Set target weight gains for remaining weeks of pregnancy	To establish set goals
		Review increased nutrient needs (calories, protein, minerals, vitamins) that occur as result of being pregnant	To ensure woman is knowledgeable about altered dietary requirements
		Review relation between weight gain and fetal growth	To reinforce that adequate weight gain is needed to promote fetal well-being
		Discuss with woman what changes can be made in diet, activity, and lifestyle	To enhance chances of meeting set weight gain goals and nutrient needs of mother and fetus
		If woman has fear of being fat, if symptoms of eating disorder are evident, or if problems in adjusting to changing body image surface, refer woman to appropriate mental health professional for evaluation	Because intensive treatment and follow-up may be required to ensure fetal health
Nausea related to physiologic alterations of first trimester of pregnancy	Nausea will not be so severe that it interferes with adequate nutrient intake or substantially reduces quality of life.	Assess state of hydration and assess pattern of weight gain during pregnancy	To ensure that woman does not have deficient fluid volume; to ensure that nausea is not preventing adequate energy intake
		Review nausea history (i.e., frequency of episodes of nausea, likelihood of nausea progressing to vomiting, factors precipitating or associated with nausea, and any relief measures that woman has tried)	To determine severity of problem and to begin to identify effective and ineffective measures for coping with nausea
		Review measures for prevention or relief of morning sickness	To ensure that woman is knowledgeable about measures that are often effective in alleviating morning sickness
		Discuss with woman what relief measures she will try	To determine whether she understands how to implement measures

Daily Food Guide and Menu Planning

The daily food plan (see Table 9-3) can be used as a guide for educating women about nutritional needs during pregnancy and lactation. This food plan is general enough to be used by women from a wide variety of cultures, including those who follow a vegetarian diet. One of the more helpful teaching strategies is to help the woman plan daily menus that follow the food plan and are affordable, have realistic preparation times, and are compatible with personal preferences and cultural practices. Information regarding cultural food patterns is provided later in this chapter.

Medical Nutrition Therapy

During pregnancy and lactation, the food plan for women with special medical nutrition therapy may have to be modified. The registered dietitian can instruct these women about their diets and assist them in meal planning. However, the nurse should understand the basic principles of the diet and be able to reinforce the teaching.

The nurse should be especially aware of the dietary modifications necessary for women with diabetes mellitus (either gestational or preexisting). This disease is relatively common, and fetal morbidity and mortality occur more often in pregnancies complicated by hyperglycemia or hypoglycemia (see discussion of diabetes in Chapter 11). Every effort should be made to maintain blood glucose levels in the normal range throughout pregnancy. The food plan of the woman with diabetes usually includes four to six meals and snacks daily, with the daily carbohydrate intake distributed fairly evenly among the meals and snacks. The complex carbohydrates—fibers and starches—should be well represented in the diet. To maintain strict control of the blood glucose level, the pregnant woman with diabetes usually must monitor her own blood glucose daily.

Counseling About Iron Supplementation

The nutrition supplement most commonly needed during pregnancy is iron. However, a variety of dietary factors can affect the completeness of absorption of an iron supplement. The Patient Teaching box summarizes important points regarding iron supplementation.

PATIENT TEACHING

Iron Supplementation

- A diet rich in vitamin C (in citrus fruits, tomatoes, melons, and strawberries) and **heme iron** (in meats) increases the absorption of iron supplement; therefore include these in the diet often.
- Bran, tea, coffee, milk, oxalates (in spinach and Swiss chard), and egg yolk decrease iron absorption. Avoid consuming them at the same time as the supplement.
- Iron is absorbed best if it is taken when the stomach is empty; that is, take it between meals with a beverage other than tea, coffee, or milk.
- Iron can be taken at bedtime if abdominal discomfort occurs when it is taken between meals.
- If an iron dose is missed, take it as soon as it is remembered if that is within 13 hours of the scheduled dose. Do not double up on the dose.
- Keep the supplement in a childproof container and out of the reach of any children in the household.
- The iron may cause stools to be black or dark green.
- Constipation is common with iron supplementation. A diet high in fiber with adequate fluid intake is recommended.

Coping with Nutrition-Related Discomforts of Pregnancy

The most common nutrition-related discomforts of pregnancy are nausea and vomiting (or "morning sickness"), constipation, and pyrosis.

Nausea and Vomiting. Nausea and vomiting of pregnancy (NVP) is most common during the first trimester. Usually, NVP causes only mild to moderate problems nutritionally, although it may be a source of substantial discomfort. Antiemetic medications, vitamin B_6, ginger, and P6 acupressure may be effective in reducing the severity of nausea, although the evidence supporting them is not strong. The pregnant woman may find the suggestions in Box 9-8 helpful in alleviating NVP.

Hyperemesis gravidarum, or severe and persistent vomiting causing weight loss, dehydration, and electrolyte abnormalities, occurs in up to 1% of pregnant women. Intravenous fluid and electrolyte replacement, enteral tube feeding, and in some instances total parenteral nutrition have been used to nourish women with hyperemesis gravidarum. There is very limited evidence that acupressure and ginger might provide some relief.

Constipation. Improved bowel function generally results from increasing the intake of fiber (e.g., bran and whole-wheat products, popcorn, and raw or lightly steamed vegetables) in the diet. Fiber helps create a bulky stool that stimulates intestinal peristalsis. The recommendation for pregnant women for fiber is 28 g daily. An adequate fluid intake (at least 50 mL/kg/day) helps hydrate the fiber and increase the bulk of the stool. Making a habit of regular physical activity that uses large muscle groups (walking, swimming, water aerobics) also helps stimulate bowel motility.

Pyrosis. **Pyrosis,** or heartburn, is usually caused by reflux of gastric contents into the esophagus. This condition can be

BOX 9-8 SUGGESTIONS FOR MANAGING NAUSEA AND VOMITING DURING PREGNANCY

- Eat dry, starchy foods such as dry toast, melba toast, or crackers on awakening in the morning and at other times when nausea occurs.
- Avoid consuming excessive amounts of fluids early in the day or when nauseated (but compensate by drinking fluids at other times).
- Eat small amounts frequently (every 2 to 3 hours), and avoid large meals that distend the stomach.
- Avoid skipping meals and thus becoming extremely hungry, which may worsen nausea. Have a snack such as cereal with milk, a small sandwich, or yogurt before bedtime.
- Avoid sudden movements. Get out of bed slowly.
- Decrease intake of fried and other fatty foods. Try high-carbohydrate foods such as toast, rice, or potatoes. Some women find high-protein meals or snacks helpful.
- Breathe fresh air to help relieve nausea. Keep the environment well ventilated (e.g., open a window), go for a walk outside, or decrease cooking odors by using an exhaust fan.
- Eat foods served at cool temperatures and foods that give off little aroma. Avoid spicy foods.
- Avoid brushing teeth immediately after eating.
- Try salty and tart foods (e.g., potato chips and lemonade) during periods of nausea. Sucking a lemon slice may help.
- Try herbal teas such as those made with raspberry leaf or peppermint to decrease nausea.

minimized by eating small, frequent meals rather than two or three larger meals daily. Because fluids increase the distention of the stomach, they should not be consumed with foods. The woman needs to drink adequate amounts between meals. Avoiding spicy foods may help alleviate the problem. Reflux can be exacerbated by lying down immediately after eating and wearing clothing that is tight across the abdomen.

Cultural Influences

Consideration of a woman's cultural food preferences enhances communication and provides a greater opportunity for following the agreed-on pattern of intake. Women in most cultures are encouraged to eat a diet typical for them. The nurse needs to be aware of what constitutes a typical diet for each cultural or ethnic group present in her patient population. However, several variations may occur within one cultural group. Thus a careful exploration of individual preferences is needed. Although ethnic and cultural food beliefs may seem at first glance to conflict with the dietary instruction provided by physicians, nurses, and dietitians, it is often possible for the empathic health care provider to identify cultural beliefs that are congruent with the modern understanding of pregnancy and fetal development. Many cultural food practices have some merit or the culture would not have survived. Food cravings during pregnancy are considered normal by many cultures, but the kinds of cravings often are culturally specific. In most cultures, women crave acceptable foods, such as chicken, fish, and greens among African-Americans. Cultural influences on food intake usually lessen if the woman and her family become more integrated into the dominant culture. Nutritional beliefs and the practices of selected cultural groups are summarized in Table 9-6.

Vegetarian Diets

Vegetarian diets represent another cultural effect on nutritional status. Foods basic to almost all vegetarian diets are vegetables, fruits, legumes, nuts, seeds, and grains, but with many variations. **Lacto-vegetarians** include milk products. Lacto-ovovegetarians consume eggs and dairy products in addition to plant products. Strict vegetarians, or **vegans,** consume only plant products. All of these types of vegetarian diets, if they are well planned, can be nutritionally adequate for pregnant and lactating women (Craig and Mangels, 2009). Because vitamin B_{12} is found only in foods of animal origin, this diet is deficient in vitamin B_{12}. As a result, strict vegetarians should take a supplement or regularly consume vitamin B_{12}—fortified foods such as fortified soy milk two or three times a day or take a supplement. Vitamin B_{12} deficiency can result in megaloblastic anemia, glossitis (inflamed red tongue), and neurologic deficits in

TABLE 9-6 POPULAR FOODS OF VARIOUS CULTURAL AND ETHNIC GROUPS AND THEIR PLACE IN MYPLATE

CULTURAL OR ETHNIC GROUP OR EATING PATTERN	FOOD GROUPS				
	GRAINS	VEGETABLE	FRUIT	DAIRY	PROTEIN
Mexican	Tortilla Taco shell Posole (corn soup) Rice Postres (pastries)*	*Other vegetables:* Chayote (Mexican squash) Jicama (root vegetable) Nopales (cactus leaves) Tomato Corn	Avocado Mango Papaya Plantano (cooking banana) Zapote (sweet, yellowish fruit)	Queso blanco (white Mexican cheese) Custard (1 cup = 1 cup milk serving) Leche (milk)	Chorizo (sausage)* Chicken, beef, goat, or pork Beans, dried, cooked
African-American soul food (Southern-style cooking)	Biscuit Cornbread Grits, rice, macaroni, or noodles Hominy Crackers Hush puppies	*Dark green:* Collard, kale, mustard, or turnip greens *Orange:* Sweet potatoes *Other:* Okra Snap, pole (green), lima, and butter beans Turnips Summer squash (yellow or zucchini) Coleslaw	Blackberries Melons Muscadines (grapes) Peaches	Buttermilk	Pork (cured ham and uncured cuts), chicken, beef, fish Peas or beans (black-eyed, crowder, purple-hull, or cream)
Vegetarian	Whole-grain bread Cereal, cooked or ready-to-eat Brown rice Whole-grain pasta Bagel	All	All	Milk and cheese (lacto-vegetarians) Soy milk, calcium-fortified Soy cheese	Cooked dried beans or peas Tofu (soybean curd) or tempeh (fermented soy) Nuts or seeds Peanut butter Egg (ovovegetarians)

Middle Eastern	Rice or bulgur (cracked wheat) Couscous Bread Pita	*Yellow:* Pumpkin or winter squash (butternut) *Other:* Peppers Tomatoes Grape leaves Cucumbers Fava beans Eggplant	Apricots Grapes Melons Dried fruits: dates, raisins, apricots	Yogurt	Lamb, goat, fish Almonds Pistachio nuts Dried beans and peas, lentils Eggs

*High fat, use sparingly.
†Varies widely depending on tribal grouping and locale.

the mother. Infants born to affected mothers are likely to have megaloblastic anemia and exhibit neurodevelopmental delays. The diet should be carefully planned to include adequate minerals. Iron and zinc may not be as well absorbed from plant foods as they are from meats, and calcium intake can be low if milk products are avoided.

Plant proteins tend to be "incomplete," in that they lack one or more amino acids required for growth and the maintenance of body tissues. However, the daily consumption of a variety of different plant proteins—grains, dried beans and peas, nuts, and seeds—can provide all of the **essential amino acids.**

KEY POINTS

- A woman's nutritional status before, during, and after pregnancy contributes, to a significant degree, to her well-being and that of her developing fetus and newborn.
- Many physiologic changes occurring during pregnancy influence the need for additional nutrients and the efficiency with which the body uses them.
- Both the total maternal weight gain and the pattern of weight gain are important determinants of the outcome of pregnancy.
- The appropriateness of the mother's prepregnancy weight for height (BMI) is a major determinant of her recommended weight gain during pregnancy.
- Nutritional risk factors include adolescent pregnancy; abuse of nicotine, alcohol, or drugs; bizarre or faddish food habits; a low or high weight for height; and frequent pregnancies.
- Iron supplementation is usually routinely recommended during pregnancy. Other supplements may be warranted when nutritional risk factors are present.
- The nurse and the woman are influenced by cultural and personal values and beliefs during nutrition counseling.
- Pregnancy complications that may be nutrition-related include anemia, gestational hypertension, gestational diabetes, and IUGR.
- Dietary adaptation can be effective intervention for some of the common discomforts of pregnancy, including nausea and vomiting, constipation, and heartburn.

CHAPTER

10

Assessment of High Risk Pregnancy

Kitty Cashion

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Explore biophysical, psychosocial, sociodemographic, and environmental influences on high risk pregnancy.
- Examine risk factors identified through history, physical examination, and diagnostic techniques.
- Discuss psychologic considerations associated with a high risk pregnancy diagnosis.
- Differentiate among screening and diagnostic techniques, including when they are used in pregnancy and for what purpose.
- Develop a teaching plan to explain screening and diagnostic techniques and implications of findings to women and their families.

In 2010, the most recent year for which figures are available, four million births occurred in the United States (Martin, Hamilton, Sutton, et al., 2012). Many of these births were the result of pregnancies considered to be *high risk* because the life or health of the mother, fetus, or newborn was jeopardized by circumstances coincidental with or unique to the pregnancy. Care of these high risk patients requires the combined efforts of medical and nursing personnel. Factors associated with a diagnosis of a high risk pregnancy are identified in this chapter. Diagnostic techniques often used to monitor the maternal-fetal unit at risk are also described.

ASSESSMENT OF RISK FACTORS

Pregnancies can be designated as high risk for any of several undesirable outcomes. In the past risk factors were evaluated only from a medical standpoint. Therefore only adverse medical, obstetric, or physiologic conditions were considered to place the woman at risk. Today a more comprehensive approach to high risk pregnancy is used, and the factors associated with high risk childbearing are grouped into broad categories based on threats to health and pregnancy outcome. Categories of risk include biophysical, psychosocial, sociodemographic, and environmental (Box 10-1). Risk factors are interrelated and cumulative in their effects.

Biophysical risks include factors that originate within the mother or fetus and affect the development or functioning of either one or both. Examples include genetic disorders, nutritional and general health status, and medical or obstetric-related illnesses. Box 10-2 lists common risk factors for several pregnancy-related problems.

Psychosocial risks consist of maternal behaviors and adverse lifestyles that have a negative effect on the health of the mother or fetus. These risks may include emotional distress, disturbed interpersonal relationships, inadequate social support, and unsafe cultural practices.

Sociodemographic risks arise from the mother and her family. These risks may place the mother and fetus at risk. Examples include lack of prenatal care, low income, marital status, and ethnicity (see Box 10-1).

Environmental factors include hazards in the workplace and the woman's general environment and may include environmental chemicals (e.g., lead, mercury), anesthetic gases, and radiation (Chambers and Weiner, 2009; Cunningham, Leveno, Bloom, et al., 2010).

PSYCHOLOGIC CONSIDERATIONS RELATED TO HIGH RISK PREGNANCY

Once a pregnancy has been identified as high risk, the pregnant woman and her fetus are monitored carefully throughout the remainder of the pregnancy. All women who undergo antepartum assessments are at risk for real and potential problems and may feel anxious. In most instances the tests are ordered because of suspected fetal compromise, deterioration of a maternal condition, or both. In the third trimester pregnant women are most concerned about

BOX 10-1 CATEGORIES OF HIGH RISK FACTORS

Biophysical Factors

- *Genetic considerations.* Genetic factors may interfere with normal fetal or neonatal development, result in congenital anomalies, or create difficulties for the mother. These factors include defective genes, transmissible inherited disorders and chromosomal anomalies, multiple pregnancy, large fetal size, and ABO incompatibility.
- *Nutritional status.* Adequate nutrition, without which fetal growth and development cannot proceed normally, is one of the most important determinants of pregnancy outcome. Conditions that influence nutritional status include the following: young age; three pregnancies in the previous 2 years; tobacco, alcohol, or drug use; inadequate dietary intake because of chronic illness or food fads; inadequate or excessive weight gain; and hematocrit value less than 33%.
- *Medical and obstetric disorders.* Complications of current and past pregnancies, obstetric-related illnesses, and pregnancy losses put the woman at risk (see Box 10-2).

Psychosocial Factors

- *Smoking.* A strong, consistent, causal relation has been established between maternal smoking and reduced birth weight. Risks include low-birth-weight infants, higher neonatal mortality rates, increased rates of miscarriage, and increased incidence of premature rupture of membranes. These risks are aggravated by low socioeconomic status, poor nutritional status, and concurrent use of alcohol.
- *Caffeine.* Birth defects in humans have not been related to caffeine consumption. However, pregnant women who consume more than 200 mg of caffeine daily (equivalent to about 12 ounces of coffee per day) may be at increased risk for miscarriage or giving birth to infants with intrauterine growth restriction.
- *Alcohol.* Although the exact effects of alcohol in pregnancy have not been quantified and its mode of action is largely unexplained, it exerts adverse effects on the fetus, resulting in fetal alcohol syndrome, fetal alcohol effects, learning disabilities, and hyperactivity.
- *Drugs.* The developing fetus may be affected adversely by drugs through several mechanisms. They can be teratogenic, cause metabolic disturbances, produce chemical effects, or cause depression or alteration of central nervous system function. This category includes medications prescribed by a health care provider or bought over the counter and commonly abused drugs such as heroin, cocaine, and marijuana. (See Chapter 11 for more information about drug and alcohol abuse.)
- *Psychologic status.* Childbearing triggers profound and complex physiologic, psychologic, and social changes, with evidence to suggest a relationship between emotional distress and birth complications. This risk factor includes conditions such as specific intrapsychic disturbances and addictive lifestyles; a history of child or spouse abuse; inadequate support systems; family disruption or dissolution; maternal role changes or conflicts; noncompliance with cultural norms; unsafe cultural, ethnic, or religious practices; and situational crises.

Sociodemographic Factors

- *Low income.* Poverty underlies many other risk factors and leads to inadequate financial resources for food and prenatal care, poor general health, increased risk of medical complications of pregnancy, and greater prevalence of adverse environmental influences.
- *Lack of prenatal care.* Failure to diagnose and treat complications early is a major risk factor arising from financial barriers or lack of access to care; depersonalization of the system resulting in long waits, routine visits, variability in health care personnel, and unpleasant physical surroundings; lack of understanding of the need for early and continued care or cultural beliefs that do not support the need; and fear of the health care system and its providers.
- *Age.* Women at both ends of the childbearing age spectrum have an increased incidence of poor outcomes; however, age may not be a risk factor in all cases. Physiologic and psychologic risks should be evaluated.
- *Adolescents.* More complications are seen in young mothers (younger than 15 years), who have a 60% higher mortality rate than those older than 20 years, and in pregnancies occurring less than 6 years after menarche. Complications include anemia, preeclampsia, prolonged labor, and contracted pelvis and cephalopelvic disproportion. Long-term social implications of early motherhood are lower educational attainment, lower income, increased dependence on government support programs, higher divorce rates, and higher parity.
- *Mature mothers.* The risks to older mothers are not from age alone but from other considerations such as number and spacing of previous pregnancies, genetic disposition of the parents, medical history, lifestyle, nutrition, and prenatal care. The increased likelihood of chronic diseases and complications that arise from more invasive medical management of a pregnancy and labor combined with demographic characteristics put an older woman at risk. Conditions more likely to be experienced by mature women include chronic hypertension and preeclampsia, diabetes, prolonged labor, cesarean birth, placenta previa, placental abruption, and death. Her fetus is at greater risk for low birth weight and macrosomia, chromosomal abnormalities, congenital malformations, and neonatal death.
- *Parity.* The number of previous pregnancies is a risk factor associated with age and includes all first pregnancies, especially a first pregnancy at either end of the childbearing age continuum. The incidence of preeclampsia and dystocia is increased with a first birth.
- *Marital status.* The increased mortality and morbidity rates for unmarried women, including an increased risk for preeclampsia, are often related to inadequate prenatal care and a young childbearing age.
- *Residence.* The availability and quality of prenatal care vary widely with geographic residence. Women in metropolitan areas have more prenatal visits than those in rural areas who have fewer opportunities for specialized care and consequently a higher incidence of maternal mortality. Health care in the inner city, where residents are usually poorer and begin childbearing earlier and continue longer, may be of lower quality than in a more affluent neighborhood.
- *Ethnicity.* Although ethnicity by itself is not a major risk, race is associated with some poor pregnancy outcomes. Non-Caucasian women are more than 3 times as likely as Caucasian women to die of pregnancy-related causes. African-American babies have the highest rates of prematurity and low birth weight, with the infant mortality rate among African-Americans being more than double that among Caucasians.

Environmental Factors

- Various environmental substances can affect fertility and fetal development, the chance of a live birth, and the child's subsequent mental and physical development. Environmental influences include infections, radiation, chemicals such as mercury and lead, therapeutic drugs, illicit drugs, industrial pollutants, cigarette smoke, stress, and diet. Paternal exposure to mutagenic agents in the workplace has been associated with an increased risk of miscarriage.

BOX 10-2 SPECIFIC PREGNANCY PROBLEMS AND RELATED RISK FACTORS

Polyhydramnios
- Poorly controlled diabetes mellitus
- Fetal congenital anomalies (e.g., gastrointestinal obstruction, twin-twin transfusion syndrome)

Oligohydramnios
- Renal agenesis (Potter syndrome)
- Premature rupture of membranes
- Prolonged pregnancy
- Uteroplacental insufficiency
- Severe intrauterine growth restriction (IUGR)
- Maternal hypertensive disorders

Intrauterine Growth Restriction

Maternal Causes
- Hypertensive disorders
- Diabetes
- Chronic renal disease
- Collagen vascular disease
- Thrombophilia
- Cyanotic heart disease
- Poor weight gain
- Smoking, alcohol use, illicit drug use
- Living at a high altitude

Fetoplacental Causes
- Chromosomal abnormalities
- Congenital malformations
- Intrauterine infection
- Genetic syndromes (e.g., trisomy 13 and trisomy 18)
- Abnormal placental development

Chromosomal Abnormalities
- Advanced maternal age
- Parental chromosomal rearrangements
- Previous pregnancy with autosomal trisomy
- Abnormal ultrasound findings during the current pregnancy (e.g., fetal structural anomalies, IUGR, amniotic fluid volume abnormalities)
- Increased risk, as calculated from noninvasive screening results (e.g., nuchal translucency and maternal serum analytes)

Data from Baschat A, Galan H, Gabbe S: Intrauterine growth restriction. In Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: normal and problem pregnancies*, ed 6, Philadelphia, 2012, Saunders; Gilbert W: Amniotic fluid disorders: In Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: normal and problem pregnancies*, ed 6, Philadelphia, 2012, Saunders; Simpson J, Richards D, Otano L, et al: Prenatal genetic diagnosis. In Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: normal and problem pregnancies,* ed 6, Philadelphia, 2012, Saunders.

protecting themselves and their fetuses and consider themselves most vulnerable to outside influences. The label of *high risk* often increases this sense of vulnerability.

When a woman is diagnosed with a high risk pregnancy, she and her family will likely experience stress related to the diagnosis. The woman may exhibit various psychologic responses, including anxiety, low self-esteem, guilt, frustration, and inability to function. A high risk pregnancy can also affect parental attachment, accomplishment of the tasks of pregnancy, and family adaptation to the pregnancy. If the woman is fearful for her well-being, she may continue to feel ambivalent about the pregnancy or may not accept its reality. She may not be able to complete preparations for the baby or go to childbirth classes if she is placed on restricted activity at home or hospitalized. The family may become frustrated because they cannot engage in activities that prepare them for parenthood. The nurse can help the woman and her family regain control and balance in their lives by providing support and encouragement, information about the pregnancy problem and its management,

BOX 10-3 COMMON MATERNAL AND FETAL INDICATIONS FOR ANTEPARTUM TESTING

- Diabetes
- Chronic hypertension
- Preeclampsia
- Fetal growth restriction
- Multiple gestation
- Oligohydramnios
- Preterm premature rupture of membranes
- Postdates or postterm gestation
- Previous stillbirth
- Decreased fetal movement
- Systemic lupus erythematosus
- Renal disease
- Cholestasis of pregnancy

From Miller LA, Miller DA, Tucker SM: *Mosby's pocket guide to fetal monitoring: a multidisciplinary approach*, ed 7, St Louis, 2013, Mosby.

and opportunities to make as many choices as possible about the woman's care.

ANTEPARTUM TESTING

Antepartum testing has two major goals. The first is to identify fetuses at risk for injury caused by acute or chronic interruption of oxygenation so permanent injury or death might be prevented. The second goal is to identify appropriately oxygenated fetuses so unnecessary intervention can be avoided (Miller, Miller, and Tucker, 2013). In most cases monitoring begins by 32 to 34 weeks of gestation and continues regularly until birth. Assessment tests should be selected on the basis of their effectiveness, and the results must be interpreted in light of the complete clinical picture. Box 10-3 lists common maternal and fetal indications for antepartum testing that are supported by currently available evidence (Miller, Miller, and Tucker, 2013).

The remainder of this chapter describes maternal and fetal assessment tests that are often used to monitor high risk pregnancies.

BIOPHYSICAL ASSESSMENT

Daily Fetal Movement Count

Assessment of fetal activity by the mother is a simple yet valuable method for monitoring the condition of the fetus. The daily fetal movement count (DFMC) (also called *kick count*) can be assessed at home and is noninvasive, inexpensive, and simple to understand and usually does not interfere with a daily routine. It is frequently used to monitor the fetus in pregnancies complicated by conditions that may affect fetal oxygenation (see Box 10-2). The presence of movements is generally a reassuring sign of fetal health. During the third trimester the fetus makes about 30 gross body movements each hour. The mother is able to recognize 70% to 80% of these movements (Greenberg, Druzin, and Gabbe, 2012).

Several different protocols are used for counting. One recommendation is to count once a day for 60 minutes (Fig. 10-1). Fig. 10-1 is an example of a form used to record fetal kick counts. Other common recommendations are that mothers count fetal activity 2 or 3 times daily (e.g., after meals or before bedtime) for 2 hours or until 10 movements are counted or all fetal movements in a 12-hour period each day until a minimum of 10 movements are counted. Except for establishing a very low number of daily fetal movements or a trend toward decreased motion, the clinical value of the absolute number of fetal movements has not been established, other than

FETAL MOVEMENT CHART

1. This chart will help us find out how your baby is doing.
2. Carefully count the number of baby movements during the same hour every evening. (Baby moves more during the evening hours.) Example: 8-9 PM every evening.
3. If the baby has not moved for 12 hours, it is important that you notify the clinic (555-1234). If the clinic is closed, a recorded message will give you further instructions for contacting a doctor who is on-call.
4. Bring this chart with you whenever you come to the clinic or hospital.

in the situation in which fetal movements cease entirely for 12 hours (the so-called *fetal alarm signal*). A count of fewer than three fetal movements within 1 hour warrants further evaluation by a non-stress test or a contraction stress test and a complete or modified biophysical profile (see later discussion). Women should be taught the significance of the presence or absence of fetal movements, the procedure for counting that is to be used, how to record findings on a daily fetal movement record, and when to notify the health care provider.

! NURSING ALERT

In assessing fetal movements it is important to remember that they are usually not present during the fetal sleep cycle; they may be reduced temporarily if the woman is taking depressant medication, drinking alcohol, or smoking a cigarette. They do not decrease as the woman nears term. Obesity decreases perception of fetal movements and consequently the ability of the mother to count them.

Ultrasonography

Sound is a form of wave energy that causes small particles in a medium to oscillate. The frequency of sound, which refers to the number of peaks or waves that move over a given point per unit of time, is expressed in hertz (Hz). Sound with a frequency of one cycle, or one peak per second, has a frequency of 1 Hz. When directional beams of sound strike an object, an echo is returned. The time delay between the emission of the sound and the return and direction of the echo is noted. From these data the distance and location of an object can be calculated. Ultrasound is sound frequency higher than that detectable by humans (greater than 20,000 Hz). Ultrasound images are a reflection of the strength of the sending beam, the strength of the returning echo, and the density of the medium (e.g., muscle [uterus], bone, tissue [placenta], fluid, or blood) through which the beam is sent and returned.

Diagnostic ultrasonography is an important, safe technique in antepartum fetal surveillance. It is considered by many to be the most valuable diagnostic tool used in obstetrics (Richards, 2012). It

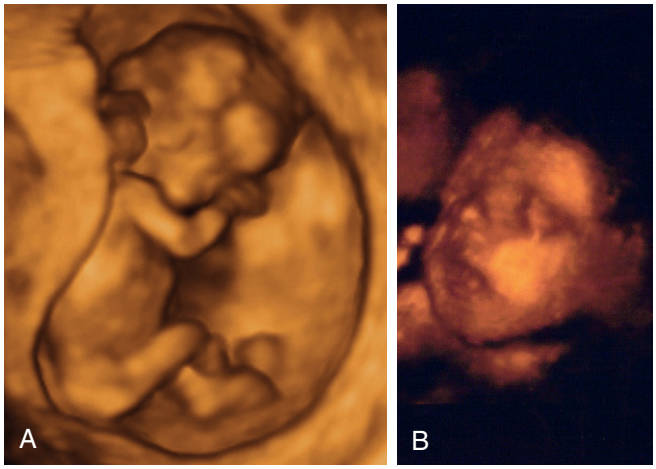

FIG 10-2 Fetus seen on three-dimensional ultrasound. **A,** Full body view of fetus at 11 weeks and 6 days of gestation. **B,** Close-up view of fetal face later in pregnancy. (*A,* Courtesy Shannon Perry, Phoenix, AZ; *B,* Courtesy Margaret Spann, New Johnsonville, TN.)

BOX 10-4 TYPES OF ULTRASOUND SCANS

Two-Dimensional (2D)

- This is the standard medical scan used in pregnancy.
- Sound waves are sent straight down from the ultrasound transducer.
- The image produced includes only two dimensions (length and width), so it appears flat.
- The image is viewed in black, white, or shades of gray.

Three-Dimensional (3D)

- This scan can be used for diagnostic purposes, but often the images are produced simply for the enjoyment of pregnant women and their families.
- Sound waves are sent out at different angles. The returning echoes are processed by a computer program, which adds a third dimension (depth) to the 2D scan, producing a three-dimensional image.
- The image is usually displayed in sepia tones rather than in black and white.

Four-Dimensional (4D)

- This scan adds a fourth dimension (time) to the 3D scan.
- The images produced are recorded and played back in succession. As the image is continuously updated, the fetus is viewed in real time.

provides critical information to health care providers regarding fetal activity and gestational age, normal versus abnormal fetal growth curves, fetal and placental anatomy, fetal well-being, and visual assistance with which invasive tests can be performed more safely (Richards, 2012; Simpson, Richards, Otano, et al., 2012).

An ultrasound examination can be performed either abdominally or transvaginally during pregnancy. Ultrasound scans produce a two- or three-dimensional view of the area being examined and can be used to create pictorial images (Fig. 10-2, *A* and *B*). Box 10-4 explains the differences in these scans and the views they produce.

Abdominal ultrasonography is more useful after the first trimester when the pregnant uterus becomes an abdominal organ. During the procedure the woman usually should have a full bladder to displace the uterus upward to provide a better image of the fetus. Transmission gel or paste is applied to the woman's abdomen to enhance the transmission and reception of the sound waves before a transducer is moved over the skin. She is positioned with small pillows under her head and knees. The display panel is positioned so the woman or her partner (or both) can observe the images on the screen if they desire.

Transvaginal ultrasonography, in which the probe is inserted into the vagina, allows pelvic anatomic features to be evaluated in greater detail and intrauterine pregnancy to be diagnosed earlier. A transvaginal ultrasound examination is well tolerated by most pregnant women because it removes the need for a full bladder. It is especially useful in obese women whose thick abdominal layers cannot be penetrated adequately with an abdominal approach. A transvaginal ultrasound may be performed with the woman in a lithotomy position or with her pelvis elevated by towels, cushions, or a folded pillow. This pelvic tilt is optimal to image the pelvic structures. A protective cover such as a condom, the finger of a clean surgical glove, or a special probe cover provided by the manufacturer is used to cover the transducer probe. The probe is lubricated with a water-soluble gel and placed in the vagina either by the examiner or by the woman herself. During the examination the position of the probe or the tilt of the examining table may be changed so the complete pelvis is in view. The procedure is not physically painful, although the woman feels pressure as the probe is moved. Transvaginal ultrasonography is optimally used in the first trimester to detect ectopic pregnancies, monitor the developing embryo, help identify abnormalities, and help establish gestational age. In some instances it may be used along with abdominal scanning to evaluate preterm labor in second- and third-trimester pregnancies.

Levels of Ultrasonography

The American College of Obstetricians and Gynecologists (ACOG, 2009) described three levels of ultrasonography. The *standard* (also called *basic*) examination is used most frequently and can be performed by ultrasonographers or other health care professionals, including nurses, who have had special training. Indications for standard ultrasonography are described in detail in the next section. In the second and third trimesters a standard ultrasound examination is used to evaluate fetal presentation, amniotic fluid volume (AFV), cardiac activity, placental position, fetal growth parameters, and number of fetuses. It is also used to perform an anatomic survey of the fetus (ACOG, 2009). *Limited* examinations are performed for specific indications such as identifying fetal presentation during labor or estimating AFV (ACOG, 2009). *Specialized* (also called *detailed*) or targeted examinations are performed if a woman is suspected of carrying an anatomically or physiologically abnormal fetus. Indications for this comprehensive examination include abnormal history or laboratory findings or the results of a previous standard or limited ultrasound examination. Specialized ultrasonography is performed by highly trained and experienced personnel (ACOG, 2009).

Indications for Use

Major indications for obstetric sonography are listed by trimester in Table 10-1. During the first trimester ultrasound examination is performed to obtain information regarding the number, size, and location of gestational sacs; the presence or absence of fetal cardiac and body movements; the presence or absence of uterine abnormalities (e.g., bicornuate uterus or fibroids) or adnexal masses (e.g., ovarian cysts or an ectopic pregnancy); and pregnancy dating.

During the second and third trimesters information regarding the following conditions is sought: fetal viability, number, position, gestational age, growth pattern, and anomalies; amniotic fluid

TABLE 10-1 MAJOR USES OF ULTRASONOGRAPHY DURING PREGNANCY

FIRST TRIMESTER	SECOND TRIMESTER	THIRD TRIMESTER
Confirm pregnancy	Establish or confirm dates	Confirm gestational age
Confirm viability	Confirm viability	Confirm viability
Determine gestational age	Detect polyhydramnios, oligohydramnios	Detect macrosomia
Rule out ectopic pregnancy	Detect congenital anomalies	Detect congenital anomalies
Detect multiple gestation	Detect intrauterine growth restriction (IUGR)	Detect IUGR
Determine cause of vaginal bleeding	Assess placental location	Determine fetal position
Use for visualization during chorionic villus sampling	Use for visualization during amniocentesis	Detect placenta previa or placental abruption
Detect maternal abnormalities such as bicornuate uterus, ovarian cysts, fibroids		Use for visualization during amniocentesis, external version
		Biophysical profile
		Amniotic fluid volume assessment
		Doppler flow studies
		Detect placental maturity

volume; placental location and condition; presence of uterine fibroids or anomalies; presence of adnexal masses; and cervical length.

Ultrasonography provides earlier diagnoses, allowing therapy to be instituted earlier in the pregnancy, thereby decreasing the severity and duration of morbidity, both physical and emotional, for the family. For instance, early diagnosis of a fetal anomaly gives the family choices such as intrauterine surgery or other therapy for the fetus, termination of the pregnancy, or preparation for the care of an infant with a disorder.

Fetal Heart Activity. Fetal heart activity can be demonstrated by about 6 weeks of gestation using transvaginal ultrasound. When the fetus is in a favorable position, good views of the fetal cardiac anatomy are possible in most patients at 13 weeks of gestation (Richards, 2012). Fetal death can be confirmed by lack of heart motion along with the presence of fetal scalp edema and maceration and overlap of the cranial bones.

Gestational Age. Gestational dating by ultrasonography is indicated for conditions such as uncertain dates for the last normal menstrual period, recent discontinuation of oral contraceptives, a bleeding episode during the first trimester, uterine size that does not agree with dates, and other high risk conditions. In fact, growing evidence suggests that pregnancies should be dated by an ultrasound performed before 22 weeks of gestation rather than by menstrual dates because the ultrasound dating is more accurate than even "sure" menstrual dates (Richards, 2012). A standard set of measurements has been accepted as being the most useful for determining gestational age. These measurements include the crown-rump length (after 10 weeks), the biparietal diameter (BPD) (after 12 weeks), the femur length (after 12 weeks), the head circumference, and the abdominal circumference (Fig. 10-3). An ultrasound

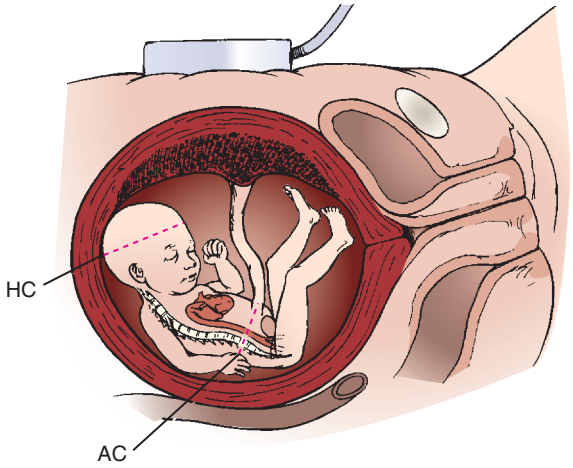

FIG 10-3 Appropriate planes of sections *(dotted lines)* for head circumference *(HC)* and abdominal circumference *(AC)*.

examination performed for pregnancy dating between 14 and 22 weeks of gestation is comparable to one performed during the first trimester in terms of accuracy. However, after that time ultrasound dating is less reliable because of variability in fetal size (Richards, 2012).

Fetal Growth. Fetal growth is determined by both intrinsic growth potential and environmental factors. Conditions that require ultrasound assessment of fetal growth include poor maternal weight gain or pattern of weight gain, previous pregnancy with intrauterine growth restriction (IUGR), chronic infections, ingestion of drugs (tobacco, alcohol, and over-the-counter and street drugs), maternal diabetes, hypertension, multifetal pregnancy, and other medical or surgical complications.

Serial evaluations of BPD, limb length, and abdominal circumference can allow differentiation among size discrepancies resulting from inaccurate dates, true IUGR, and macrosomia. IUGR may be symmetric (the fetus is small in all parameters) or asymmetric (head and body growth do not match). Symmetric IUGR reflects a chronic or long-standing insult and may be caused by low genetic growth potential, intrauterine infection, chromosomal anomaly, maternal undernutrition, or heavy smoking. Asymmetric growth suggests an acute or late-occurring deprivation such as placental insufficiency resulting from hypertension, renal disease, or cardiovascular disease. Reduced fetal growth is still one of the most frequent conditions associated with stillbirth. Macrosomic infants (those weighing 4000 g or more) are at increased risk for traumatic injury and asphyxia during birth. Macrosomia may also be characterized as symmetric or asymmetric.

Fetal Anatomy. Anatomic structures that can be identified by ultrasonography (depending on the gestational age) include the following: head (including ventricles and blood vessels), neck, spine, heart, stomach, small bowel, liver, kidneys, bladder, and limbs. Ultrasonography permits the confirmation of normal anatomy and detection of major fetal malformations. The presence of an anomaly may influence the location of birth (e.g., a subspecialty center versus a basic care center) and the method of birth (vaginal versus cesarean) to optimize neonatal outcomes. For example, plans are often made for a fetus with a condition that will require immediate surgery to be born in or near a hospital able to provide that care rather than in a small community hospital that is totally unequipped to meet the newborn's needs.

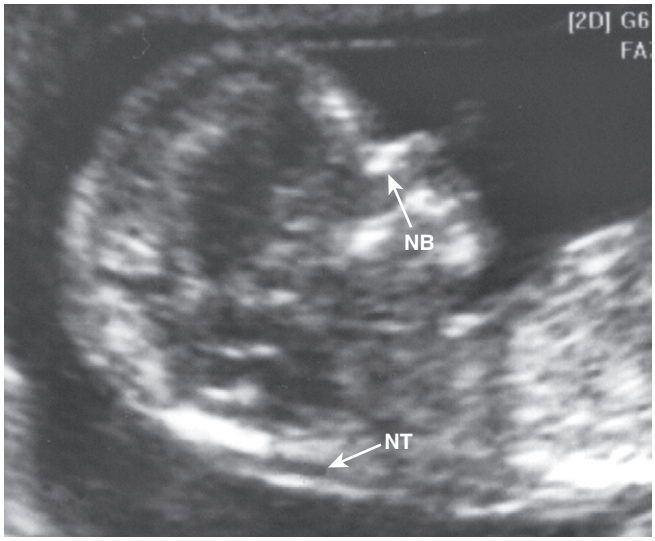

FIG 10-4 Midsagittal view of a 12-week fetus showing the nuchal translucency *(NT)* and nasal bone *(NB)*.

The number of fetuses and their presentations can be assessed by ultrasonography, allowing plans for therapy and mode of birth to be made in advance.

Fetal Genetic Disorders and Physical Anomalies. A prenatal screening technique called *nuchal translucency* (NT) screening uses ultrasound measurement of fluid in the nape of the fetal neck between 10 and 14 weeks of gestation to identify possible fetal abnormalities (Fig. 10-4). A fluid collection that is greater than 3 mm is considered abnormal. When combined with low maternal serum marker levels, elevated NT indicates a possible increased risk of certain chromosomal abnormalities in the fetus, including trisomies 13, 18, and 21. An elevated NT alone indicates an increased risk of fetal cardiac disease. If the NT is abnormal, diagnostic genetic testing is recommended (ACOG, 2009; Gilbert, 2011).

Other ultrasound findings, including the presence or absence (and length, if present) of a nasal bone, short femur or humerus, echogenic intracardiac focus, echogenic bowel, and pyelectasis (enlargement of the renal pelvis, the part of the kidney that collects urine), have been associated with trisomy 21 (Down syndrome) in the fetus. These findings are considered soft markers only; they are not diagnostic for the anomaly. Women in whom these soft markers are found who are at low risk to have a fetus with trisomy 21 should receive expert counseling about the advisability of further diagnostic testing (Simpson, Richards, Otano, et al., 2012).

Placental Position and Function. The pattern of uterine and placental growth and the fullness of the maternal bladder influence the apparent location of the placenta by ultrasonography. During the first trimester differentiation between the endometrium and small placenta is difficult. By 14 to 16 weeks the placenta is clearly defined; but, if it is seen to be low lying, its relationship to the internal cervical os can sometimes be altered dramatically by varying the fullness of the maternal bladder. In approximately 4% to 6% of all pregnancies in which ultrasound scanning is performed during the second trimester, the placenta seems to be overlying the os. However, most cases of placenta previa diagnosed during the second trimester resolve by term, primarily because of the elongation of the lower uterine segment as pregnancy advances. Therefore, if placenta previa is diagnosed during the second trimester, repeated ultrasounds should be performed as pregnancy progresses until the placenta moves well away from the cervical os or it becomes clear that the previa will persist (Francois and Foley, 2012; Richards, 2012).

Another use for ultrasonography is grading of placental aging. Calcium and fibrin deposits in an aging placenta result in intervillous hemorrhagic infarcts. Also, as blood vessels in the placenta age and thicken, oxygen transport is affected. However, whether these placental changes adversely affect fetal outcomes in postterm pregnancies is unknown, given that most fetuses continue to grow (Gilbert, 2011).

Adjunct to Other Invasive Tests. The safety of amniocentesis is increased when the positions of the fetus, placenta, umbilical cord, and pockets of amniotic fluid can be identified accurately. Ultrasound scanning has reduced risks previously associated with amniocentesis such as fetomaternal hemorrhage from a pierced placenta. Percutaneous umbilical blood sampling and chorionic villus sampling also are guided by ultrasonography to identify the cord and chorion frondosum accurately.

Fetal Well-being. Physiologic parameters of the fetus that can be assessed with ultrasound scanning include AFV, vascular waveforms from the fetal circulation, heart motion, fetal breathing movements (FBMs), fetal urine production, and fetal limb and head movements. Assessment of these parameters, alone or in combination, yields a fairly reliable picture of fetal well-being. The significance of these findings is discussed in the following sections.

Doppler Blood Flow Analysis. One of the major advances in perinatal medicine is the ability to study blood flow noninvasively in the fetus and placenta with ultrasound. Doppler blood flow analysis is a helpful tool in the management of pregnancies at risk because of maternal hypertension and diabetes mellitus, IUGR, multiple fetuses, and preterm labor because it provides an indication of fetal adaptation and reserve.

When a sound wave is reflected from a moving target, a change occurs in the frequency of the reflected wave relative to the transmitted wave, called the *Doppler effect*. An ultrasound beam scattered by a group of red blood cells (RBCs) is an example of this effect. The velocity of the RBCs can be determined by measuring the change in the frequency of the sound wave reflected off the cells (Fig. 10-5).

The shifted frequencies can be displayed as a plot of velocity versus time, and the shape of these waveforms can be analyzed to give information about blood flow and resistance in a given circulation. Velocity waveforms from the umbilical and uterine arteries, reported as systolic/diastolic (S/D) ratios, can be first detected at 15 weeks of pregnancy. Because of the progressive decline in resistance in both the umbilical and uterine arteries, this ratio normally decreases as pregnancy advances. Findings of absent or reversed end-diastolic blood flow and S/D ratios above 3 indicate placental vascular disease. IUGR may result from this placental insufficiency. In addition to IUGR, abnormal elevations in the S/D ratio are seen in hypertensive disorders of pregnancy or other causes of uteroplacental insufficiency (UPI) (Baschat, Galan, and Gabbe, 2012; Gilbert, 2011). In postterm pregnancies evaluated by Doppler umbilical flow studies, an elevated S/D ratio indicates a poorly perfused placenta. Abnormal results also are seen with certain chromosomal abnormalities (trisomy 13 and 18) in the fetus and lupus erythematosus in the mother. Exposure to nicotine from maternal smoking also has been reported to increase the S/D ratio (see Fig. 10-5).

Amniotic Fluid Volume. Abnormalities in AFV are frequently associated with fetal disorders. Subjective determinants of oligohydramnios (decreased fluid) include the absence of fluid pockets in the uterine cavity and the impression of crowding of small fetal parts. An objective criterion of decreased AFV is met if the largest pocket of fluid measured in two perpendicular planes is less than

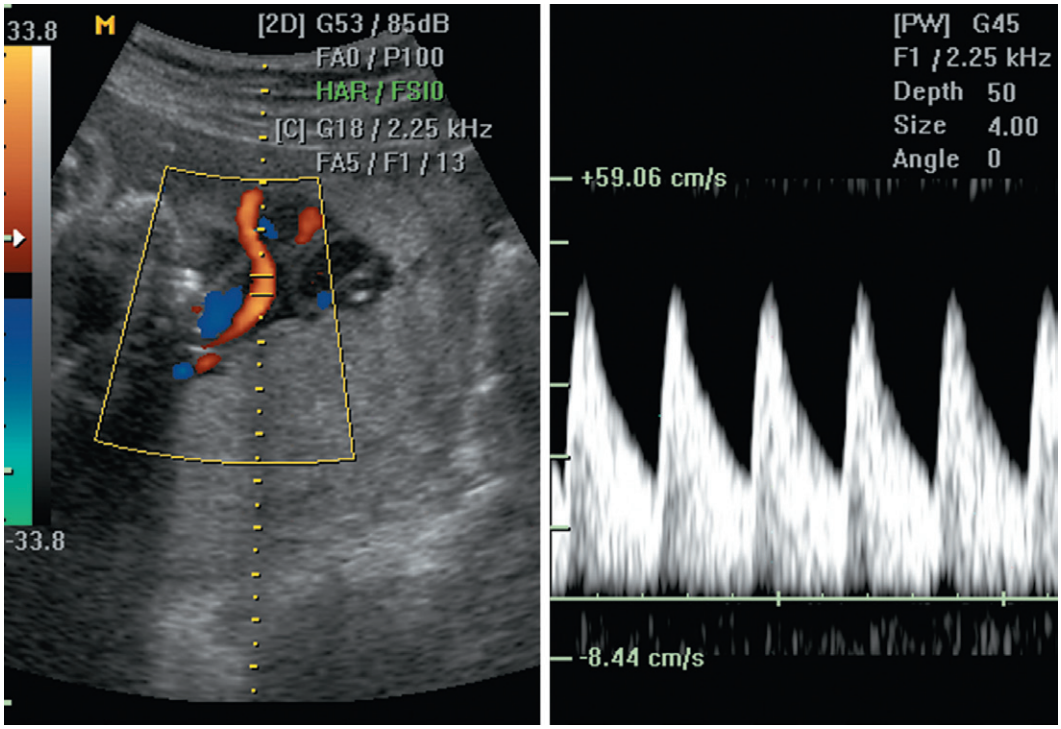

FIG 10-5 Color and spectral Doppler evaluation of the umbilical artery. In the left panel the coiling arteries and vein are shown. *Red* indicates flow toward the transducer, and *blue* is flow away. The sample gate for the pulse Doppler is superimposed. On the right is the result of the pulse Doppler, depicting a normal flow velocity waveform.

2 cm (Harman, 2009). Increased amniotic fluid is called *polyhydramnios* or sometimes just *hydramnios*. Subjective criteria for polyhydramnios include multiple large pockets of fluid, the impression of a floating fetus, and free movement of fetal limbs. Hydramnios is usually defined as pockets of amniotic fluid measuring more than 8 cm (Gilbert, 2012).

The total AFV can be evaluated by a method in which the vertical depths (in centimeters) of the largest pocket of amniotic fluid in all four quadrants surrounding the maternal umbilicus are totaled, providing an amniotic fluid index (AFI). A normal AFI is 10 cm or greater, with the upper range of normal around 25 cm. AFI values between 5 and 10 cm are considered to be low normal, whereas an AFI of less than 5 cm indicates oligohydramnios. With polyhydramnios the AFI would be above 25 cm (Miller, Miller, and Tucker, 2013). Oligohydramnios is associated with congenital anomalies (e.g., renal agenesis [Potter syndrome]), growth restriction, and an abnormal fetal heart rate pattern during labor (caused by compression of the umbilical cord due to the decreased amount of amniotic fluid). Polyhydramnios is associated with neural tube defects (NTDs), obstruction of the fetal gastrointestinal tract, multiple fetuses, and fetal hydrops.

Biophysical Profile. Real-time ultrasound permits detailed assessment of the physical and physiologic characteristics of the developing fetus and cataloging of normal and abnormal biophysical responses to stimuli. The **biophysical profile (BPP)** is a noninvasive dynamic assessment of a fetus that is based on acute and chronic markers of fetal disease. The BPP includes AFV, FBMs, fetal movements, and fetal tone determined by ultrasound and fetal heart rate (FHR) reactivity determined by means of the nonstress test. Therefore the BPP can be considered a physical examination of the fetus, including determination of vital signs. FHR reactivity, FBMs, fetal movement, and fetal tone reflect current central nervous system (CNS) status, whereas the AFV demonstrates the adequacy of placental function over a longer period of time (Miller, Miller, and Tucker, 2013). BPP scoring and management are detailed in Tables 10-2 and 10-3.

The BPP is used frequently in the late second and the third trimester for antepartum fetal testing because it is a reliable predictor of fetal well-being. A BPP of 8 or 10 with a normal AFV is considered normal. Advantages of the test include excellent sensitivity and a low false-negative rate (Miller, Miller, and Tucker, 2013). One limitation of the test is that, if the fetus is in a quiet sleep state, the BPP can require a long period of observation. Also, unless the ultrasound examination is videotaped, it cannot be reviewed (Greenberg, Druzin, and Gabbe, 2012).

Modified Biophysical Profile. The modified BPP (mBPP) is being used increasingly as a way to shorten the testing time required for the complete BPP by assessing the components that are most predictive of perinatal outcome. The mBPP combines the nonstress test, which assesses the current fetal condition, with measurement of the quantity of amniotic fluid, an indicator of placental function over a longer period of time. The AFI (rather than the AFV) is often used to measure the amount of amniotic fluid present. Desired test results are a reactive nonstress test and a normal AFI. An AFI greater than 5 is generally considered normal (Greenberg, Druzin, and Gabbe, 2012; Miller, Miller, and Tucker, 2013).

Nursing Role

Although a growing number of nurses perform ultrasound scans and BPPs in certain centers, the main roles of nurses are counseling and educating women about the procedure. Ultrasound is widely used and in fact is considered a standard part of current prenatal

TABLE 10-2 SCORING THE BIOPHYSICAL PROFILE

BIOPHYSICAL VARIABLE	SCORE 2	SCORE 0
Fetal breathing movements	At least one episode of fetal breathing movements of at least 30-second duration in a 30-minute observation	Absent fetal breathing movements or less than 30 seconds of sustained fetal breathing movements in 30 minutes
Fetal movements	At least three trunk/limb movements in 30 minutes	Fewer than three episodes of trunk/limb movements in 30 minutes
Fetal tone	At least one episode of active extension with return to flexion of fetal limb or trunk; opening and closing of hand considered normal tone	Absence of movement or slow extension/flexion
Amniotic fluid index (AFI)	AFI >5 cm or at least one pocket >2 cm	AFI ≤5 cm and no single pocket >2 cm
Nonstress test	Reactive	Nonreactive

TABLE 10-3 BIOPHYSICAL PROFILE MANAGEMENT

SCORE	INTERPRETATION	MANAGEMENT
10	Normal; low risk for chronic asphyxia	Repeat testing at weekly to twice-weekly intervals.
8	Normal; low risk for chronic asphyxia	Repeat testing at weekly to twice-weekly intervals.
6	Suspect chronic asphyxia	If ≥36-37 weeks of gestation or <36 weeks with positive testing for fetal pulmonary maturity, consider delivery; if <36 weeks and/or fetal pulmonary maturity testing negative, repeat biophysical profile in 4 to 6 hr; deliver if oligohydramnios is present.
4	Suspect chronic asphyxia	If ≥36 weeks of gestation, deliver; if <32 weeks of gestation, repeat score.
0-2	Strongly suspect chronic asphyxia	Extend testing time to 120 min; if persistent score ≤4, deliver, regardless of gestational age.

Modified from Manning FA, Harman CR, Morrison I, et al: Fetal assessment based on fetal biophysical profile scoring, *Am J Obstet Gynecol* 162:703, 1990; and Manning FA: Biophysical profile scoring. In Nijhuis J, editor: *Fetal behaviour,* New York, 1992, Oxford University Press, p 241.

care. Unlike many diagnostic tests, most women look forward to and enjoy their prenatal ultrasound. Exposure to diagnostic ultrasonography during pregnancy appears to be safe for the fetus (Richards, 2012).

Use of Ultrasonography for Nonmedical or "Entertainment" Purposes

In recent years the use of three- and four-dimensional ultrasonography for nonmedical purposes has become increasingly popular with pregnant women and their families. Although insurance does not cover the cost, women can make appointments to have ultrasound images made of the fetus, just as professional photographs are often taken of infants and children. Both the American Institute of Ultrasound in Medicine and the ACOG have published statements that strongly discourage this practice. Although ultrasonography is considered safe, exposure of the fetus to high-frequency sound waves without a clear medical indication for doing so should be avoided. In addition, casual ultrasonography performed by people who are not qualified health care professionals could give false reassurance to women or result in the discovery of abnormalities in settings that are not conducive to discussion and follow-up of findings (ACOG, 2009; Richards, 2012).

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive radiologic technique used for obstetric and gynecologic diagnosis. Similar to computed tomography (CT), MRI provides excellent pictures of soft tissue. Unlike CT, ionizing radiation is not used. Therefore vascular structures within the body can be visualized and evaluated without injecting an iodinated contrast medium, thus eliminating any known biologic risk. Similar to sonography, MRI is noninvasive and can provide images in multiple planes, but no interference occurs from skeletal, fatty, or gas-filled structures, and imaging of deep pelvic structures does not require a full bladder.

With MRI the examiner can evaluate fetal structure (CNS, thorax, abdomen, genitourinary tract, musculoskeletal system) and overall growth, the placenta (position, density, and presence of gestational trophoblastic disease), and the quantity of amniotic fluid. Maternal structures (uterus, cervix, adnexa, and pelvis), the biochemical status (pH, adenosine triphosphate content) of tissues and organs, and soft-tissue, metabolic, or functional anomalies can also be evaluated.

The woman is placed on a table in the supine position and moved into the bore of the main magnet, which is similar in appearance to a CT scanner. Depending on the reason for the study, the procedure may take from 20 to 60 minutes, during which time the woman must be perfectly still except for short respites. Because of the long time needed to produce MRIs, the fetus will probably move, which will obscure anatomic details. The only way to ensure that this problem does not occur is to administer a sedative to the mother, but this approach should be reserved for selected cases in which visualization of fetal detail is critical.

MRI has little effect on the fetus. Concerns that the FHR or fetal movement would decrease have not been supported.

BIOCHEMICAL ASSESSMENT

Biochemical assessment involves biologic examination (e.g., of chromosomes in exfoliated cells) and chemical determinations (e.g., lecithin/sphingomyelin [L/S] ratio, or surfactant/albumin [S/A] ratio [TDX FLM assay]) (Table 10-4). Procedures used to obtain the

TABLE 10-4 SUMMARY OF BIOCHEMICAL MONITORING TECHNIQUES

TEST	POSSIBLE FINDINGS	CLINICAL SIGNIFICANCE
Maternal Blood		
Coombs' test	Titer of 1:8 and increasing	Significant Rh incompatibility
AFP	See AFP later in table	
Amniotic Fluid Analysis		
Lung profile:		Fetal lung maturity
L/S ratio	2:1	
Phosphatidylglycerol	Present	
S/A ratio (TDX FLM assay)	≥55 mg/g	
Creatinine	>2 mg/dL	Gestational age >36 weeks
Lipid cells	>10%	Gestational age >35 weeks
AFP	High levels after 15 weeks of gestation	Open neural tube or other defect
Osmolality	Declines after 20 weeks of gestation	Advancing gestational age
Genetic disorders: Sex-linked Chromosomal Metabolic	Dependent on cultured cells for karyotype and enzymatic activity	Counseling possibly required

BOX 10-5 FETAL RIGHTS

Amniocentesis, percutaneous umbilical blood sampling (PUBS), and chorionic villus sampling (CVS) are prenatal tests used for diagnosing fetal defects in pregnancy. They are invasive and carry risks to the mother and fetus. A consideration of induced abortion is linked to the performance of these tests because no treatment for genetically affected fetuses has been developed; therefore the issue of fetal rights is a key ethical concern in prenatal testing for fetal defects.

needed specimens include amniocentesis, percutaneous umbilical blood sampling, chorionic villus sampling, and maternal sampling (Box 10-5).

Amniocentesis

Amniocentesis is performed to obtain amniotic fluid, which contains fetal cells. Under direct ultrasonographic visualization, a needle is inserted transabdominally into the uterus, amniotic fluid is withdrawn into a syringe, and the various assessments are performed (Fig. 10-6). Amniocentesis is possible after week 14 of pregnancy, when the uterus becomes an abdominal organ and sufficient amniotic fluid is available for testing. Indications for the procedure include prenatal diagnosis of genetic disorders or congenital anomalies (NTDs in particular), assessment of pulmonary maturity, and rarely diagnosis of fetal hemolytic disease.

Complications in the mother and fetus occur in less than 1% of cases and include the following:

- *Maternal:* Leakage of amniotic fluid, hemorrhage, fetomaternal hemorrhage with possible maternal Rh isoimmunization, infection, labor, placental abruption, inadvertent damage to the intestines or bladder, and amniotic fluid embolism (anaphylactoid syndrome of pregnancy)
- *Fetal:* Death, hemorrhage, infection (amnionitis), and direct injury from the needle

Many of the complications have been minimized or eliminated by using ultrasonography to direct the procedure.

SAFETY ALERT

Because of the possibility of fetomaternal hemorrhage, administering Rh_oD immunoglobulin to the woman who is Rh negative is standard practice after an amniocentesis.

Indications for Use

Genetic Concerns. Historically prenatal assessment of genetic disorders focused on women older than 35 years (Box 10-6), women with a previous child with a chromosomal abnormality, or a family history of chromosomal anomalies. Inherited errors of metabolism (such as Tay-Sachs disease), hemophilia, thalassemia, and other disorders for which marker genes are known also can be detected by prenatal screening. Fetal cells can be cultured for karyotyping of chromosomes (see Chapter 6). Karyotyping also permits determination of fetal gender, which is important if an X-linked disorder (occurring almost always in a male fetus) is suspected.

Biochemical analysis of enzymes in amniotic fluid can detect inborn errors of metabolism or fetal structural anomalies. For example, alpha-fetoprotein (AFP) levels in amniotic fluid are assessed as a follow-up for elevated levels in maternal serum. High AFP levels in amniotic fluid help confirm the diagnosis of an NTD such as spina bifida or anencephaly or an abdominal wall defect such as omphalocele. The elevation results from the increased leakage of cerebrospinal or abdominal fluid into the amniotic fluid through the closure defect. AFP levels may also be elevated in a normal multifetal pregnancy and intestinal atresia, presumably caused by lack of fetal swallowing.

A concurrent test that finds the presence of acetylcholinesterase almost always indicates a fetal defect (Wapner, Jenkins, and Khalek, 2009). In such instances follow-up ultrasound examination is recommended.

Fetal Maturity. Late in pregnancy accurate assessment of fetal lung maturity is possible by examining amniotic fluid for the presence of **phosphatidylglycerol (PG).** Determination of the L/S ratio and the S/A ratio [TDx FLM assay] are other methods to evaluate it. The FLM assay is often used as the primary test for determining fetal lung maturity in clinical practice because it is simple to perform and accurate. FLM test results are similar to those of the PG test and the L/S ratio in terms of predicting pulmonary maturity (Mercer, 2009) (see Table 10-4).

Fetal Hemolytic Disease. In the past amniocentesis was used for identification and follow-up of fetal hemolytic disease in cases of

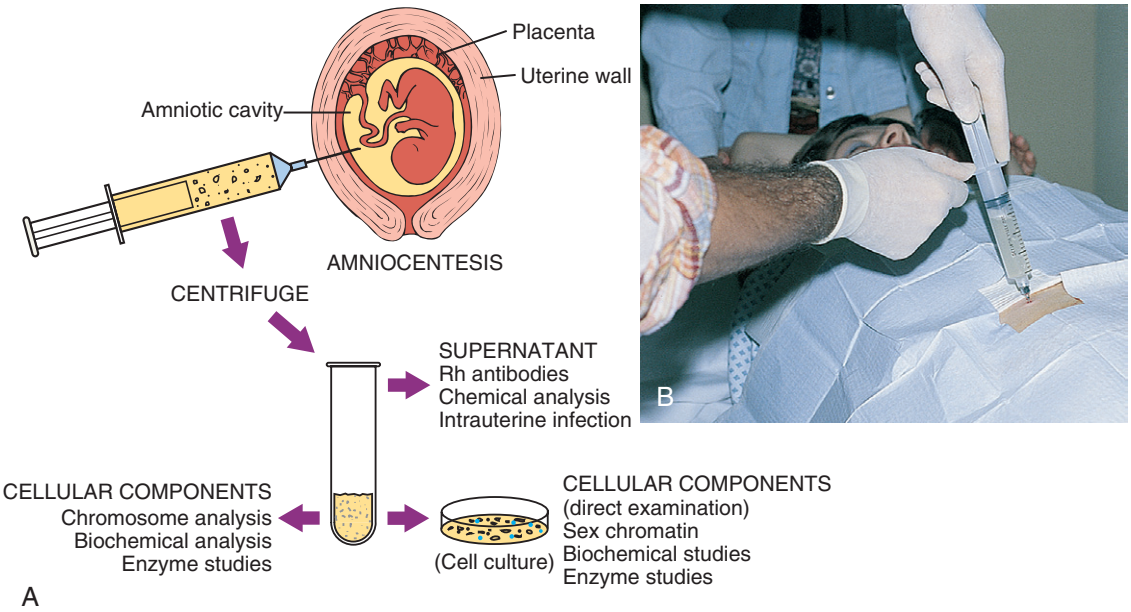

FIG 10-6 **A,** Amniocentesis and laboratory use of amniotic fluid aspirant. **B,** Transabdominal amniocentesis. (*B,* Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

BOX 10-6 ELIMINATION OF MATERNAL AGE AS AN INDICATION FOR INVASIVE PRENATAL DIAGNOSIS

Maternal age of 35 years and older has been a standard indication for invasive prenatal testing since 1979. However, because most genetically abnormal children are born to parents of varying ages who have no history of abnormality, genetic screening is now recommended for all women, regardless of age (Gilbert, 2011). The American College of Obstetricians and Gynecologists (ACOG) published new guidelines in 2007 (and reaffirmed them in 2011) stating that no specific age should be used as a threshold for invasive or noninvasive screening. Furthermore, all women, regardless of age, should have the option of invasive testing without first having screening (ACOG, 2007).

isoimmunization. Amniocentesis is now only performed for this reason in rare circumstances because of the availability of noninvasive testing. Doppler velocimetry of the fetal middle cerebral artery is now the method of choice to monitor accurately and noninvasively for fetal anemia in isoimmunized pregnancies (Moise, 2012).

Chorionic Villus Sampling

The combined advantages of earlier diagnosis and rapid results have made **chorionic villus sampling (CVS)** a popular technique for genetic studies in the first trimester. Indications for CVS are similar to those for amniocentesis, although CVS cannot be used for maternal serum marker screening because no fluid is obtained. CVS performed in the second trimester carries no greater risk of pregnancy loss than amniocentesis and is considered equal to amniocentesis in diagnostic accuracy. When performed after the first trimester, the procedure is better known as *late CVS* or *placental biopsy* (Simpson, Richards, Otano, et al., 2012).

CVS can be performed in the first or second trimester, ideally between 10 and 13 weeks of gestation, and involves the removal of a small tissue specimen from the fetal portion of the placenta

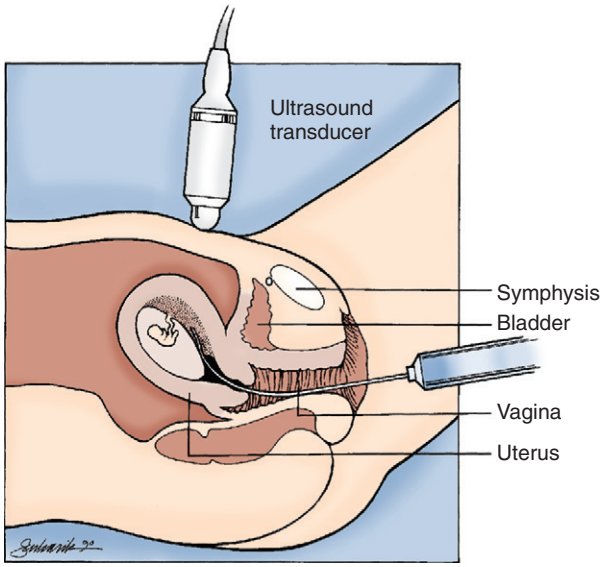

FIG 10-7 Transcervical chorionic villus sampling. (From Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: normal and problem pregnancies,* ed 6, Philadelphia, 2012, Saunders.)

(Figs. 10-7 and 10-8). Because chorionic villi originate in the zygote, this tissue reflects the genetic makeup of the fetus (Gilbert, 2011).

CVS procedures can be accomplished transcervically or transabdominally. In transcervical sampling a sterile catheter is introduced into the cervix under continuous ultrasonographic guidance, and a small portion of the chorionic villi is aspirated with a syringe. The aspiration cannula and obturator must be placed at a suitable site, and rupture of the amniotic sac must be avoided (see Fig. 10-7). The transcervical procedure is contraindicated if a cervical infection such as chlamydia or herpes is present (Gilbert, 2011).

If the abdominal approach is used, an 18- or 20-gauge spinal needle with stylet is inserted under sterile conditions through the abdominal wall into the chorion frondosum under ultrasound

guidance. The stylet is then withdrawn, and the chorionic tissue is aspirated into a syringe (see Fig. 10-8).

CVS is a relatively safe procedure. The incidence of IUGR, placental abruption, and preterm birth is no higher in women undergoing CVS than would be expected in the general population. In the early 1990s there was controversy concerning an increased risk for fetal limb reduction defects associated with CVS. However, the consensus of further studies is that, when CVS is performed after 9 completed weeks of gestation, the risk for limb reduction defects is no higher than it is in the general population (Simpson, Richards, Otano, et al., 2012).

SAFETY ALERT

Because of the possibility of fetomaternal hemorrhage, women who are Rh negative should receive immunoglobulin after CVS to prevent isoimmunization, regardless of whether the procedure is performed transcervically or transabdominally, unless the fetus is known to be Rh negative (Simpson, Richards, Otano, et al., 2012).

Use of amniocentesis and CVS is declining because of advances in noninvasive screening techniques. These techniques include measurement of NT, maternal serum screening tests in the first and second trimesters, and ultrasonography in the second trimester (Wapner, Jenkins, and Khalek, 2009).

Percutaneous Umbilical Blood Sampling

Direct access to the fetal circulation during the second and third trimesters is possible through percutaneous umbilical blood sampling (PUBS) (also called cordocentesis). PUBS can be used for fetal blood sampling and transfusion. However, PUBS has been replaced in many centers by placental biopsy because it is a safer, easier, and faster alternative. Also, improvements in cytogenetic and molecular diagnostic testing have decreased the need for fetal blood samples. Many tests that were once performed using fetal blood can now be done using deoxyribonucleic acid (DNA)–based analysis of chorionic villi (Simpson, Richards, Otano, et al., 2012).

PUBS involves the insertion of a needle directly into a fetal umbilical vessel, preferably the vein, under ultrasound guidance. Ideally the umbilical cord is punctured near its insertion into the placenta (Figs. 10-9 and 10-10). At this point the cord is well anchored and will not move, and the risk of maternal blood contamination (from the placenta) is slight. Generally a small amount of blood is removed and tested immediately by the Kleihauer-Betke procedure (Apt test) to ensure that it is fetal in origin (Simpson, Richards, Otano, et al., 2012). Indications for use of PUBS include prenatal diagnosis of inherited blood disorders, karyotyping of malformed fetuses, detection of fetal infection, and assessment and treatment of isoimmunization and thrombocytopenia in the fetus (Wapner, Jenkins, and Khalek, 2009). Complications that can occur

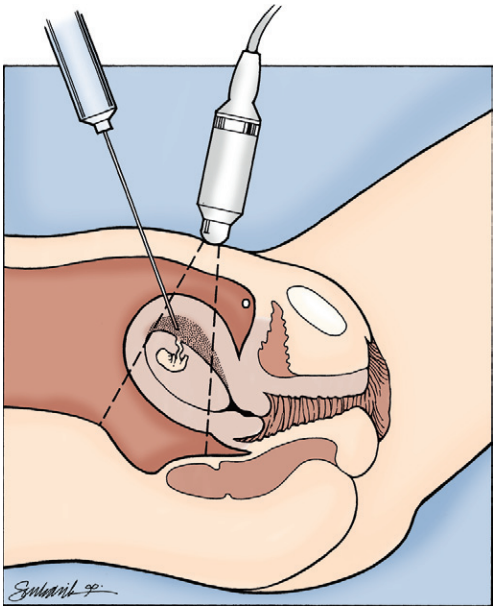

FIG 10-8 Transabdominal chorionic villus sampling. (From Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: normal and problem pregnancies,* ed 6, Philadelphia, 2012, Saunders.)

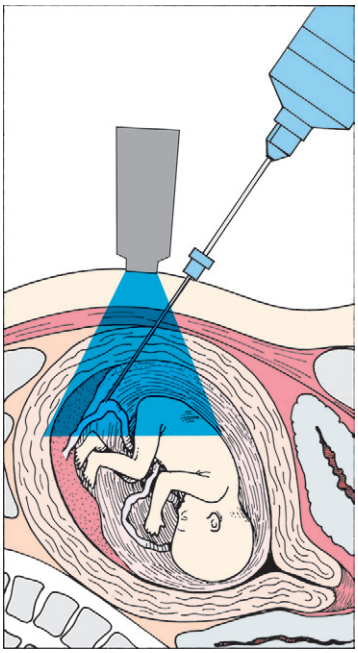

FIG 10-9 Technique for percutaneous umbilical blood sampling guided by ultrasound.

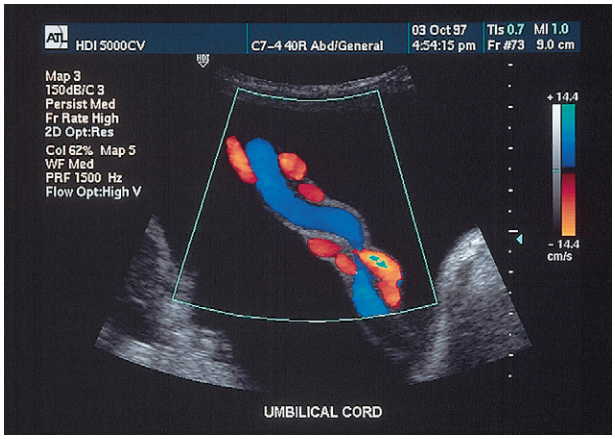

FIG 10-10 Umbilical cord as seen on ultrasound at 26 weeks of gestation. (Courtesy Advanced Technology Laboratories, Bothell, WA.)

include loss of the pregnancy, hematomas, bleeding from the puncture site in the umbilical cord, transient fetal bradycardia, and fetomaternal hemorrhage. Maternal complications are rare but include hemorrhage and transplacental hemorrhage (Simpson, Richards, Otano, et al., 2012).

In fetuses at risk for isoimmune hemolytic anemia, PUBS permits precise identification of fetal blood type and RBC count and may prevent the need for further intervention. If the fetus is positive for the presence of maternal antibodies, a direct blood test can confirm the degree of anemia resulting from hemolysis. Intrauterine transfusion of severely anemic fetuses can be performed 4 to 5 weeks earlier than through the intraperitoneal route.

Follow-up includes continuous FHR monitoring for 1 to 2 hours after the procedure. Women should also be taught to count fetal movements at home (Gilbert, 2011).

Maternal Assays

Alpha-Fetoprotein

Maternal serum **alpha-fetoprotein** (MSAFP) levels are used as a screening tool for NTDs in pregnancy. Through this technique approximately 80% to 85% of all open NTDs and open abdominal wall defects can be detected early. Screening is recommended for all pregnant women.

The cause of NTDs is not well understood, but 95% of all affected infants are born to women with no family history of similar anomalies (Wapner, Jenkins, and Khalek, 2009). The defect occurs in approximately 2 of 1000 births in the United States. The rate of NTDs is decreasing as a result of the use of folate preconceptionally and during early pregnancy for prevention of this condition (Manning, 2009).

AFP is produced by the fetal liver, and increasing levels are detectable in the serum of pregnant women from 14 to 34 weeks of gestation. Although amniotic fluid AFP measurement is diagnostic for NTD, MSAFP is a screening tool only and identifies candidates for the more definitive procedures of amniocentesis and ultrasound examination. MSAFP screening can be performed with reasonable reliability any time between 15 and 20 weeks of gestation (16 to 18 weeks being ideal) (Wapner, Jenkins, and Khalek, 2009).

Once the maternal level of AFP is determined, it is compared with normal values for each week of gestation. Values also should be correlated with maternal age, weight, race, presence of a multifetal pregnancy, and whether the woman has insulin-dependent diabetes. If findings are abnormal, follow-up procedures include genetic counseling for families with a history of NTD, repeated AFP, specialized ultrasound examination, and possibly amniocentesis (Cunningham, Leveno, Bloom, et al., 2010).

Multiple Marker Screens

Screening to detect fetal chromosomal abnormalities, particularly trisomy 21 (Down syndrome) is now available, beginning in the first trimester of pregnancy. This first-trimester screen is done at 11 to 14 weeks of gestation. It includes measurement of two maternal biochemical markers, pregnancy-associated placental protein (PAPP-A) and human chorionic gonadotropin (hCG) or the free beta-human chorionic gonadotropin (β-hCG) subunit, and evaluation of fetal NT, or a combination of both. In the presence of a fetus with trisomy 21, hCG levels are higher than normal in the first trimester, whereas PAPP-A levels are lower than normal. First-trimester screening using PAPP-A and hCG or β-hCG levels has been shown to be as accurate for detecting fetuses with trisomy 21 as triple screening in the second trimester (Cunningham, Leveno, Bloom, et al., 2010; Wapner, Jenkins, and Khalek, 2009).

About one third of all fetuses with an increased NT have a chromosomal abnormality; half of these are trisomy 21. Combining the serum marker and NT values results in the detection of Down syndrome in 79% to 87% of cases. These results are comparable to those obtained with quad screening in the second trimester (Cunningham, Leveno, Bloom, et al., 2010).

In the second trimester triple and quad screening are available to screen for fetuses with trisomy 21 and trisomy 18. The *triple-marker screen,* performed at 16 to 18 weeks of gestation, measures the levels of three maternal serum markers: MSAFP, unconjugated estriol, and hCG. In the presence of a fetus with trisomy 21 the MSAFP and unconjugated estriol levels are low, whereas the hCG level is elevated. Low values in all three markers are associated with trisomy 18 (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011).

The *quad-screen* adds an additional marker, a placental hormone called *inhibin A,* to increase the accuracy of screening for Down syndrome in women less than 35 years of age. Low inhibin A levels indicate the possibility of Down syndrome (Gilbert, 2011). The addition of inhibin A to the other three markers increases the detection rate for Down syndrome to about 75% in women who are less than 35 years of age and to more than 80% in women 35 years of age or older (Simpson, Richards, Otano, et al., 2012). Similar to triple marker screening, the optimal time to perform the quad screen is between 16 and 18 weeks of gestation (Gilbert, 2011).

The ability of multiple marker tests to detect chromosomal abnormalities depends on the accuracy of gestational age assessment. These tests are screening procedures only and are not diagnostic. A positive screening test result indicates an increased risk but is not diagnostic of trisomy 21 or another chromosome abnormality. Women with positive results should be offered diagnostic testing by amniocentesis or fetal blood sampling for fetal karyotyping (Cunningham, Leveno, Bloom, et al., 2010).

Coombs Test

The indirect Coombs test is a screening tool for Rh incompatibility. If the maternal titer for Rh antibodies is greater than 1:8, amniocentesis for determination of bilirubin in amniotic fluid is indicated to establish the severity of fetal hemolytic anemia. However, as previously discussed, middle cerebral artery Doppler studies to determine the degree of fetal hemolysis have almost entirely replaced serial amniocentesis (Moise, 2012). The Coombs test can also detect other antibodies that may place the fetus at risk for incompatibility with maternal antigens.

Cell-Free Deoxyribonucleic Acid in Maternal Blood

A new screening method for noninvasive prenatal genetic diagnosis has recently become available for use in the clinical setting. Cell-free DNA screening already provides a definitive diagnosis noninvasively for fetal Rh status, fetal gender, and certain paternally transmitted single gene disorders (Simpson, Richards, Otano, et al., 2012).

The method works by amplifying cell-free DNA. If the fetus has a normal karyotype, the amount of DNA is consistent with the known standard for the normal amount. For example, if more than the expected amount of chromosome 21 DNA is detected, it can then be assumed that the fetus is contributing the extra amount and therefore has trisomy 21. The same is true for trisomy 13 and 18. The test cannot actually distinguish fetal from maternal DNA, but it can accurately predict the fetal status by measuring the amount of DNA circulating in maternal blood and comparing it to known standards. The cell-free DNA screen in combination with ultrasound does not provide a definitive diagnosis for all cases of fetal

trisomy 21. Women who have a positive cell-free circulating DNA test without confirming ultrasound findings or a negative blood screen with abnormal ultrasound findings require invasive diagnostic testing such as amniocentesis or CVS for a definitive diagnosis (Palomaki, Kloza, Lambert-Messerlian, et al., 2011).

Circulating cell-free DNA studies for the detection of fetal chromosomal abnormalities can be performed any time after 10 weeks of gestation. The test is offered to women considered to be at risk for chromosomal abnormalities, including those with advanced maternal age, screen-positive maternal serum screens, or ultrasound abnormalities. Women who have previously given birth to a child with a chromosomal abnormality are also candidates for the screen. It is simple to perform; a sample of maternal blood is obtained by venipuncture and sent to a commercial laboratory. Results are usually available in about 10 business days. The screen has been shown to be 98% effective at detecting trisomy 21 and 99% effective at detecting trisomies 13 or 18. In less than 1% of cases no result is available because not enough DNA was retrieved to perform the screen (Palomaki, Kloza, Lambert-Messerlian, et al., 2011; Palomaki, Deciu, Kloza, et al., 2012).

ANTEPARTUM ASSESSMENT USING ELECTRONIC FETAL MONITORING

Indications

First- and second-trimester antepartum assessment is directed primarily at the diagnosis of fetal anomalies. The goal of third-trimester testing is to determine whether the intrauterine environment continues to support the fetus. The testing is often used to determine the timing of childbirth for women at risk for UPI. Gradual loss of placental function results first in inadequate nutrient delivery to the fetus, leading to IUGR. Subsequently respiratory function also is compromised, resulting in fetal hypoxia. Evidence-based recommendations for condition-specific testing schemes in cases of identified risk factors have been difficult to develop and often do not exist. There is no ideal single test or testing strategy for all high risk pregnancies (Greenberg, Druzin, and Gabbe, 2012).

However, there is evidence to support antepartum assessment using electronic fetal monitoring in pregnancies complicated by the risk factors listed in Box 10-7. Currently the nonstress test and the mBPP are the primary methods used for antepartum fetal evaluation in high risk patients at most sites. The complete BPP and the contraction stress test are used for follow-up evaluation in patients who have a persistently nonreactive nonstress test or mBPP. Traditionally testing has begun at 32 to 34 weeks of gestation, with earlier initiation of testing recommended for women with multiple high risk conditions. Testing is usually performed once or twice weekly (Greenberg, Druzin, and Gabbe, 2012).

BOX 10-7 INDICATIONS FOR FETAL ASSESSMENT USING ELECTRONIC FETAL MONITORING

- Diabetes
- Hypertension
- Intrauterine growth restriction
- Multiple gestation
- Oligohydramnios
- Intrahepatic cholestasis
- Renal disease
- Decreased fetal movement
- Previous fetal death
- Postterm pregnancy
- Systemic lupus erythematosus

Data from Greenberg M, Druzin M, Gabbe S: Antepartum fetal evaluation. In Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: Normal and problem pregnancies*, ed 6, Philadelphia, 2012, Saunders.

Nonstress Test

The **nonstress test (NST)** is the most widely applied technique for antepartum evaluation of the fetus. The basis for the NST is that the normal fetus produces characteristic heart rate patterns in response to fetal movement, uterine contractions, or stimulation. In the term fetus, accelerations are associated with movement more than 85% of the time (Greenberg, Druzin, and Gabbe, 2012). The most common reason for the absence of FHR accelerations is the quiet fetal sleep state. However, medications such as narcotics, barbiturates, and beta-blockers; maternal smoking; and the presence of fetal malformations can also adversely affect the test (Gilbert, 2011; Greenberg, Druzin, and Gabbe, 2012). The NST can be performed easily and quickly in an outpatient setting because it is noninvasive, easy to perform and interpret, relatively inexpensive, and has no known contraindications. In most cases only 10 to 15 minutes are required to complete the test. Disadvantages include the requirement for twice-weekly testing and a high false-positive rate. The test also is slightly less sensitive in detecting fetal compromise than the contraction stress test or the BPP (Greenberg, Druzin, and Gabbe, 2012; Miller, Miller, and Tucker, 2013).

Procedure

The woman is seated in a reclining chair (or in semi-Fowler position) with a slight lateral tilt to optimize uterine perfusion and prevent supine hypotension. The FHR is recorded with a Doppler transducer, and a tocodynamometer is applied to detect uterine contractions or fetal movements. The tracing is observed for signs of fetal activity and a concurrent acceleration of FHR. If evidence of fetal movement is not apparent on the tracing, the woman may be asked to depress a button on a handheld event marker connected to the monitor when she feels fetal movement. The movement is then noted on the tracing. Because almost all accelerations are accompanied by fetal movement, the movements need not be recorded for the test to be considered reactive. The test is usually completed within 20 to 30 minutes, but more time may be required if the fetus must be awakened from a sleep state.

Care providers sometimes suggest that the woman drink orange juice or be given glucose to increase her blood sugar level and thereby stimulate fetal movements. Although this practice is common, there is no evidence that it increases fetal activity (Greenberg, Druzin, and Gabbe, 2012).

Vibroacoustic stimulation is often used to stimulate fetal activity if the initial NST result is nonreactive and thus hopefully shortens the time required to complete the test (Greenberg, Druzin, and Gabbe, 2012).

Interpretation

NST results are either reactive (Fig. 10-11) or nonreactive (Fig. 10-12). Box 10-8 lists criteria for both results.

A nonreactive test requires further evaluation. The testing period is often extended, usually for an additional 20 minutes, with the expectation that the fetal sleep state will change and the test will become reactive. During this time vibroacoustic stimulation (see later discussion) may be used to stimulate fetal activity. If the test does not meet the criteria after 40 minutes, a BPP usually will be

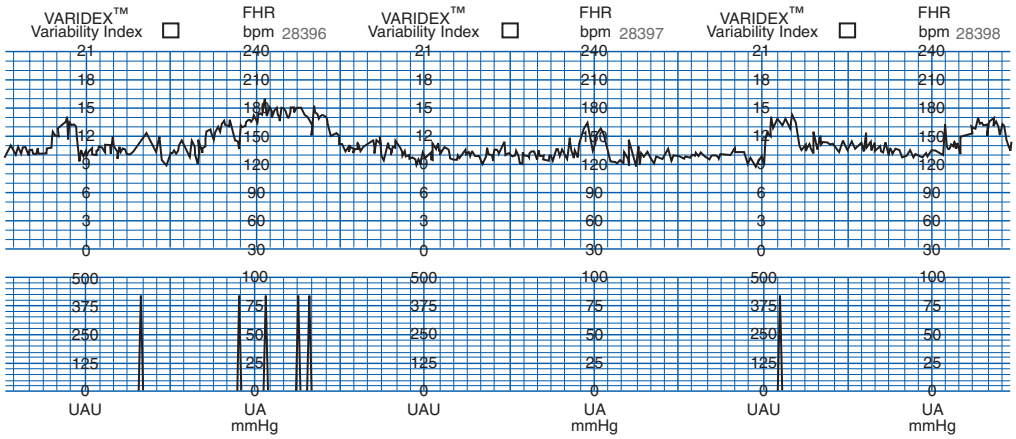

FIG 10-11 Reactive nonstress test. (From Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: normal and problem pregnancies,* ed 6, Philadelphia, 2012, Saunders.)

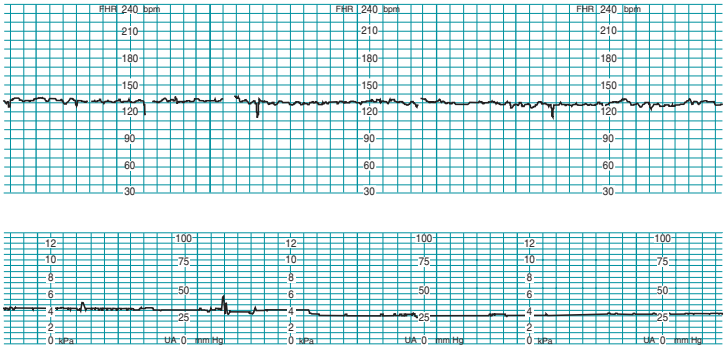

FIG 10-12 Segment of nonreactive nonstress test in term pregnancy. The lack of accelerations meeting minimum criteria continued for 40 minutes. (From Miller LA, Miller DA, Tucker SM: *Mosby's pocket guide to fetal monitoring: a multidisciplinary approach*, ed 7, St Louis, 2013, Mosby.)

performed. Once NST testing is initiated, it is usually repeated once or twice weekly for the remainder of the pregnancy (Greenberg, Druzin, and Gabbe, 2012) (see Critical Thinking Case Study).

Vibroacoustic Stimulation

Vibroacoustic stimulation (also called the *fetal acoustic stimulation test [FAST]*) is another method of testing antepartum FHR response. This test is generally performed in conjunction with the NST and uses a combination of sound and vibration to stimulate the fetus. Whether the acoustic or the vibratory component alters the fetal state is unclear. The fetus is monitored for 5 minutes before

BOX 10-8 INTERPRETATION OF THE NONSTRESS TEST

Reactive test: Two accelerations in a 20-minute period, each lasting at least 15 seconds and peaking at least 15 beats/min above the baseline. (Before 32 weeks of gestation, an acceleration is defined as a rise of at least 10 beats/min lasting at least 10 seconds from onset to offset) (see Fig. 10-11).

Nonreactive test: A test that does not demonstrate at least two qualifying accelerations within a 20-minute window (see Fig. 10-12).

From Miller LA, Miller DA, Tucker SM: *Mosby's pocket guide to fetal monitoring: a multidisciplinary approach*, ed 7, St Louis, 2013, Mosby.

CRITICAL THINKING CASE STUDY

Fetal Assessment Using the Nonstress Test

LaTonya is a 30-year-old G5 T3 P0 A1 L3 who is now at 32 weeks of gestation. LaTonya was diagnosed with diabetes 4 years ago and also has chronic hypertension. Her physician has scheduled her for twice-weekly nonstress testing, and this appointment is her first. You are the nurse assigned to perform LaTonya's nonstress test (NST) today. As you help her get comfortable and attach the fetal heart rate and contraction monitors, LaTonya grumbles, "I don't see why I had to come get this test done. It was really hard to find a babysitter for my kids, and I live on the other side of town!"

1. Evidence—Is there sufficient evidence regarding the benefits of performing fetal assessment using the nonstress test during the third trimester of pregnancy in women who have preexisting diabetes and chronic hypertension?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. The physiologic principle on which the NST is based
   b. Advantages of the NST
   c. The desired result of the NST
   d. LaTonya's understanding of why the test is necessary
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

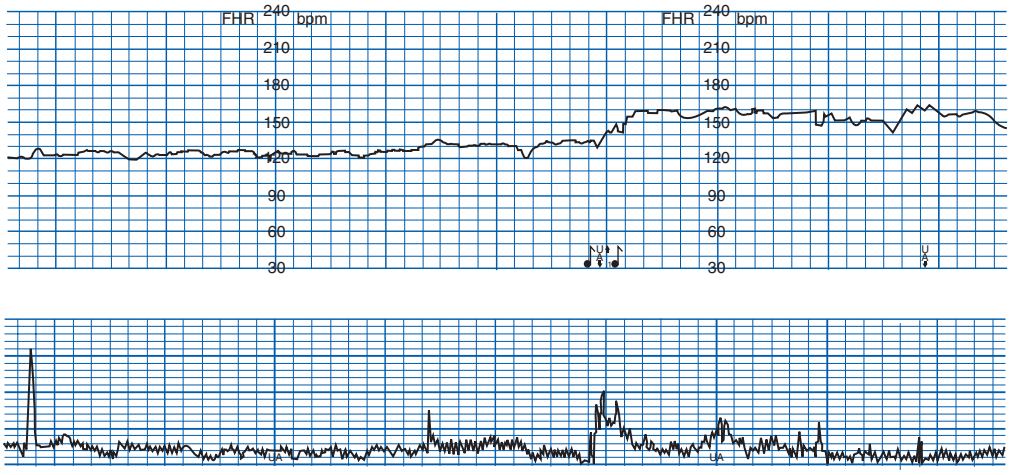

FIG 10-13 Reactive nonstress test after vibroacoustic stimulation. The stimulus was applied at the point marked by the musical notes. A sustained fetal heart rate acceleration was produced. (From Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: normal and problem pregnancies,* ed 6, Philadelphia, 2012, Saunders.)

stimulation to obtain a baseline FHR. If the fetal baseline pattern is nonreactive, the sound source (usually a laryngeal stimulator) is then activated for 3 seconds on the maternal abdomen over the fetal head. The desired result is a reactive NST, which usually occurs within 3 minutes of stimulation. The accelerations produced may have a significant increase in duration (Fig. 10-13). The test may be repeated at 1-minute intervals up to 3 times when no response is noted. Further evaluation is needed with BPP or contraction stress test if the pattern is still nonreactive (Greenberg, Druzin, and Gabbe, 2012).

Contraction Stress Test

The **contraction stress test (CST)** or **oxytocin challenge test (OCT)** was the first widely used electronic fetal assessment test. It was devised as a graded stress test of the fetus, and its purpose was to identify the jeopardized fetus that was stable at rest but showed evidence of compromise after stress. Uterine contractions decrease uterine blood flow and placental perfusion. If this decrease is sufficient to produce hypoxia in the fetus, a deceleration in FHR results.

! NURSING ALERT

In a healthy fetoplacental unit uterine contractions do not usually produce late decelerations; whereas, if underlying UPI exists, contractions produce late decelerations.

The CST provides an earlier warning of fetal compromise than the NST and produces fewer false-positive results. However, the CST is more time consuming and expensive than the NST. It is also an invasive procedure if oxytocin stimulation is required. In general the CST cannot be performed on women who should not give birth vaginally at the time the test is done. Absolute contraindications for the CST are the following: preterm labor, placenta previa, vasa previa, reduced cervical competence, multiple gestations, and previous classic incision for cesarean birth (Miller, Miller, and Tucker, 2013). Because of these disadvantages, the CST is used infrequently.

Procedure

The woman is placed in semi-Fowler position or sits in a reclining chair with a slight lateral tilt to optimize uterine perfusion and avoid supine hypotension. She is monitored electronically with the fetal ultrasound transducer and uterine tocodynamometer. The tracing is observed for 10 to 20 minutes for baseline rate and variability and the possible occurrence of spontaneous contractions. The two methods of CST are the nipple-stimulated contraction test and the more commonly used oxytocin-stimulated contraction test.

Nipple-Stimulated Contraction Test. Several methods of nipple stimulation have been described. In one approach the woman applies warm, moist washcloths to both breasts for several minutes. She is then asked to massage one nipple for 10 minutes. Massaging the nipple causes a release of oxytocin from the posterior pituitary. An alternative approach is for her to massage one nipple through her clothes for 2 minutes, rest for 5 minutes, and repeat the cycles of massage and rest as necessary to achieve adequate uterine activity. When adequate contractions or hyperstimulation (defined as uterine contractions lasting more than 90 seconds or five or more contractions in 10 minutes) occurs, stimulation should be stopped.

Oxytocin-Stimulated Contraction Test. Exogenous oxytocin also can be used to stimulate uterine contractions. An intravenous (IV) infusion is begun, and a dilute solution of oxytocin (e.g., 30 units in 500 mL of fluid) is infused into the tubing of the main IV line through a piggyback port and delivered by an infusion pump to ensure an accurate dose. One method of oxytocin infusion is to begin at 0.5 milliunits/min and double the dose every 20 minutes until three uterine contractions of moderate intensity, each lasting 40 to 60 seconds, are observed within a 10-minute period. These criteria for contractions were selected to approximate the stress experienced by the fetus during the first stage of labor (Greenberg, Druzin, and Gabbe, 2012).

Interpretation

CST results are negative, positive, equivocal, suspicious, or unsatisfactory. If no late decelerations are observed with the contractions, the findings are considered negative (Fig. 10-14, *A*). Repetitive late decelerations render the test results positive (see Fig. 10-14, *B*). Table 10-5 lists criteria for each possible test result and the clinical significance of each.

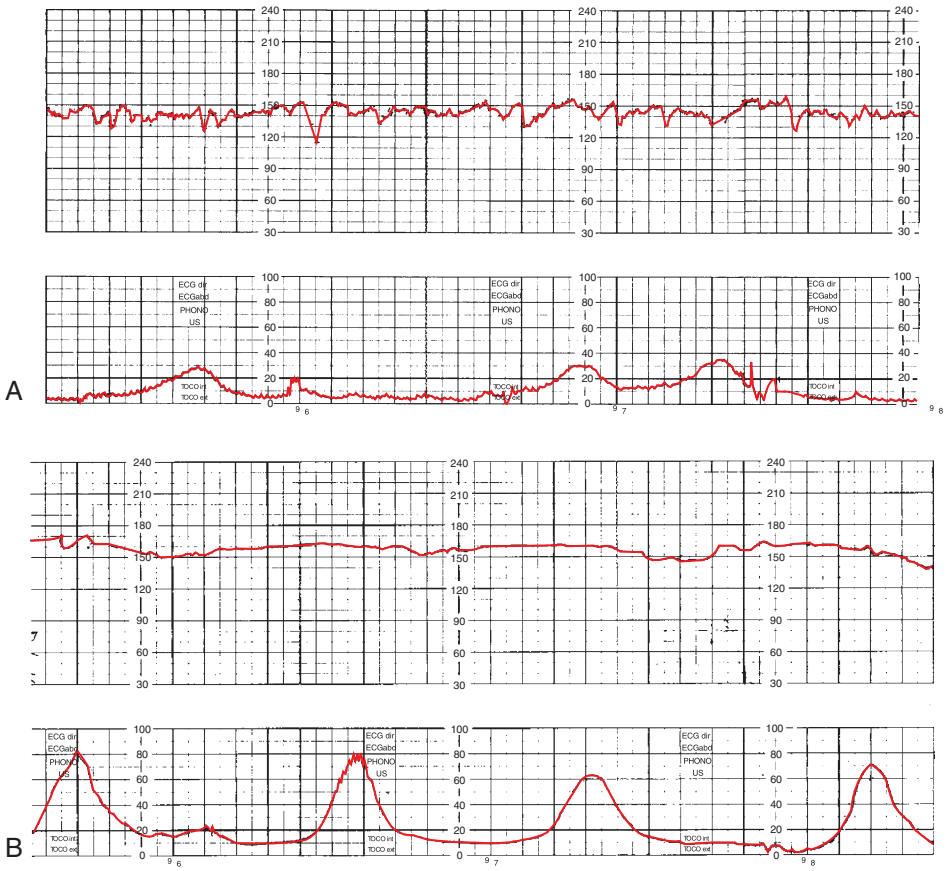

FIG 10-14 Contraction stress test (CST). **A,** Negative CST. **B,** Positive CST. (From Tucker SM: *Mosby's pocket guide to fetal monitoring: a multidisciplinary approach,* ed 5, St Louis, 2004, Mosby.)

TABLE 10-5 INTERPRETATION OF THE CONTRACTION STRESS TEST

INTERPRETATION	CLINICAL SIGNIFICANCE
Negative	
At least three uterine contractions in a 10-minute period, with no late or significant variable decelerations	Usually resume routine weekly testing schedule
Positive	
Late decelerations occur with 50% or more of contractions, even if there are fewer than three contractions in 10 minutes	Usually warrants hospital admission for further evaluation and/or delivery
Suspicious or Equivocal	
Prolonged, variable, or late decelerations occurring with less than 50% of the contractions	Repeat testing next day
Equivocal-Hyperstimulatory	
Decelerations that occur in the presence of contractions more frequent than every 2 min or lasting longer than 90 seconds	Repeat testing next day
Unsatisfactory	
Failure to produce three contractions within a 10-minute window or inability to trace the fetal heart rate	Repeat test next day

From Miller LA, Miller DA, Tucker SM: *Mosby's pocket guide to fetal monitoring: a multidisciplinary approach*, ed 7, St Louis, 2013, Mosby.

The desired CST result is negative because it has consistently been associated with good fetal outcomes. The likelihood of fetal death occurring within 1 week of a negative CST is less than 1 in 1000 (Greenberg, Druzin, and Gabbe, 2012). Positive CST results have been associated with intrauterine fetal death, late FHR decelerations in labor, IUGR, and meconium-stained amniotic fluid. A positive CST result usually leads to hospitalization for further close observation or birth. Unsatisfactory, suspicious, and equivocal tests must be repeated within 24 hours (Miller, Miller, and Tucker, 2013).

NURSES' ROLE IN ASSESSMENT OF THE HIGH RISK PREGNANCY

The nurse's role is primarily that of educator and support person when the woman is undergoing examinations such as ultrasonography, MRI, CVS, PUBS, and amniocentesis. In some instances the nurse may assist another health care provider with the procedure. In many settings nurses perform NSTs, CSTs, and BPPs; conduct an initial assessment; and begin necessary interventions for nonreassuring results. These nursing procedures are accomplished after additional education and training, under guidance of established protocols, and in collaboration with obstetric providers. Patient teaching, which is an integral component of this role, involves preparing the woman for the procedure, interpreting the findings, and providing psychosocial support when needed.

KEY POINTS

- A high risk pregnancy is one in which the life or well-being of the mother, fetus, or newborn is jeopardized by circumstances coincidental with or unique to pregnancy.
- The pregnancy, fetus, or neonate can be placed at risk by biophysical, psychosocial, sociodemographic, and environmental factors.
- Biophysical assessment techniques include fetal movement counts, ultrasonography, and MRI.
- Biochemical monitoring techniques include amniocentesis, PUBS, CVS, MSAFP, and multiple marker screens.
- Reactive NSTs and negative CSTs suggest fetal well-being.
- Most assessment tests have some degree of risk for the mother and fetus and usually cause some anxiety for the woman and her family.
- The nurse's roles in assessment of the high risk pregnancy are primarily that of educator and support person.

CHAPTER

11

High Risk Perinatal Care: Preexisting Conditions

Kitty Cashion

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Differentiate the types of diabetes mellitus and their respective risk factors in pregnancy.
- Compare insulin requirements during pregnancy, during the postpartum period, and with lactation.
- Identify maternal and fetal risks or complications associated with diabetes in pregnancy.
- Develop a plan of care for the pregnant woman with pregestational or gestational diabetes.
- Compare the management of a pregnant woman with hyperthyroidism with one who has hypothyroidism.
- Differentiate the management of various cardiovascular disorders in pregnant women.
- Discuss the different types of anemia and their effects during pregnancy.
- Explain the care of pregnant women with pulmonary disorders.
- Discuss the effects of neurologic disorders on pregnancy.
- Describe the care of women whose pregnancies are complicated by autoimmune disorders.
- Discuss the care of pregnant women who use, abuse, or are dependent on alcohol or illicit or prescription drugs.

For most women pregnancy represents a normal part of life. However, for some women it presents a significant risk because it is superimposed on a chronic illness. With well-motivated patients who actively participate in the treatment plan and with careful management from a multidisciplinary health care team, positive pregnancy outcomes are often possible.

Providing safe and effective care for women experiencing high risk pregnancy and their fetuses is a challenge. Although unique maternal and fetal needs prompted by these conditions exist, these women also experience many of the same pregnancy-related feelings, needs, and concerns as their "normal" counterparts. The primary objective of nursing care must be to guide and support the woman and her family in achieving optimal outcomes for both the pregnant woman and the fetus.

This chapter focuses on metabolic disorders, including diabetes mellitus and thyroid disorders; cardiovascular disorders; selected disorders of the respiratory, integumentary, and central nervous systems; and autoimmune disorders. Substance abuse is also discussed. For each disorder, management throughout the entire perinatal period (antepartum, intrapartum, and postpartum) is included in this chapter; thus all the information for each condition is located in one place in the text.

DIABETES MELLITUS

Worldwide, the incidence of diabetes mellitus is increasing at a rapid rate. In 2011 an estimated 25.8 million people in the United States (8.3% of the total population) had diabetes. Of these, 7 million were undiagnosed. If current trends continue, by 2050 one in three U.S. adults will have diabetes (National Center for Chronic Disease Prevention and Health Promotion, 2011). In the United States experts predict a marked increase in the number of women with preexisting diabetes who will become pregnant (Moore and Catalano, 2009). Diabetes mellitus is currently the most common endocrine disorder associated with pregnancy, occurring in approximately 4% to 14% of pregnant women (Gilbert, 2011). The perinatal mortality rate for well-managed diabetic pregnancies, excluding major congenital malformations, is approximately the same as for any other pregnancy (Landon, Catalano, and Gabbe, 2012). The key to an optimal pregnancy outcome is strict maternal glucose control before conception and throughout the gestational period. Consequently for women with diabetes, much emphasis is placed on preconception counseling.

Pregnancy complicated by diabetes is still considered high risk. It is most successfully managed by a multidisciplinary approach

involving the obstetrician, perinatologist, internist or endocrinologist, ophthalmologist, nephrologist, neonatologist, nurse, nutritionist or dietitian, and social worker, as needed. A favorable outcome requires commitment and active participation by the pregnant woman and her family.

Pathogenesis

Diabetes mellitus refers to a group of metabolic diseases characterized by hyperglycemia resulting from defects in insulin secretion, insulin action, or both (ADA, 2009). Insulin, produced by the beta cells in the islets of Langerhans in the pancreas, regulates blood glucose levels by enabling glucose to enter adipose and muscle cells, where it is used for energy. When insulin is insufficient or ineffective in promoting glucose uptake by the muscle and adipose cells, glucose accumulates in the bloodstream, and hyperglycemia results. Hyperglycemia causes hyperosmolarity of the blood, which attracts intracellular fluid into the vascular system, resulting in cellular dehydration and expanded blood volume. Consequently the kidneys function to excrete large volumes of urine (polyuria) in an attempt to regulate excess vascular volume and excrete the unusable glucose **(glycosuria).** Polyuria, along with cellular dehydration, causes excessive thirst (polydipsia).

The body compensates for its inability to convert carbohydrate (glucose) into energy by burning proteins (muscle) and fats. However, the end products of this metabolism are **ketones** and fatty acids, which in excess quantities produce ketoacidosis and acetonuria. Weight loss occurs as a result of the breakdown of fat and muscle tissue. This tissue breakdown causes a state of starvation that compels the individual to eat excessive amounts of food (polyphagia).

Over time diabetes causes significant changes in the microvascular and macrovascular circulations. These structural changes affect a variety of organ systems, particularly the heart, eyes, kidneys, and nerves. Complications resulting from diabetes include premature atherosclerosis, retinopathy, nephropathy, and neuropathy.

Diabetes may be caused either by impaired insulin secretion, when the beta cells of the pancreas are destroyed by an autoimmune process, or by inadequate insulin action in target tissues at one or more points along the metabolic pathway. Both of these conditions are commonly present in the same person; and determining which, if either, abnormality is the primary cause of the disease is difficult (ADA, 2009). For additional information on diabetes, visit the ADA website at www.diabetes.org.

Classification

The current classification system includes four groups: type 1 diabetes, type 2 diabetes, other specific types (e.g., diabetes caused by genetic defects in beta cell function or insulin action, disease or injury of the pancreas, or drug-induced diabetes), and gestational diabetes mellitus (GDM) (ADA, 2009; Moore and Catalano, 2009).

Type 1 diabetes includes cases that are caused primarily by pancreatic islet beta cell destruction and that are prone to ketoacidosis. People with type 1 diabetes usually have an abrupt onset of illness at a young age and an absolute insulin deficiency. Type 1 diabetes includes cases thought to be caused by an autoimmune process and those for which the cause is unknown (ADA, 2009; Landon, Catalano, and Gabbe, 2012).

Type 2 diabetes is the most prevalent form of the disease and includes individuals who have insulin resistance and usually relative (rather than absolute) insulin deficiency. Specific causes of type 2 diabetes are unknown at this time. It often goes undiagnosed for years because hyperglycemia develops gradually and is often not severe enough for the person to recognize the classic signs of polyuria, polydipsia, and polyphagia. Most people who develop type 2 diabetes are obese or have an increased amount of body fat distributed primarily in the abdominal area. Other risk factors for the development of type 2 diabetes include aging, a sedentary lifestyle, family history and genetics, puberty, hypertension, and prior gestational diabetes. Type 2 diabetes often has a strong genetic predisposition (ADA, 2009; Moore and Catalano, 2009).

Pregestational diabetes mellitus is the label sometimes given to type 1 or type 2 diabetes that existed before pregnancy.

Gestational diabetes mellitus (GDM) is any degree of glucose intolerance with the onset or first recognition occurring during pregnancy. This definition is appropriate whether or not medication is used for treatment or the diabetes persists after pregnancy. It does not exclude the possibility that the glucose intolerance preceded the pregnancy or that medication might be required for optimal glucose control. Women diagnosed with gestational diabetes should be retested 6 to 12 weeks after the pregnancy ends (Landon, Catalano, and Gabbe, 2012).

White's Classification of Diabetes in Pregnancy

Dr. Priscilla White, a physician who worked with pregnant women with diabetes during the 1940s, developed a classification system specifically for use with this group of women (Table 11-1). White's system was based on age at diagnosis; duration of illness; and presence of end-organ involvement, especially eye and kidney (Landon, Catalano, and Gabbe, 2012; Moore and Catalano, 2009). Her classification system has been modified through the years but is still used frequently to assess both maternal and fetal risk. Women in classes A through C generally have positive pregnancy outcomes as long as their blood glucose levels are well controlled. However, women in classes D through T usually have poorer pregnancy outcomes because they have already developed the vascular damage that often accompanies long-standing diabetes.

TABLE 11-1 WHITE'S CLASSIFICATION OF DIABETES IN PREGNANCY (MODIFIED)

Gestational Diabetes	
Class A_1	Woman has two or more abnormal values on OGTT with normal fasting blood sugar. Blood glucose levels are diet controlled.
Class A_2	Woman was not known to have diabetes before pregnancy but requires medication for blood glucose control.
Pregestational Diabetes	
Class B	Onset of disease occurs after age 20 and duration of illness <10 years.
Class C	Onset of disease occurs between 10 and 19 years of age or duration of illness for 10 to 19 years or both.
Class D	Onset of disease occurs at <10 years of age or duration of illness >20 years or both.
Class F	Patient has developed diabetic nephropathy.
Class R	Patient has developed retinitis proliferans.
Class T	Patient has had a renal transplant.

OGTT, Oral glucose tolerance test.

Metabolic Changes Associated with Pregnancy

Normal pregnancy is characterized by complex alterations in maternal glucose metabolism, insulin production, and metabolic homeostasis. During normal pregnancy adjustments in maternal metabolism allow for adequate nutrition for the mother and the developing fetus. Glucose, the primary fuel used by the fetus, is transported across the placenta through the process of carrier-mediated facilitated diffusion, meaning that the glucose levels in the fetus are directly proportional to maternal levels. Although glucose crosses the placenta, insulin does not. Around the tenth week of gestation the fetus begins to secrete its own insulin at levels adequate to use the glucose obtained from the mother. Therefore, as maternal glucose levels rise, fetal glucose levels are increased, resulting in increased fetal insulin secretion.

During the first trimester of pregnancy the pregnant woman's metabolic status is significantly influenced by the rising levels of estrogen and progesterone. These hormones stimulate the beta cells in the pancreas to increase insulin production, which promotes increased peripheral use of glucose and decreased blood glucose, with fasting levels being reduced by approximately 10% (Fig. 11-1, *A*). At the same time an increase in tissue glycogen stores and a decrease in hepatic glucose production occur, which further encourage lower fasting glucose levels. As a result of these normal metabolic changes of pregnancy, women with insulin-dependent diabetes are prone to hypoglycemia during the first trimester.

During the second and third trimesters pregnancy exerts a "diabetogenic" effect on the maternal metabolic status. Because of the major hormonal changes, decreased tolerance to glucose, increased insulin resistance, decreased hepatic glycogen stores, and increased hepatic production of glucose occur. Rising levels of human chorionic somatomammotropin, estrogen, progesterone, prolactin, cortisol, and insulinase increase insulin resistance through their actions as insulin antagonists. Insulin resistance is a glucose-sparing mechanism that ensures an abundant supply of glucose for the fetus. Maternal insulin requirements gradually increase from approximately 18 to 24 weeks of gestation to approximately 36 weeks of gestation. Maternal insulin requirements may double or quadruple by the end of the pregnancy (see Fig. 11-1, *B* and *C*).

At birth expulsion of the placenta prompts an abrupt drop in levels of circulating placental hormones, cortisol, and insulinase (see Fig. 11-1, *D*). Maternal tissues quickly regain their prepregnancy sensitivity to insulin. For the nonbreastfeeding mother the prepregnancy insulin-carbohydrate balance usually returns in approximately 7 to 10 days (see Fig. 11-1, *E*). Lactation uses maternal glucose; therefore the breastfeeding mother's insulin requirements remain low during lactation. On completion of weaning the mother's prepregnancy insulin requirement is reestablished (see Fig. 11-1, *F*).

PREGESTATIONAL DIABETES MELLITUS

Only about 10% of pregnancies complicated by diabetes occur in women who have preexisting disease (Landon, Catalano, and Gabbe, 2012). Women who have pregestational diabetes mellitus may have either type 1 or 2 diabetes, which may be complicated by vascular disease, retinopathy, nephropathy, or other diabetic complications. Type 2 is a more common diagnosis than type 1. Almost all women with pregestational diabetes are insulin dependent during pregnancy. According to White's classification system, these women fall into classes B through T (see Table 11-1).

The diabetogenic state of pregnancy imposed on the compromised metabolic system of the woman with pregestational diabetes has significant implications. The normal hormonal adaptations of pregnancy affect glycemic control, and pregnancy may accelerate the progress of vascular complications.

During the first trimester, when maternal blood glucose levels are normally reduced and the insulin response to glucose is enhanced, glycemic control is improved. The insulin dose for the woman with well-controlled diabetes may have to be reduced to prevent hypoglycemia. Nausea, vomiting, and cravings typical of early pregnancy result in dietary fluctuations that influence maternal glucose levels and may also necessitate a reduction in the insulin dose.

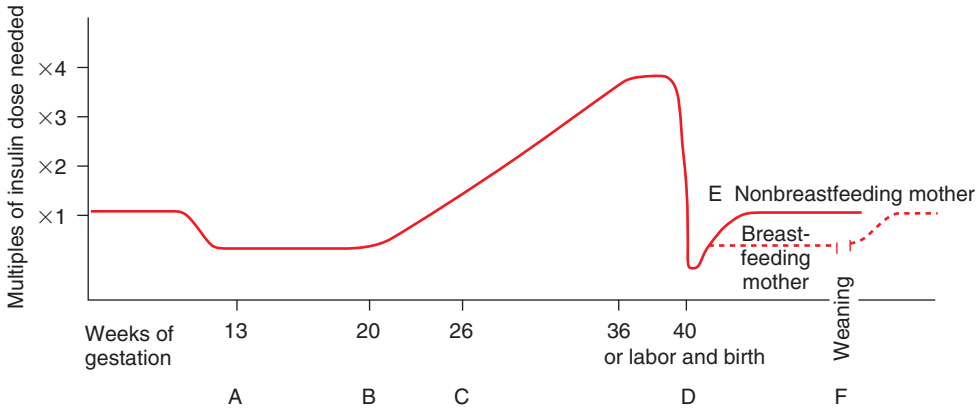

FIG 11-1 Changing insulin needs during pregnancy. **A,** First trimester: Insulin need is reduced because of increased insulin production by pancreas and increased peripheral sensitivity to insulin; nausea, vomiting, and decreased food intake by mother and glucose transfer to embryo or fetus contribute to hypoglycemia. **B,** Second trimester: Insulin needs begin to increase as placental hormones, cortisol, and insulinase act as insulin antagonists, decreasing effectiveness of insulin. **C,** Third trimester: Insulin needs may double or even quadruple but usually level off after 36 weeks of gestation. **D,** Day of birth: Maternal insulin requirements decrease drastically to approach prepregnancy levels. **E,** Breastfeeding mother maintains lower insulin requirements, as much as 25% less than those of prepregnancy; insulin needs of nonbreastfeeding mother return to prepregnancy levels in 7 to 10 days. **F,** Weaning of breastfeeding infant causes mother's insulin needs to return to prepregnancy levels.

Because insulin requirements steadily increase after the first trimester, the insulin dose must be adjusted accordingly to prevent hyperglycemia. Insulin resistance begins as early as 14 to 16 weeks of gestation and continues to rise until it stabilizes during the last few weeks of pregnancy.

Preconception Counseling

Preconception counseling is recommended for all women of reproductive age who have diabetes because it is associated with less perinatal mortality and fewer congenital anomalies (Moore and Catalano, 2009). Under ideal circumstances women with pregestational diabetes are counseled before the time of conception to plan the optimal time for pregnancy, establish glycemic control before conception, and diagnose any vascular complications of diabetes. However, estimates indicate that less than 20% of women with diabetes in the United States participate in preconception counseling (Landon, Catalano, and Gabbe, 2012).

The woman's partner should be included in the counseling to assess the couple's level of understanding related to the effects of pregnancy on the diabetic condition and the potential complications of pregnancy as a result of diabetes. The couple should also be informed of the anticipated alterations in management of diabetes during pregnancy and the need for a multidisciplinary team approach to health care. Financial implications of diabetic pregnancy and other demands related to frequent maternal and fetal surveillance should be discussed. Contraception is another important aspect of preconception counseling to help the couple plan effectively for pregnancy.

Maternal Risks and Complications

Although maternal morbidity and mortality rates have improved significantly, the pregnant woman with diabetes remains at risk for the development of complications during pregnancy. Poor glycemic control around the time of conception and in the early weeks of pregnancy is associated with an increased incidence of miscarriage. Women with good glycemic control before conception and in the first trimester are no more likely to miscarry than women who do not have diabetes (Moore and Catalano, 2009) (see Evidence-Based Practice box).

Poor glycemic control later in pregnancy, particularly in women without vascular disease, increases the rate of fetal macrosomia. **Macrosomia** has been defined as a birth weight more than 4000 to 4500 g or greater than the 90th percentile. It occurs in approximately 40% of pregestational diabetic pregnancies and up to 50% of pregnancies complicated by GDM (Landon, Catalano, and Gabbe, 2012). Infants born to women with diabetes tend to have a disproportionate increase in shoulder, trunk, and chest size. Because of this tendency the risk of shoulder dystocia is greater in these babies than in other macrosomic infants. Therefore women with diabetes face an increased likelihood of cesarean birth because of failure of fetal descent or labor progress or of operative vaginal birth (birth involving the use of episiotomy, forceps, or vacuum extractor) (Moore and Catalano, 2009).

Women with preexisting diabetes are at risk for several obstetric and medical complications. In general the risk of developing these complications increases with the duration and severity of the woman's diabetes. In one study the rates of preeclampsia, preterm birth, cesarean birth, and maternal mortality were much higher in women with preexisting diabetes than in women who did not have this disease. For example, approximately a third of women who have had diabetes for more than 20 years develop preeclampsia. Women with nephropathy and hypertension in addition to diabetes are also increasingly likely to develop preeclampsia. The rate of hypertensive disorders in all types of pregnancies complicated by diabetes is 15% to 30%. Chronic hypertension occurs in 10% to 20% of all pregnant women with diabetes and in up to 40% of women who have preexisting renal or retinal vascular disease (Moore and Catalano, 2009).

Hydramnios (polyhydramnios) frequently develops during the third trimester of pregnancy in women with diabetes. Its cause is unknown. One theory is that hydramnios in women with diabetes is caused by an increased glucose concentration in amniotic fluid resulting from maternal and fetal hyperglycemia. The complications most frequently associated with hydramnios (usually defined as an amniotic fluid index [AFI] greater than 24 to 25 cm) are abruptio placentae (placental abruption), uterine dysfunction, and postpartum hemorrhage (Cunningham, Leveno, Bloom, et al., 2010).

Infections are more common and more serious in pregnant women with diabetes than in those without the disease. Disorders of carbohydrate metabolism alter the normal resistance of the body to infection. The inflammatory response, leukocyte function, and vaginal pH are all affected. Vaginal infections, particularly monilial vaginitis, are more common. Urinary tract infections (UTIs) are also more prevalent. Infection is serious because it causes increased insulin resistance and may result in ketoacidosis.

Ketoacidosis (accumulation of ketones in the blood resulting from hyperglycemia and leading to metabolic acidosis) occurs most often during the second and third trimesters, when the diabetogenic effect of pregnancy is the greatest. When the maternal metabolism is stressed by illness or infection, the woman is at increased risk for **diabetic ketoacidosis (DKA).** DKA can also be caused by poor compliance with treatment or the onset of previously undiagnosed diabetes (Moore and Catalano, 2009). The use of beta-mimetic drugs such as terbutaline (Brethine) for tocolysis to stop preterm labor or corticosteroids given to enhance fetal lung maturation may also contribute to the risk for hyperglycemia and subsequent DKA (Cunningham, Leveno, Bloom, et al., 2010; Iams, Romero, and Creasy, 2009).

DKA may occur with blood glucose levels barely exceeding 200 mg/dL, compared with 300 to 350 mg/dL in the nonpregnant state. In response to stress factors such as infection or illness, **hyperglycemia** occurs as a result of increased hepatic glucose production and decreased peripheral glucose use. Stress hormones, which act to impair insulin action and further contribute to insulin deficiency, are released. Fatty acids are mobilized from fat stores to enter the circulation. As they are oxidized, ketone bodies are released into the peripheral circulation. The woman's buffering system is unable to compensate, and metabolic acidosis develops. The excessive blood glucose and ketone bodies result in osmotic diuresis with subsequent loss of fluid and electrolytes, volume depletion, and cellular dehydration. DKA is a medical emergency. Prompt treatment is necessary to prevent maternal coma or death. Ketoacidosis occurring at any time during pregnancy can lead to intrauterine fetal death. The incidence of DKA has decreased in recent years because of advances in clinical management and blood glucose monitoring (Inturrisi, Lintner, and Sorem, 2013). Currently it affects only about 1% of pregnant women with diabetes (Cunningham, Leveno, Bloom, et al., 2010). The rate of intrauterine fetal demise (IUFD) with DKA, formerly approximately 35%, is 10% or less (Moore and Catalano, 2009) (Table 11-2).

The risk of **hypoglycemia** (a less than normal amount of glucose in the blood) is also increased during pregnancy. Early in pregnancy, when hepatic production of glucose is diminished and peripheral use of glucose is enhanced, hypoglycemia occurs frequently, often during sleep. Later in pregnancy it may also result as insulin doses

EVIDENCE-BASED PRACTICE

Glycemic Control and Vitamin D for Improving Pregnancy Outcomes in Patients with Diabetes

Ask the Question

For women with diabetes, which preconception and pregnancy interventions help improve fetal and maternal outcomes?

Search for the Evidence

Search Strategies

English research-based publications on diabetes in pregnancy were included.

Databases Used

Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional website for AWHONN

Critically Analyze the Evidence

- Preexisting type 1 or 2 diabetes in pregnancy is a known risk for increased birth weight and perinatal loss. Loose glycemic control is associated with increased risk for preeclampsia, macrosomia, and cesarean birth. Moderate and tight glycemic controls have improved outcomes, but tight control leads to significantly more hypoglycemia and longer hospital stays. Moderate control is recommended (Middleton, Crowther and Simmonds, 2012).
- Vitamin D is a steroid hormone that is necessary for bone metabolism and vascular, immune, metabolic, and placental function. Vitamin D deficiency in pregnancy is associated with gestational diabetes, higher fasting blood sugar, and higher insulin levels (Poel, Hummel, Lips, et al., 2012; Senti, Thiele, and Anderson, 2012). Vitamin D deficiency may also be associated with preeclampsia, preterm labor, cesarean birth, and infections. Clinical recommendations for vitamin D during pregnancy are 600 international units (IU) daily (Urrutia and Thorp, 2012).
- A meta-analysis found that preconception glycemic control in women with preexisting diabetes leads to significantly lower hemoglobin $A1_c$ ($HgA1_c$) in the first trimester and fewer congenital anomalies, preterm births, perinatal mortality, and maternal complications (Wahabi, Alzeidan, Bawazeer, et al., 2010).

Apply the Evidence: Nursing Implications

- For women with diabetes who are contemplating pregnancy, preconception attention to glycemic control should be a part of patient education by the nurse. Women should know that lower $HgA1_c$ and moderate glycemic control before and during pregnancy are associated with significantly improved maternal and birth outcomes.
- All women need preconception information about vitamin D deficiency, which is associated with gestational diabetes. Vitamin D supplementation of 600 international units daily is recommended during pregnancy. A blood test can confirm adequate vitamin D levels.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence summaries.

Moderate, not tight, glycemic control results in the best outcomes.

Skills

Locate evidence reports related to clinical practice topics and guidelines.

Meta-analyses show that vitamin D, 600 IU, in pregnancy is associated with less gestational diabetes.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Attention to preconception counseling for glycemic control and vitamin D results in better pregnancy outcomes.

are adjusted to maintain **euglycemia** (a normal blood glucose level). Women with a prepregnancy history of severe hypoglycemia are at increased risk for severe hypoglycemia during gestation. Mild-to-moderate hypoglycemic episodes do not appear to have significant damaging effects on fetal well-being (see Table 11-2).

Fetal and Neonatal Risks and Complications

From the moment of conception the infant of a woman with diabetes faces an increased risk of complications that may occur during the antepartum, intrapartum, or neonatal periods. Infant morbidity and mortality rates associated with diabetic pregnancy are significantly reduced with strict control of maternal glucose levels before and during pregnancy.

Despite the improvements in care of pregnant women with diabetes, IUFD results in *stillbirth* and remains a major concern. Approximately 2% to 5% of all fetal deaths occur in women whose pregnancies are complicated by preexisting diabetes. Hyperglycemia, ketoacidosis, congenital anomalies, infections, and maternal obesity are thought to be reasons for fetal death. In the third trimester fetal acidosis is the most likely cause of fetal death (Paidas and Hossain, 2009).

The most important cause of perinatal loss in diabetic pregnancy is congenital malformations, which account for 30% to 50% of all perinatal loss in pregnancies complicated by diabetes (Landon, Catalano, and Gabbe, 2012). The incidence of congenital malformations is related to the severity and duration of the diabetes. Hyperglycemia during the first trimester of pregnancy, when organs and organ systems are forming, is the main cause of diabetes-associated birth defects. Anomalies commonly seen in infants affect primarily the cardiovascular system, the central nervous system (CNS), and

TABLE 11-2 DIFFERENTIATION OF HYPOGLYCEMIA (INSULIN SHOCK) AND HYPERGLYCEMIA (DIABETIC KETOACIDOSIS)

CAUSES	ONSET	SYMPTOMS	INTERVENTIONS
Hypoglycemia (Insulin Shock)			
Excess insulin Insufficient food (delayed or missed meals) Excessive exercise or work Indigestion, diarrhea, vomiting	Rapid (regular insulin) Gradual (modified insulin or oral hypoglycemic agents)	Irritability Hunger Sweating Nervousness Personality change Weakness Fatigue Blurred or double vision Dizziness Headache Pallor; clammy skin Shallow respirations Rapid pulse Laboratory values Urine: Negative for sugar and acetone Blood glucose: ≤60 mg/dL	Check blood glucose level when symptoms first appear. Eat or drink 15 g fast sugar (simple carbohydrate) immediately. Recheck blood glucose level in 15 minutes and eat or drink another 15 g fast sugar (simple carbohydrate) if glucose remains low. Recheck blood glucose level in 15 minutes. Notify primary health care provider if no change in glucose level. If woman is unconscious, administer 50% dextrose IV push, 5% to 10% dextrose in water IV drip, or 1 mg glucagon subcutaneously. Obtain blood and urine specimens for laboratory testing.
Hyperglycemia (DKA)			
Insufficient insulin Excess or wrong kind of food Infection, injuries, illness Emotional stress Insufficient exercise	Slow (hours to days)	Thirst Nausea or vomiting Abdominal pain Constipation Drowsiness Dim vision Increased urination Headache Flushed, dry skin Rapid breathing Weak, rapid pulse Acetone (fruity) breath odor Laboratory values Urine: Positive for sugar and acetone Blood glucose: ≥200 mg/dL	Notify primary health care provider. Administer insulin in accordance with blood glucose levels. Give IV fluids such as normal saline solution or one-half normal saline solution; potassium when urinary output is adequate; bicarbonate for pH <7. Monitor laboratory testing of blood and urine.

DKA, Diabetic ketoacidosis; *IV*, intravenous.

the skeletal system (Cunningham, Leveno, Bloom, et al., 2010; Moore and Catalano, 2009) (see Chapter 25).

The fetal pancreas begins to secrete insulin at 10 to 14 weeks of gestation. The fetus responds to maternal hyperglycemia by secreting large amounts of insulin (hyperinsulinism). Insulin acts as a growth hormone, causing the fetus to produce excess stores of glycogen, protein, and adipose tissue and leading to increased fetal size, or macrosomia. Birth injuries are more common in infants born to mothers with diabetes compared with mothers who do not have diabetes, and macrosomic fetuses have the highest risk for this complication. Common birth injuries associated with diabetic pregnancies include brachial plexus palsy, facial nerve injury, humerus or clavicle fracture, and cephalhematoma. Most of these injuries are associated with difficult vaginal birth and shoulder dystocia (Moore and Catalano, 2009). Hypoglycemia at birth is also a risk for infants born to mothers with diabetes. Degree of hypoglycemia is influenced by maternal glucose control during the last half of pregnancy and during labor and birth (Landon, Catalano, and Gabbe, 2012). (For further discussion of neonatal complications related to maternal diabetes, see Chapter 25).

CARE MANAGEMENT

Antepartum

When a pregnant woman with diabetes initiates prenatal care, a thorough evaluation of her health status is completed. At the initial visit a complete physical examination is performed to assess the woman's health status. In addition to the routine prenatal examination, specific efforts are made to assess the effects of the diabetes, especially retinopathy, nephropathy, peripheral and autonomic neuropathy, peripheral vascular, and cardiac involvement (Gilbert, 2011).

Routine prenatal laboratory tests are performed, and baseline renal function may be assessed with a 24-hour urine collection for total protein excretion and creatinine clearance. Urinalysis and culture are performed to assess for the presence of a UTI, which is

FIG 11-2 **A,** Clinic nurse collects blood to determine glucose level. **B,** Nurse interprets glucose value displayed by monitor. (Courtesy Dee Lowdermilk, UNC Ambulatory Care Clinics, Chapel Hill, NC.)

common in diabetic pregnancy. Because of the risk of coexisting thyroid disease, thyroid function tests may also be performed (see later discussion of thyroid disorders). The **glycosylated hemoglobin $A1_c$** level may be measured to assess recent glycemic control. With prolonged hyperglycemia some of the hemoglobin remains saturated with glucose for the life of the red blood cell (RBC). Therefore a test for glycosylated hemoglobin provides a "diabetic report card," an evaluation of glycemic control over the previous 4 to 6 weeks. Hemoglobin $A1_c$ levels greater than 6 indicate elevated glucose levels during the previous 4 to 6 weeks (Gilbert, 2011). Fasting blood glucose or random (1 to 2 hours after eating) glucose levels may be assessed during antepartum visits (Fig. 11-2). Self-monitoring blood glucose records may also be reviewed.

Because of her high risk status, a woman with pregestational diabetes is monitored much more frequently and thoroughly than other pregnant women. During the first and second trimesters of pregnancy, her routine prenatal care visits are scheduled every 1 to 2 weeks. In the last trimester she will likely be seen 1 or 2 times each week. In the past routine hospitalization for management of the diabetes such as insulin dose changes was common. With the availability of improved home glucose monitoring and the growing reluctance of third-party payers to reimburse for hospitalization, pregnant women with diabetes generally are now managed as outpatients. Some patient and family education and maternal and fetal assessment may be performed in the home, depending on the woman's insurance coverage and care provider preference.

Achieving and maintaining constant euglycemia, with plasma glucose levels in the range of 65 to 95 mg/dL before meals and no higher than 130 to 140 mg/dL when measured 1 hour after a meal (Table 11-3), is the primary goal of medical therapy (Moore and Catalano, 2009). Euglycemia is achieved through a combination of diet, insulin, and exercise. Providing the woman with the knowledge, skill, and motivation she needs to achieve and maintain excellent blood glucose control is the primary nursing goal.

Achieving euglycemia requires commitment on the part of the woman and her family to make the necessary lifestyle changes, which can sometimes seem overwhelming. Maintaining tight blood glucose control necessitates that the woman follow a consistent daily schedule. She must get up and go to bed, eat, exercise, and take insulin at the same time each day. Blood glucose measurements are taken frequently to determine how well the major components of therapy (diet, insulin, and exercise) are working together to control blood glucose levels (see Community Focus box). The pregnant woman with diabetes should wear a medical identification bracelet at all times and carry insulin, syringes, and sources of fast sugar (simple carbohydrate) with her whenever she is away from home.

TABLE 11-3 TARGET BLOOD GLUCOSE LEVELS DURING PREGNANCY

TIME OF DAY	TARGET PLASMA GLUCOSE LEVEL (MG/DL)
Premeal or fasting	>65 but <95
Postmeal (1 hr)	<130-140
Postmeal (2 hr)	≤120
2 AM to 6 AM	>60

COMMUNITY FOCUS

Accessibility of Diabetes Supplies

Visit your local pharmacy and examine the diabetes equipment and supplies that are available. Locate glucose meters, urine test strips, insulin syringes, and insulin pens. How much does each of these items cost? Check to see which items are covered by most types of insurance and Medicaid. Read the directions for use of each item. How easily could you follow the instructions? Could a woman with low literacy skills read and understand them? Do the directions contain illustrations? Are they written in more than one language (e.g., in Spanish or French) in addition to English? Does the pharmacy have someone who can teach women? How can you use the information you have obtained in this exercise in your patient teaching?

Because the woman with pregestational diabetes is at increased risk for infections, eye problems, and neurologic changes, foot and general skin care are important. A daily bath that includes thorough perineal and foot care is important. For dry skin lotions, creams, or oils can be applied. Tight clothing should be avoided. Shoes or slippers that fit properly should be worn at all times and are best worn with socks or stockings. Feet should be inspected regularly; toenails should be cut straight across, and professional help should be sought for any foot problems. Extremes of temperature should be avoided.

Diet. The woman with pregestational diabetes has usually had nutrition counseling regarding management of her diabetes.

PATIENT TEACHING

Dietary Management of Diabetic Pregnancy

- Follow the prescribed diet plan.
- Eat a well-balanced diet, including daily food requirements for a normal pregnancy.
- Divide daily food intake among three meals and two or three snacks, depending on individual needs.
- Eat a substantial bedtime snack to prevent a severe drop in blood glucose level during the night.
- Take daily vitamins and iron as prescribed by the health care provider.
- Avoid foods high in refined sugar.
- Eat consistently each day; never skip meals or snacks.
- Eat foods high in dietary fiber.
- Avoid alcohol, nicotine, and caffeine.

However, because pregnancy produces special nutrition concerns and needs, the woman must be educated to incorporate these changes into dietary planning. The woman who has "controlled" her diabetes for several years may find the changes in her insulin and dietary needs mandated by pregnancy to be difficult. Nutrition counseling is usually provided by a registered dietitian.

Dietary management during diabetic pregnancy must be based on blood (not urine) glucose levels. The diet is individualized to allow for increased fetal and metabolic requirements, with consideration of such factors as prepregnancy weight and dietary habits, overall health, ethnic background, lifestyle, stage of pregnancy, knowledge of nutrition, and insulin therapy. The dietary goals are to provide weight gain consistent with a normal pregnancy, prevent ketoacidosis, and minimize wide fluctuation of blood glucose levels.

For nonobese women dietary counseling based on preconception body mass index (BMI) is 30 to 35 kcal/kg/day (Cunningham, Leveno, Bloom, et al., 2010). In contrast, for obese women with a BMI greater than 30, experts recommend that the caloric intake total 25 kcal/kg/day (Moore and Catalano, 2009). The average diet includes 2200 calories (first trimester) to 2500 calories (second and third trimesters). Total calories may be distributed among three meals and one evening snack or, more commonly, three meals and two or three snacks. Meals should be eaten on time and never skipped. Going more than 4 hours without food intake increases the risk for episodes of hypoglycemia. Snacks must be planned carefully in accordance with insulin therapy to prevent fluctuations in blood glucose levels. A large bedtime snack of at least 25 g of carbohydrate with some protein or fat is recommended to help prevent hypoglycemia and starvation ketosis during the night (Moore and Catalano, 2009).

The ideal diet is composed of 55% carbohydrate, 20% protein, and 25% fat, with less than 10% as saturated fat (Cunningham, Leveno, Bloom, et al., 2010) (see Patient Teaching box). Simple carbohydrates are limited. Complex carbohydrates that are high in fiber content are recommended because the starch and protein in such foods help regulate the blood glucose level by more sustained glucose release (Gilbert, 2011; Moore and Catalano, 2009).

Exercise. Although studies have shown that exercise enhances the use of glucose and decreases insulin need in women without diabetes, data regarding exercise in women with pregestational diabetes are limited. Any prescription of exercise during pregnancy for women with diabetes should be given by the primary health care provider and monitored closely to prevent complications. Regular exercise may be contraindicated in women with diabetes who also have uncontrolled hypertension, advanced retinopathy, or severe autonomic or peripheral neuropathy (Gilbert, 2011).

When exercise is prescribed by the health care provider as part of the treatment plan, specific instructions are given to the woman. Aerobic exercise with resistance training for at least 30 minutes most days of the week is the best type of exercise (Gilbert, 2011). Other exercises that may be recommended are non–weight-bearing activities such as arm exercises or use of a recumbent bicycle. The best time for exercise is after meals, when the blood glucose level is rising. To monitor the effect of insulin on blood glucose levels the woman can measure her blood glucose before, during, and after exercise.

! NURSING ALERT

Uterine contractions may occur during exercise. The woman should be advised to stop exercising immediately if they are detected, drink two to three glasses of water, and lie down on her side for an hour. If the contractions continue, she should contact her health care provider.

Insulin Therapy. Adequate insulin is the primary factor in the maintenance of euglycemia during pregnancy, thus ensuring proper glucose metabolism of the woman and fetus. Insulin requirements during pregnancy change dramatically as the pregnancy progresses, necessitating frequent adjustments in the dose. In the first trimester, from weeks 3 to 7 of gestation, insulin requirements are increased followed by a decrease between weeks 7 and 15 of gestation. The commonly prescribed dose is 0.7 units/kg in the first trimester for women with type 1 diabetes. During the second and third trimesters, because of insulin resistance, the dose must be increased significantly to maintain target glucose levels. Insulin requirements normally plateau after 35 weeks of gestation and often drop significantly after 38 weeks (Moore and Catalano, 2009).

For the woman with type 1 pregestational diabetes who has typically been accustomed to one injection per day of intermediate-acting insulin, multiple daily injections of mixed insulin are a new experience. The woman with type 2 diabetes previously treated with oral hypoglycemics is faced with the task of learning to self-administer injections of insulin. The nurse is instrumental in the education and support of women with pregestational diabetes in regard to insulin administration and adjustment of the insulin dose to maintain euglycemia (see Patient Teaching box on p. 275 and Box 11-1).

Since 1982 most insulin preparations have been produced by inserting portions of DNA ("recombinant DNA") into special laboratory-cultivated bacteria or yeast cells. The cells then produce synthetic human insulin (Humulin), which is less likely to cause antibody formation than animal-derived (beef or pork) insulin. More recently insulin products called *insulin analogs,* in which the structure differs slightly from human insulin, have been produced. This small alteration in insulin structure results in changes in the onset and peak of action of the medication. The most commonly used insulin preparations include rapid-acting, short-acting, intermediate-acting, and long-acting (Landon, Catalano, and Gabbe, 2012) (Table 11-4). Mixtures of short- and intermediate-acting insulins in several proportions are also available.

Lispro (Humalog) and aspart (NovoLog) are commonly prescribed rapid-acting insulins with a shorter duration of action than regular insulin. They are preferred for use during pregnancy (Landon, Catalano, and Gabbe, 2012). Advantages of rapid-acting insulins include convenience because they are injected immediately before mealtime, less hyperglycemia after meals, and fewer hypoglycemic episodes in some people. Because their effects last only 3 to 5

BOX 11-1 HELPFUL HINTS FOR USING INSULIN

- The most common type of insulin used during pregnancy is a biosynthetic human insulin (Humulin) made by programming *Escherichia coli* bacteria to produce insulin.
- Insulin is classified either as rapid acting, short acting, intermediate acting, or long acting (see Table 11-4).
- Unused vials of insulin should be stored in the refrigerator until reaching their expiration date. Insulin should not be frozen. Vials currently in use can be stored at room temperature for up to a month. They should not be stored in direct sunlight.
- Regular insulin can be mixed with NPH insulin in the same syringe. Lispro insulin can also be mixed in a syringe with NPH or Ultralente insulin. Once mixed, the syringe can be used immediately or stored for future use. If it is used later, the syringe should be rotated 20 times before injection.
- Glargine insulin is administered at bedtime. It cannot be mixed with any other insulin in the same syringe. Prepared syringes are stable for 2 weeks in the refrigerator.
- Insulin may be administered by pen injector, jet injector, or insulin pump, in addition to syringe.
- The abdomen is the preferred injection site because insulin is best absorbed there. Other possible injection sites are the upper outer arm (not the deltoid area), the thighs, and the buttocks.
- Each injection should be given 1 inch from the previous injection. Each individual injection site should not be used more often than once in 30 days.

PATIENT TEACHING

Self-Administration of Insulin

Procedure for Mixing NPH (Intermediate-Acting) and Regular (Short-Acting) Insulin

- Wash hands thoroughly and gather supplies. Be sure that insulin syringe corresponds to concentration of insulin you are using.
- Check insulin bottle to be certain that it is the appropriate type and check expiration date.
- Gently rotate (do not shake) insulin vial to mix insulin.
- Wipe off rubber stopper of each vial with alcohol.
- Draw into syringe the amount of air equal to total dose.
- Inject air equal to NPH dose into NPH vial. Remove needle from vial.
- Inject air equal to regular insulin dose into regular insulin vial.
- Invert regular insulin bottle and withdraw regular insulin dose.
- Without adding more air to NPH vial, carefully withdraw NPH dose.

Procedure for Self-Injection of Insulin

- Select proper injection site.
- Injection site should be clean. No need to use alcohol. If alcohol is used, let it dry before injecting.
- Pinch skin up to form a subcutaneous pocket and, holding syringe as you would hold a pencil, puncture skin at a 45- to 90-degree angle. If a great deal of fatty tissue is at the site, spread skin taut and inject syringe at a 90-degree angle.
- Slowly inject insulin.
- As you withdraw needle, cover injection site with sterile gauze and apply gentle pressure to prevent bleeding.
- Record insulin dose and time of injection.

TABLE 11-4 COMMON INSULIN PREPARATIONS

TYPE OF INSULIN	EXAMPLES GENERIC (TRADE) NAME	ONSET OF ACTION	PEAK OF ACTION	DURATION OF ACTION
Rapid-acting	Lispro (Humalog)	15 min	30-90 min	4-5 hr
	Aspart (NovoLog)	15 min	1-3 hr	3-5 hr
Short-acting	Humulin R	30 min	2-4 hr	5-7 hr
	Novolin R	30 min	2.5-5 hr	6-8 hr
Intermediate-acting	Humulin NPH	1-2 hr	6-12 hr	18-24 hr
	Novolin N	1.5 hr	4-20 hr	24 hr
	Humulin Lente	1-3 hr	6-12 hr	18-24 hr
	Novolin L	2.5 hr	7-15 hr	22 hr
Long-acting	Humulin Ultralente	4-6 hr	8-20 hr	>36 hr
	Glargine (Lantus)	1 hr	None	24 hr

Data from Landon MB, Catalano PM, Gabbe SG: Diabetes mellitus complicating pregnancy. In Gabbe SG, Niebyl JR, Simpson JL, et al, editors: *Obstetrics: normal and problem pregnancies*, ed 6, Philadelphia, 2012, Saunders.
L, Lente; *NPH* (or *N*), neutral protamine Hagedorn; *R,* regular.

hours, most patients require a longer-acting insulin in addition to the rapid-acting insulin to maintain optimal blood glucose levels (Landon, Catalano, and Gabbe, 2012; Moore and Catalano, 2009) (see Table 11-4). Glargine (Lantus) is long-acting insulin lasting approximately 24 hours. Small amounts of glargine insulin are released slowly, with no pronounced peak. This preparation is most often used with women who have insulin-resistant diabetes (type 2) requiring high doses of long-acting insulin. Glargine insulin is combined with rapid-acting insulin to prevent hypoglycemia. Glargine insulin appears to be safe for use during pregnancy. When it is administered with rapid-acting or short-acting insulin, unpredictable spikes in insulin levels and resulting hypoglycemia appear to occur less often (Landon, Catalano, and Gabbe, 2012) (see Table 11-4).

Most women with insulin-dependent diabetes are managed with two or three injections per day (Landon, Catalano, and Gabbe, 2012). Usually two thirds of the daily insulin dose, with intermediate-acting and short-acting insulin combined in a 2:1 ratio, is given

FIG 11-3 Insulin pump shows basal rate for pregnant women with diabetes. (Courtesy MiniMed, Inc., Sylmar, CA.)

before breakfast. The remaining one third is administered in the evening. It may be given as a combination of short- and intermediate-acting insulin before dinner or split, with rapid-acting insulin at dinner and intermediate-acting insulin at bedtime (Landon, Catalano, and Gabbe, 2012). An alternative insulin regimen that works well for some women is to administer short-acting insulin before each meal and longer-acting insulin at bedtime (Moore and Catalano, 2009).

Continuous subcutaneous insulin infusion (CSII) systems are used increasingly during pregnancy. The insulin pump is designed to mimic more closely the function of the pancreas in secreting insulin (Fig. 11-3). This portable battery-powered device is worn similar to a pager during most daily activities. The pump infuses rapid-acting insulin (usually lispro) (Landon, Catalano, and Gabbe, 2012) at a set basal rate and has the capacity to deliver up to four different basal rates in 24 hours. It also delivers bolus doses of insulin before meals to control postprandial blood glucose levels. A fine-gauge plastic catheter is inserted into subcutaneous tissue, usually in the abdomen, and attached to the pump syringe by connecting tubing. The subcutaneous catheter and connecting tubing are changed every 2 to 3 days, although the infusion tubing can be left in place for several weeks without local complications. Although the insulin pump is convenient and generally provides good glycemic control, complications such as pump failure, precipitation of insulin inside the pump mechanism, abscess formation, and poor uptake from the infusion site can still occur. Therefore use of the insulin pump requires a knowledgeable, motivated woman; skilled health care providers; and prompt 24-hour availability of emergency assistance (Moore and Catalano, 2009).

Monitoring Blood Glucose Levels. Blood glucose testing at home with a glucose reflectance meter is considered the standard of care for monitoring blood glucose levels during pregnancy. It provides the most important tool available to the woman to assess her degree of glycemic control. Most of the newer reflectance meters are calibrated to provide plasma (rather than whole blood) glucose values. Plasma glucose values are 10% to 15% lower than those measured in whole blood from the same sample (Moore and Catalano, 2009).

SAFETY ALERT

The nurse must be knowledgeable about the specific glucose reflectance meter that the woman uses because target glucose values depend on the type of meter used (Moore and Catalano, 2009).

PATIENT TEACHING

Self-Testing of Blood Glucose Level

- Gather supplies, check expiration date, and read instructions on testing materials. Prepare glucose reflectance meter for use according to manufacturer directions.
- Wash hands in warm water (warmth increases circulation).
- Select site on side of any finger (all fingers should be used in rotation).
- Pierce site with lancet (may use automatic spring-loaded, puncturing device). Cleaning site with alcohol is not necessary.
- Drop hand down to side; with other hand gently squeeze finger from hand to fingertip.
- Allow blood to fill entire testing area on the strip.
- Determine blood glucose value using glucose reflectance meter following manufacturer instructions.
- Record results.
- Repeat as instructed by health care provider and as needed for signs of hypoglycemia or hyperglycemia.

To perform blood glucose monitoring a drop of blood is obtained, usually by means of a fingerstick, and placed on a test strip. Some newer glucose meters allow the user to obtain the blood sample from the forearm rather than a finger. After a specified amount of time the glucose level is displayed by the meter (see Patient Teaching box). Blood glucose levels are routinely measured at various times throughout the day such as before breakfast, lunch, and dinner; 2 hours after each meal; at bedtime; and in the middle of the night. When any readjustment in the insulin dose or diet is made, more frequent measurement of blood glucose is warranted. If nausea, vomiting, or diarrhea occurs or if any infection is present, the woman is asked to monitor her blood glucose levels more closely than usual.

NURSING ALERT

Hyperglycemia is most likely to be identified in 2-hour postmeal values because blood glucose levels peak approximately 2 hours after a meal.

Target levels of blood glucose during pregnancy are lower than nonpregnant values (see Table 11-3). Acceptable fasting levels are generally between 65 and 95 mg/dL, and 1-hour postmeal levels should be less than 130 to 140 mg/dL (Moore and Catalano, 2009). Two-hour postmeal levels should be 120 mg/dL or less (Landon, Catalano, and Gabbe, 2012). The woman should be told to report episodes of hypoglycemia (less than 60 mg/dL) and hyperglycemia (more than 200 mg/dL) immediately to her health care provider so adjustments in diet or insulin therapy can be made.

Pregnant women with diabetes are much more likely to develop hypoglycemia than hyperglycemia. Most episodes of mild or moderate hypoglycemia can be treated with oral intake of 15 g of simple carbohydrate (fast sugar) (see Patient Teaching box on p. 277). If severe hypoglycemia occurs, in which case the woman experiences a decrease in or loss of consciousness or an inability to swallow, she will require a parenteral injection of glucagon or intravenous (IV) glucose. Because hypoglycemia can develop rapidly and impaired judgment can be associated with even moderate episodes, family members, friends, and work colleagues must be able to recognize signs and symptoms quickly and initiate proper treatment if necessary.

PATIENT TEACHING

Treatment for Hypoglycemia

- Be familiar with signs and symptoms of hypoglycemia (nervousness, headache, fatigue, shaking, irritability, tachycardia, hunger, blurred vision, sweaty skin, tingling of mouth or extremities).
- Check blood glucose level immediately when hypoglycemic symptoms occur.
- If blood glucose is less than 60 mg/dL, immediately eat or drink something that contains 15 g of fast sugar (simple carbohydrate). Examples are:
  - ½ cup (4 oz) unsweetened orange juice
  - ½ cup (4 oz) regular (not diet) soda
  - 5 or 6 hard candies
  - 1 cup (8 oz) skim milk
  - 2 or 3 glucose tablets
- Rest for 15 minutes; then recheck blood glucose.
- If glucose level is greater than 60 mg/dL, eat a meal to stabilize sugar level.
- If glucose level is still less than 60 mg/dL, eat or drink another serving of one of the fast sugars listed previously.
- Wait 15 minutes; then recheck blood glucose. If level is still less than 60 mg/dL, notify health care provider immediately.

PATIENT TEACHING

What to Do When Illness Occurs

- Be sure to take insulin even if unable to eat or appetite is less than normal. (Insulin needs are increased with illness or infection.)
- Call health care provider and relay the following information:
  - Symptoms of illness (e.g., nausea, vomiting, diarrhea)
  - Elevated temperature
  - Most recent blood glucose level
  - Urine ketones
  - Time and amount of last insulin dose
- Increase oral intake of fluids to prevent dehydration.
- Rest as much as possible.
- If you are unable to reach your health care provider and blood glucose exceeds 200 mg/dL with urine ketones present, seek emergency treatment at nearest health care facility. Do not attempt to self-treat for this condition.

Hyperglycemia is less likely than hypoglycemia to occur, although it can rapidly progress to DKA, which is associated with an increased risk of fetal death (Cunningham, Leveno, Bloom et al., 2010; Moore and Catalano, 2009). Women and family members should be particularly alert for signs and symptoms of hyperglycemia, especially when infections or other illnesses occur (see Patient Teaching box).

Urine Testing. Urine testing for glucose is not beneficial during pregnancy. Because of the lowered renal threshold for glucose, the degree of glycosuria does not accurately reflect the blood glucose level. However, urine testing for ketones continues to have a place in diabetic management. Monitoring for urine ketones may detect inadequate caloric or carbohydrate intake or skipped meals or snacks. Testing may also be performed when illness occurs or when the blood glucose level is greater than 200 mg/dL (Gilbert, 2011).

Complications Requiring Hospitalization. Occasionally hospitalization is necessary to regulate insulin therapy and stabilize glucose levels. Infection, which can lead to hyperglycemia and DKA, is an indication for hospitalization, regardless of gestational age. Hospitalization during the third trimester for close maternal and fetal observation may be indicated for women whose diabetes is poorly controlled. In addition, women with diabetes are 10% to 20% more likely than women who do not have diabetes to also have preexisting hypertension or develop preeclampsia, which may necessitate hospitalization (Moore and Catalano, 2009).

Fetal Surveillance. Diagnostic techniques for fetal surveillance are often performed to assess fetal growth and well-being. The goals of fetal surveillance are to detect fetal compromise as early as possible and prevent IUFD or unnecessary preterm birth.

Early in pregnancy the estimated date of birth is determined. A baseline sonogram is obtained during the first trimester to assess gestational age. Follow-up ultrasound examinations are usually performed during the pregnancy (as often as every 4 to 6 weeks) to monitor fetal growth; estimate fetal weight; and detect hydramnios, macrosomia, and congenital anomalies.

Because the fetus of a woman with diabetes is at increased risk for neural tube defects (e.g., spina bifida, anencephaly, microcephaly), measurement of maternal serum alpha-fetoprotein is performed between 15 and 20 weeks of gestation (ideally between 16 and 18 weeks of gestation) (Wapner, Jenkins, and Khalek, 2009). This assessment is often performed in conjunction with a detailed ultrasound study to examine the fetus for neural tube defects.

Fetal echocardiography may be performed between 20 and 22 weeks of gestation to detect cardiac anomalies, especially in women who had less-than-desirable glucose control early in pregnancy, as demonstrated by a hemoglobin $A1_c$ level above 6% at the first prenatal visit (Gilbert, 2011; Moore and Catalano, 2009). Some practitioners repeat this fetal surveillance test at 34 weeks of gestation. Doppler studies of the umbilical artery may be performed in women with vascular disease to detect placental compromise.

Most fetal surveillance measures are concentrated in the third trimester, when the risk of fetal compromise is greatest. The goals of antepartum testing during the third trimester are to prevent IUFD and maximize the opportunity for the woman to safely give birth vaginally. Pregnant women should be taught how to make daily fetal movement counts, beginning at 28 weeks of gestation (see Chapter 10) (Moore and Catalano, 2009).

The nonstress test (NST) is the preferred primary method to evaluate fetal well-being. It is usually begun by 32 weeks of gestation and performed at least twice weekly. If the NST is nonreactive, a biophysical profile or contraction stress test will be performed. Testing often begins earlier, between 28 and 32 weeks of gestation, in women who have vascular disease or poor glucose control (Landon, Catalano, and Gabbe, 2012) (see Chapter 10).

Determination of Date and Mode of Birth. The optimal time for birth is between 38.5 and 40 weeks of gestation, as long as good metabolic control is maintained and parameters of antepartum fetal surveillance remain within normal limits. Reasons to proceed with birth before this time include poor metabolic control, worsening hypertensive disorders, fetal macrosomia, or fetal growth restriction (Moore and Catalano, 2009).

Many practitioners plan for elective labor induction between 38 and 40 weeks of gestation. To confirm fetal lung maturity an amniocentesis should be performed when birth will occur before 38.5 weeks of gestation. For the pregnancy complicated by diabetes, fetal lung maturation is best predicted by the amniotic fluid phosphatidylglycerol (greater than 3%). If the fetal lungs are still immature, birth should be postponed until 40 weeks of gestation as long as fetal assessment test results remain reassuring. However, after that time

the benefits of conservative management are outweighed by the increasing risk of fetal compromise if the pregnancy is allowed to continue. Despite poor fetal lung maturity, birth may be necessary when testing suggests fetal compromise or worsening maternal condition such as deteriorating renal function or severe preeclampsia (Moore and Catalano, 2009).

Although vaginal birth is expected for most women with pregestational diabetes, the cesarean rate for these women ranges from 50% to 80% (Cunningham, Leveno, Bloom, et al., 2010). The ACOG recommends that cesarean birth be considered when the estimated fetal weight is expected to be greater than 4500 g in an attempt to reduce the risk of shoulder dystocia. This recommendation appears to result in a small improvement in neonatal outcome (Moore and Catalano, 2009). Abnormal fetal status and induction failures before term also contribute to the high rate of cesarean birth in these women (Gilbert, 2011).

Intrapartum

During the intrapartum period the woman with pregestational diabetes must be monitored closely to prevent complications related to dehydration, hypoglycemia, and hyperglycemia. An IV line is inserted for infusion of a maintenance fluid. Initially this infusion may be normal saline. Once active labor begins or glucose levels fall below 70 mg/dL, the infusion is changed to one containing 5% dextrose. This fluid provides the energy (calories) necessary for the woman to accomplish the work and manage the stress of labor and birth. Most commonly insulin is administered by continuous infusion, piggybacked into the main IV line. Only regular (short-acting) insulin can be administered intravenously. Determination of blood glucose levels is made every hour, and fluids and insulin are adjusted to maintain the blood glucose level at 140 mg/dL or less. Maintaining this target glucose level is essential because hyperglycemia during labor can cause metabolic problems in the neonate, particularly hypoglycemia (Landon, Catalano, and Gabbe, 2012).

If a cesarean birth is planned, it should be scheduled in the early morning to facilitate glycemic control. Women should take their full dose of insulin the night before surgery. No morning insulin is given on the day of surgery, and the woman is given nothing by mouth. Epidural anesthesia is recommended because hypoglycemia can be detected earlier if the woman is awake. After surgery glucose levels should be monitored carefully. Generally sliding scale insulin is used to control blood glucose levels until the woman resumes a regular diet (Moore and Catalano, 2009).

Postpartum

In the immediate postpartum period insulin requirements decrease substantially because the major source of insulin resistance, the placenta, has been removed. Women may require only one third to one half of their last pregnancy insulin doses on the first postpartum day, provided that they are eating a full diet. Many women with type 2 diabetes do not require insulin at all for the first 1 to 2 days after giving birth (Landon, Catalano, and Gabbe, 2012). Women who give birth by cesarean may require an IV infusion of glucose and insulin until they resume a regular diet (Moore and Catalano, 2009). After birth, several days may be required to reestablish carbohydrate homeostasis (see Fig. 11-1, *D* and *E*). Blood glucose levels are monitored carefully in the postpartum period; the insulin dose is adjusted, often using a sliding scale (the amount of insulin to be administered is determined by the woman's blood glucose level at the time the dose is given). The woman who has insulin-dependent diabetes must realize the importance of eating on time even if the baby needs to be fed or other pressing demands exist (Moore and Catalano, 2009).

Possible postpartum complications include preeclampsia or eclampsia, hemorrhage, and infection. Hemorrhage is a possibility if the mother's uterus was overdistended (hydramnios, macrosomic fetus) or overstimulated (oxytocin induction). Postpartum infections such as endometritis are more likely to occur in women with diabetes than in women who do not have diabetes.

Mothers are encouraged to breastfeed. In addition to the advantages of maternal satisfaction and pleasure, breastfeeding has an antidiabetogenic effect for the children of women with diabetes and women with GDM (Moore and Catalano, 2009). This effect is important because a child born to a mother with type 2 diabetes has a 70% chance of also developing type 2 diabetes later in life. In addition, children who were exposed to hyperglycemia prenatally have an increased risk for obesity in childhood (Gilbert, 2011).

Insulin requirements in breastfeeding women may be one half of prepregnancy levels because of the carbohydrate used in human milk production. Because glucose levels are lower than normal, breastfeeding women are at increased risk for hypoglycemia, especially in the early postpartum period and after breastfeeding sessions, particularly after late-night nursing (Gilbert, 2011; Moore and Catalano, 2009). Breastfeeding mothers with diabetes may be at increased risk for mastitis and yeast infections of the breast. The insulin dose, which is decreased during lactation, must be recalculated at weaning (see Fig. 11-1, *F*).

The mother may have early breastfeeding difficulties. Poor metabolic control may delay lactogenesis and contribute to decreased milk production (Moore and Catalano, 2009). Initial contact with and opportunity to breastfeed the infant may be delayed for mothers who gave birth by cesarean or if infants are placed in neonatal intensive care units or special care nurseries for observation during the first few hours after birth. Support and assistance from nursing staff and lactation specialists can facilitate the mother's early experience with breastfeeding and encourage her to continue nursing.

The new mother needs information about family planning and contraception. Although family planning is important for all women, it is essential for the woman with pregestational diabetes to safeguard her own health and promote optimal outcomes in future pregnancies. The risks and benefits of contraceptive methods should be discussed with the mother and her partner before discharge from the hospital. Barrier methods are often recommended as safe, inexpensive options that have no inherent risks for women with diabetes. The intrauterine device (IUD) may also be used without concerns about an increased risk of infection (Landon, Catalano, and Gabbe, 2012).

Use of oral contraceptives by women with diabetes is controversial because of the risk of thromboembolic and vascular complications and the effect on carbohydrate metabolism. In nonsmoking women who are younger than 35 years old and do not have vascular disease, combination low-dose oral contraceptives may be prescribed. Progestin-only oral contraceptives also may be used because they affect carbohydrate metabolism minimally if at all (Cunningham, Leveno, Bloom, et al., 2010). Close monitoring of blood pressure and lipid levels is necessary to detect complications (Landon, Catalano, and Gabbe, 2012).

Opinion is divided about the use of long-acting parenteral progestins such as medroxyprogesterone (Depo-Provera). Some health care providers recommend their use, particularly in women who are noncompliant with daily dosing oral contraceptives. In contrast, other health care providers believe that this method may adversely affect glycemic control. In addition, although Depo-Provera may

lower serum triglyceride and high-density lipoprotein (HDL) cholesterol levels, it does not lower total cholesterol or low-density lipoprotein (LDL) levels. For this reason it is not recommended as a first-choice method of contraception for women with diabetes (Landon, Catalano, and Gabbe, 2012).

The transdermal (patch) and transvaginal (vaginal ring) are newer contraceptive methods, particularly effective in women who prefer weekly or every-third-week dosing, respectively. For women weighing more than 90 kg (198 lbs) the contraceptive failure rate with transdermal administration is higher than in normal-weight women. Therefore this method would be contraindicated in obese women. Women who choose the patch as their contraceptive method should have no risk factors for cardiovascular or thromboembolic disease (Cunningham, Leveno, Bloom, et al., 2010).

The risks associated with pregnancy increase with the duration and severity of diabetes. In addition, pregnancy may contribute to the vascular changes associated with diabetes. This information needs to be discussed thoroughly with the woman and her partner. Sterilization is often recommended for the woman who has completed her family, has poor metabolic control, or has significant vascular problems.

GESTATIONAL DIABETES MELLITUS

GDM complicates approximately 3% to 9% of all pregnancies (Moore and Catalano, 2009) and accounts for more than 90% of all cases of diabetic pregnancy (Landon, Catalano, and Gabbe, 2012). It occurs more often now than in the past in the United States, probably because of increasing rates of overweight and obesity (ACOG, 2011). According to White's classification system, women with GDM fall into classes A_1 and A_2 (see Table 11-1). It is more likely to occur among Hispanic, Native American, Asian, and African-American women than Caucasians and is likely to recur in future pregnancies; the risk for development of overt diabetes in later life is also increased (Moore and Catalano, 2009). This tendency is especially true of women whose GDM is diagnosed early in pregnancy (Landon, Catalano, and Gabbe, 2012). Classic risk factors for GDM include a family history of diabetes and a previous pregnancy that resulted in an unexplained stillbirth or the birth of a malformed or macrosomic fetus. Other risk factors for GDM include obesity, hypertension, glycosuria, and maternal age older than 25 years. Interestingly, more than half of all women diagnosed with GDM do not have these risk factors (Landon, Catalano, and Gabbe, 2012).

Although most women are screened for GDM between 24 and 28 weeks of gestation, those with strong risk factors should be screened earlier in pregnancy. Women with morbid obesity, a strong family history of diabetes, a history of GDM in a previous pregnancy, or a history of giving birth to a macrosomic stillborn infant or an infant weighing more than 4500 g are candidates for early screening. If the early screening results are normal, they should be rescreened at 24 to 28 weeks of gestation (Landon, Catalano, and Gabbe, 2012).

GDM is usually diagnosed during the second half of pregnancy. As fetal nutrient demands rise during the late second and the third trimesters, maternal nutrient ingestion induces greater and more sustained levels of blood glucose. At the same time maternal insulin resistance is also increasing because of the insulin-antagonistic effects of the placental hormones, cortisol, and insulinase. Consequently maternal insulin demands rise as much as threefold. Most pregnant women are capable of increasing insulin production to compensate for insulin resistance and maintain euglycemia. However, when the pancreas is unable to produce sufficient insulin or the insulin is not used effectively, GDM can result.

Fetal Risks

No increase in the incidence of birth defects has been found among infants of women who develop GDM after the first trimester because the critical period of organ formation has already passed by that time (Moore and Catalano, 2009). However, Anderson, Waller, Canfield, et al., (2005) found that women who were obese before conception (BMI more than 30 kg/m^2) and developed GDM were at greater risk to give birth to infants with CNS defects.

Screening for Gestational Diabetes Mellitus

All pregnant women not known to have pregestational diabetes should be screened for GDM by history, clinical risk factors, or laboratory screening of blood glucose levels. Based on history and clinical risk factors, some women are at low risk for the development of GDM. Therefore glucose testing for this low risk population is not cost-effective (ADA, 2009). This group includes normal-weight women younger than 25 years of age who have no family history of diabetes, are not members of an ethnic or a racial group known to have a high prevalence of the disease, and have no history of abnormal glucose tolerance or adverse obstetric outcomes usually associated with GDM (ADA, 2009).

Two different screening methods for GDM are currently in use. In the one-step procedure a diagnostic oral glucose tolerance test is performed without prior glucose screening. In the United States a two-step screening method generally is used. The first step is a screen consisting of a 50-g oral glucose load followed by a plasma glucose measurement 1 hour later. The woman need not be fasting when the screen is done. A glucose value of 130 to 140 mg/dL is considered a positive screen. An initial positive screening result is followed by step 2, a 3-hour (100-g) oral glucose tolerance test (OGTT) (Landon, Catalano, and Gabbe, 2012). ACOG currently recommends use of the two-step screening procedure because there is no evidence at this time that the one-step method leads to clinically significant improvements in maternal or newborn outcomes. However, use of the one-step method would significantly increase health care costs (ACOG, 2011).

The OGTT is administered after an overnight fast and at least 3 days of unrestricted diet (at least 150 g of carbohydrate) and physical activity. The woman is instructed to avoid caffeine because it increases glucose levels and to abstain from smoking for 12 hours before the test. The 3-hour OGTT requires a fasting blood glucose level, which is drawn before giving a 100-g glucose load. Blood glucose levels are then drawn 1, 2, and 3 hours later. The woman is diagnosed with GDM if two or more values are met or exceeded (Moore and Catalano, 2009) (Fig. 11-4).

Nursing diagnoses and expected outcomes of care for women with GDM are basically the same as those for women with pregestational diabetes except that the time frame for planning may be shortened with GDM because the diagnosis is usually made later in pregnancy (see Nursing Care Plan).

CARE MANAGEMENT

Antepartum

When the diagnosis of GDM is made, treatment begins immediately, allowing little or no time for the woman and her family to adjust to the diagnosis before they are expected to participate in the treatment plan. With each step of the treatment plan the nurse and other health care providers should educate the woman and her family,

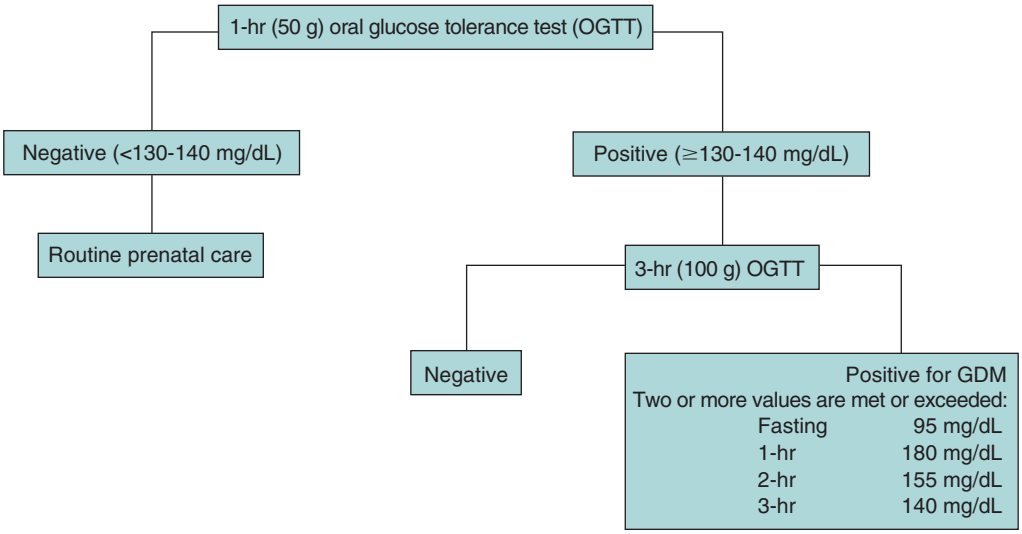

FIG 11-4 Screening and diagnosis for gestational diabetes. *GDM,* Gestational diabetes mellitus. (Data from American Diabetes Association (ADA): Position statement: diagnosis and classification of diabetes mellitus, *Diabetes Care* 32(suppl):S62–S67, 2009; Moore TR, Catalano PM: Diabetes in pregnancy. In Creasy RK, Resnik R, Iams JD, et al, editors: *Creasy & Resnik's maternal-fetal medicine: principles and practice*, ed 6, Philadelphia, 2009, Saunders.)

providing detailed and comprehensive explanations to ensure understanding, participation, and adherence to the necessary interventions. Potential complications should be discussed, and the need for maintenance of euglycemia throughout the remainder of the pregnancy reinforced. Knowing that GDM typically disappears when the pregnancy is over may be reassuring for the woman and her family.

As with pregestational diabetes, the aim of therapy in women with GDM is strict blood glucose control. Fasting blood glucose levels should range from 65 to 95 mg/dL, and 1-hour postmeal blood glucose levels should be less than 130 to 140 mg/dL (Moore and Catalano, 2009). Postmeal glucose levels at 2 hours should be less than 120 mg/dL (Landon, Catalano, and Gabbe, 2012) (see Table 11-3).

Diet. Dietary modification is the mainstay of treatment for GDM. The woman with GDM is placed on a standard diabetic diet. The usual prescription is 30 kcal/kg/day based on a normal preconception weight. For obese women the usual prescription is up to 25 kcal/kg/day, which translates into 1500 to 2000 kcal/day. Carbohydrate intake is restricted to approximately 50% of caloric intake (Moore and Catalano, 2009). Dietary counseling by a registered dietitian is recommended.

Exercise. Several studies have examined the benefits of exercise in women with GDM. Three randomized trials found that exercise improved cardiovascular fitness without improving pregnancy outcome. Another study found that exercise decreased the need for insulin in overweight women with GDM (Cunningham, Leveno, Bloom, et al., 2010).

Monitoring Blood Glucose Levels. Blood glucose monitoring is necessary to determine whether euglycemia can be maintained by diet and exercise. Women are instructed to monitor their blood sugar daily. The frequency and timing of blood glucose monitoring should be individualized for each woman. A typical schedule for monitoring blood glucose is on rising in the morning, after breakfast, before and after lunch, after dinner, and at bedtime (Moore and Catalano, 2009). Women with GDM usually perform self-monitoring at home with additional monitoring at the clinic or office visit.

Medications for Controlling Blood Glucose Levels. Approximately 25% of women with GDM require insulin during the pregnancy to maintain satisfactory blood glucose levels, despite compliance with the prescribed diet (Landon, Catalano, and Gabbe, 2012). In contrast to women with insulin-dependent diabetes, women with GDM are managed initially with diet and exercise alone. If fasting plasma glucose levels are greater than 95 mg/dL or 2-hour postmeal levels are greater than 120 mg/dL, insulin therapy is begun (Cunningham, Leveno, Bloom, et al., 2010) (see Table 11-3).

For the past several years oral hypoglycemic therapy has been used as an alternative to insulin in women with GDM who require medication in addition to diet for blood glucose control. Women who are unable or unwilling to take insulin by injection or are cognitively impaired also may be candidates for oral hypoglycemic medication.

Glyburide is the oral agent most frequently prescribed. The fact that only minimal amounts of glyburide cross the placenta to the fetus makes it a good drug for use during pregnancy (Moore and Catalano, 2009). Several studies have shown that glyburide controls blood glucose levels as well as insulin does in women with GDM. Furthermore, research revealed no increase in hypoglycemia or macrosomia in neonates whose mothers took glyburide. However, in one study neonates born to women taking glyburide were found to be more likely to experience birth injury or require phototherapy (Landon, Catalano, and Gabbe, 2012). Glyburide may not work as well in women who are obese or who had higher levels of hyperglycemia discovered early in pregnancy (Landon, Catalano, and Gabbe, 2012). Studies have shown that glyburide should be taken at least 30 minutes (preferably 1 hour) before a meal so its peak effect covers the 2-hour postmeal blood glucose level. Because episodes of hypoglycemia can occur between meals, women taking glyburide should always carry with them sources of fast sugar (Moore and Catalano, 2009).

Metformin is another oral hypoglycemic agent sometimes used in the management of GDM. Although metformin crosses the placenta, it does not appear to be teratogenic. However, glyburide may

NURSING CARE PLAN

The Pregnant Woman with Gestational Diabetes

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
Deficient Knowledge related to gestational diabetes as evidenced by the woman's questions and concerns	Woman will be able to verbalize important information regarding gestational diabetes, its management, and potential effects on the pregnancy and fetus.	Assess woman's current knowledge base regarding the disease process, management, effects on pregnancy and fetus, and potential complications.	To provide database for further teaching
		Explain pathophysiologic aspects of diabetes, effects on pregnancy and fetus, and potential complications.	To promote compliance with treatment plan
		Explain principles of diabetic diet and have woman plan her meals for 1 day following these principles.	To promote self-management and compliance with treatment plan
		Demonstrate procedure for blood glucose monitoring and obtain return demonstration.	To establish woman's comfort and competence with procedure
		Demonstrate procedure for insulin administration, should this become necessary, and obtain return demonstration.	To establish woman's comfort and competence with procedure
		Explain importance of correctly taking oral hypoglycemic medication (right dose, right time), should this become necessary.	To promote self-management and compliance with treatment plan
		Review signs and symptoms of hypoglycemia and hyperglycemia and appropriate interventions for both.	To promote prompt recognition of complications and self-management
		Provide contact numbers for health care team for prompt interventions and answers to questions on ongoing basis.	To promote comfort
		Review expected plan of care.	To allay anxiety and enlist cooperation of woman in her care
Risk for Fetal Injury related to elevated maternal glucose levels.	The fetus will remain free of injury and be born at term in a healthy state.	Assess woman's current diabetic control.	To identify risk for fetal macrosomia
		Monitor fundal height during each prenatal visit.	To identify appropriate fetal growth
		Assess fetal movement and heart rate during each prenatal visit and perform fetal assessment tests as ordered during the third trimester.	To assess fetal well-being.
Anxiety related to threat to maternal and fetal well-being as evidenced by the woman's verbal expressions of concern	The woman will identify sources of anxiety and report feeling less anxious.	Through therapeutic communication promote open relationship with woman.	To promote trust
		Listen to woman's feelings and concerns.	To assess for any misconception or misinformation that may be contributing to anxiety
		Review potential dangers by providing factual information.	To correct any misconceptions or misinformation
		Encourage woman to share concerns with her health care team.	To promote collaboration in her care

be better than metformin at controlling blood glucose levels in women with GDM (Landon, Catalano, and Gabbe, 2012).

Fetal Surveillance. Women with GDM whose blood glucose levels are well controlled by diet are at low risk for an IUFD. Therefore antepartum fetal testing is not performed routinely in these women unless they also have hypertension, a history of a prior stillbirth, or suspected macrosomia. Women with these complications or those who require insulin for blood glucose control may have twice-weekly NSTs beginning at 32 weeks of gestation. Women with uncomplicated GDM begin fetal testing at 40 weeks of gestation. In general women with GDM can continue pregnancy until 40 weeks of gestation and the spontaneous onset of labor. However, fetal growth should be monitored carefully because the risk for macrosomia as the pregnancy approaches 40 weeks of gestation is apparently increased (Landon, Catalano, and Gabbe, 2012).

Intrapartum

During the labor and birth process blood glucose levels are monitored hourly to maintain levels at 80 to 120 mg/dL (Moore and Catalano, 2009). Levels within this range decrease the incidence of neonatal hypoglycemia. Infusing rapid-acting insulin intravenously may be necessary during labor to maintain these levels. However, it is usually possible to maintain excellent glucose control in women with Class A_1 GDM during labor by simply avoiding IV fluids containing dextrose (Gilbert, 2011; Moore and Catalano, 2009). Although GDM is not an indication for cesarean birth, this

procedure may be necessary in the presence of preeclampsia or macrosomia.

Postpartum

Most women with GDM return to normal glucose levels after childbirth. However, the recurrence risk for GDM in the next pregnancy is 35% to 75%. Women who have had GDM also have a 35% to 60% risk for developing type 2 diabetes mellitus within the next 20 years (Gilbert, 2011). Currently ACOG recommends assessing all women who had GDM for carbohydrate intolerance with a 75-g, 2-hr OGTT or a fasting plasma glucose level at 6 to 12 weeks after delivery. The optimal frequency of subsequent testing has not been established. However, the ADA recommends repeat testing at least every 3 years for women with a history of GDM and normal postpartum glucose testing results (Landon, Catalano, and Gabbe, 2012). Obesity is a major risk factor for the later development of diabetes. Women with a history of GDM, particularly those who are overweight, should be encouraged to make lifestyle changes that include weight loss and exercise to reduce this risk (Gilbert, 2011). Children born to women with GDM are also at risk for becoming obese in childhood or adolescence (Landon, Catalano, and Gabbe, 2012).

THYROID DISORDERS

Hyperthyroidism

Hyperthyroidism in pregnancy is rare, occurring in approximately 1 of every 1000 to 2000 pregnancies (Cunningham, Leveno, Bloom, et al., 2010). In 90% to 95% of pregnant women it is caused by Graves' disease (Nader, 2009). Clinical manifestations of hyperthyroidism include heat intolerance, diaphoresis, fatigue, anxiety, emotional lability, and tachycardia. Many of these symptoms also occur with pregnancy; thus the disorder can be difficult to diagnose. Signs that may help differentiate hyperthyroidism from normal pregnancy changes include weight loss, goiter, and a pulse rate greater than 100 beats/min (Nader, 2009). Laboratory findings include elevated free thyroxine (T_4) and triiodothyronine (T_3) levels and greatly suppressed thyroid-stimulating hormone (TSH) levels (Cunningham, Leveno, Bloom, et al., 2010; Nader, 2009). Moderate and severe hyperthyroidism must be treated during pregnancy. Untreated or inadequately treated women have an increased risk of miscarriage; preterm birth; and giving birth to stillborn infants or infants with goiter, hyperthyroidism, or hypothyroidism. However, most neonates born to women with hyperthyroidism have normal thyroid function. Women with hyperthyroidism are at increased risk for developing severe preeclampsia and heart failure (Cunningham, Leveno, Bloom, et al., 2010; Nader, 2009).

The primary treatment of hyperthyroidism during pregnancy is drug therapy. The medications most often prescribed in the United States are propylthiouracil (PTU) or methimazole (MM). Both drugs are effective at controlling symptoms, but both have potentially dangerous maternal and fetal side effects. PTU can cause hepatic toxicity serious enough to require liver transplantation. When prescribed during the first trimester of pregnancy, MM can cause choanal atresia or esophageal atresia, facial anomalies, and developmental delay in exposed fetuses. Although the likelihood of maternal and fetal side effects from both drugs is low, a panel convened by the U.S. Food and Drug Administration (FDA) and the American Thyroid Association recommended that PTU be used only in the first trimester of pregnancy. Women requiring drug therapy for hyperthyroidism should be switched to MM for the remainder of pregnancy (Mestman, 2012).

The usual starting dose of PTU is 100 to 150 mg three times a day. For MM the initial dose is generally 20 mg/day. Women usually show clinical improvement (weight gain and less tachycardia) within 2 to 6 weeks after beginning therapy. Once clinical improvement occurs, the dose of PTU or MM may be cut in half. If symptoms worsen the medication dosage is doubled (Mestman, 2012). During therapy thyroid test results are used to taper the drug to the smallest effective dose to prevent development of unnecessary fetal or neonatal hypothyroidism. In many women the medication can be discontinued by 32 to 36 weeks of gestation. PTU readily crosses the placenta and may cause fetal hypothyroidism, which is characterized by goiter, bradycardia, and intrauterine growth restriction (IUGR) (Nader, 2009).

Both medications work well in and are well tolerated by most women. The most common maternal side effects of both PTU and MM are pruritus and skin rash. Other possible side effects include drug-related fever, bronchospasm, migratory polyarthritis, a lupus-like syndrome, and cholestatic jaundice (Mestman, 2012; Nader, 2009). The most severe side effect is agranulocytosis, which occurs rarely and usually develops only in older women and in those taking high doses of the drug. Symptoms of agranulocytosis are fever and unexpected sore throat, which should be reported immediately to the health care provider; and the woman should stop taking the medication (Cunningham, Leveno, Bloom, et al., 2010; Mestman, 2012; Nader, 2009). Beta-adrenergic blockers such as propranolol (Inderal) or atenolol (Tenormin) may be used in severe hyperthyroidism to control maternal symptoms, especially heart rate. However, long-term use of these medications is not recommended because of the potential for IUGR, bradycardia, and hypoglycemia (Nader, 2009).

After birth women taking either PTU or MM who choose to breastfeed should be informed that the medications do not appear to adversely affect the neonate's thyroid function. The woman should take her antithyroid medication just after breastfeeding, thus allowing a 3- to 4-hour period before nursing again (Mestman, 2012; Nader, 2009).

Radioactive iodine must not be used in diagnosis or treatment of hyperthyroidism in pregnancy because therapeutic doses given to treat maternal thyroid disease may also destroy the fetal thyroid (Cunningham, Leveno, Bloom, et al., 2010). In severe cases surgical treatment of hyperthyroidism, subtotal thyroidectomy, can be performed during pregnancy. Surgery is best performed during the second trimester of pregnancy, although it can be done during the first or third trimester if necessary. Surgery is usually reserved for women with severe disease, those for whom drug therapy proves toxic, and those who are unable to follow the prescribed medical regimen. Risks associated with the surgery are hypoparathyroidism, recurrent laryngeal nerve paralysis, and anesthesia-related complications (Nader, 2009).

! NURSING ALERT

A serious but uncommon complication of undiagnosed or partially treated hyperthyroidism is thyroid storm, which can occur in response to stress such as labor and vaginal birth, infection, preeclampsia, or surgery. A woman with this emergency disorder may have fever, restlessness, tachycardia, vomiting, hypotension, or stupor. Prompt treatment is essential. IV fluids and oxygen are administered, along with high doses of PTU. After administration of PTU, iodide is given. Other medications include antipyretics, dexamethasone, and beta-blockers (Cunningham, Leveno, Bloom, et al., 2010; Nader, 2009).

Hypothyroidism

Hypothyroidism occurs in two to three pregnancies per 1000. Because severe hypothyroidism is often associated with infertility and an increased risk of miscarriage, it is not often seen during pregnancy (Cunningham, Leveno, Bloom, et al., 2010). Although iodine deficiency is rare in the United States, it is a common cause of maternal, fetal, and neonatal hypothyroidism in the rest of the world (Nader, 2009). Adult hypothyroidism is usually caused by glandular destruction by autoantibodies, most commonly because of Hashimoto's thyroiditis. Characteristic symptoms of hypothyroidism include weight gain, lethargy, decrease in exercise capacity, and cold intolerance. Women who are moderately symptomatic can also develop constipation, hoarseness, hair loss, brittle nails, and dry skin. Laboratory values in pregnancy include elevated levels of TSH, with or without low T_4 levels (Nader, 2009).

Pregnant women with untreated hypothyroidism are at increased risk for miscarriage, preeclampsia, gestational hypertension, placental abruption, preterm birth, and stillbirth. Infants born to mothers with hypothyroidism may also be of low birth weight (Cunningham, Leveno, Bloom, et al., 2010; Nader, 2009). These outcomes can be improved with early treatment (Nader, 2009).

Thyroid hormone supplements are used to treat hypothyroidism. Levothyroxine (e.g., T_4 [Synthroid]) is most often prescribed during pregnancy. The usual beginning dosage is 0.1 to 0.15 mg/day, with adjustment by 25 to 50 mcg every 4 to 6 weeks as necessary based on the maternal TSH level (Cunningham, Leveno, Bloom, et al., 2010; Nader, 2009). The aim of drug therapy is to maintain the TSH level at the lower end of the normal range for pregnant women. Women with little or no functioning thyroid tissue require higher doses of levothyroxine. In addition, as pregnancy progresses increased doses of thyroid hormone are usually required. This increased demand during pregnancy is probably related to increased estrogen levels (Cunningham, Leveno, Bloom, et al., 2010; Nader, 2009).

! NURSING ALERT

If taking iron supplementation, pregnant women should be told to take levothyroxine at a different time of day than their iron tablets because ferrous sulfate decreases absorption of T_4 (Nader, 2009).

The fetus depends on maternal thyroid hormones until approximately 18 weeks of gestation, when fetal production begins. Normal maternal T_4 levels early in pregnancy are important for proper fetal brain development. Studies have shown that even mild maternal hypothyroidism during the first trimester has been associated with long-term neuropsychologic damage in their children. More research needs to be conducted on this topic (Mestman, 2012).

CARE MANAGEMENT

Education of the pregnant woman with thyroid dysfunction is essential to promote compliance with the plan of treatment. Important points to discuss with the woman and her family include the disorder and its potential effect on her, her family, and her fetus; the medication regimen and possible side effects; the need for continuing medical supervision; and the importance of compliance.

The woman often needs the nurse's help to cope with the discomforts and frustrations associated with symptoms of the disorder. For example, the woman with hyperthyroidism who has nervousness and hyperactivity along with weakness and fatigue can benefit from suggestions to channel excess energies into quiet diversional activities such as reading or crafts. Discomfort associated with hypersensitivity to heat (hyperthyroidism) or cold intolerance (hypothyroidism) can be minimized by appropriate clothing and regulation of environmental temperatures and by avoiding temperature extremes.

Nutrition counseling with a registered dietitian may provide guidance in selecting a well-balanced diet. The woman with hyperthyroidism who has increased appetite and poor weight gain and the hypothyroid woman who has anorexia and lethargy need counseling to ensure adequate intake of nutritionally sound foods to meet both maternal and fetal needs.

MATERNAL PHENYLKETONURIA

Phenylketonuria (PKU), a recognized cause of cognitive impairment, is an inborn error of metabolism caused by an autosomal recessive trait that creates a deficiency in the enzyme phenylalanine hydrolase. Absence of this enzyme impairs the ability of the body to metabolize the amino acid phenylalanine found in all protein foods. Consequently toxic accumulation of phenylalanine in the blood occurs, which interferes with brain development and function. Individuals with this disorder also have hypopigmentation of hair, eyes, and skin because phenylalanine inhibits melanin production. PKU affects 1 in every 10,000 to 15,000 Caucasian newborns (Cunningham, Leveno, Bloom, et al., 2010).

PKU was the first inborn error of metabolism for which to be universally screened in the United States. Since 1961 all newborns have been tested soon after birth for this disorder. Prompt diagnosis and therapy with a phenylalanine-restricted diet significantly decreases the incidence of cognitive impairment (Aminoff, 2009). The special diet should be followed indefinitely because individuals who do not continue phenylalanine restriction have been reported to have significantly lower IQs (Cunningham, Leveno, Bloom, et al., 2010).

The keys to the prevention of fetal anomalies caused by PKU are the identification of women in their reproductive years with the disorder and dietary compliance for women who are diagnosed. Screening for undiagnosed homozygous maternal PKU at the first prenatal visit may be warranted, especially in individuals with a family history of the disorder, with low intelligence of uncertain origin, or who have given birth to microcephalic infants. Ideally women with PKU begin dietary phenylalanine restriction before conception and continue it throughout pregnancy (Gilbert, 2011). The dietary modification normally excludes all high-protein foods such as meat, milk, eggs, and nuts and wheat products, making it very similar to a vegan diet (Feillet and Agostoni, 2010; Gilbert, 2011). Phenylalanine levels are monitored at least once and preferably twice a week throughout pregnancy (Gilbert, 2011). Experts recommend that maternal phenylalanine levels be less than 6 mg/dL for at least 3 months before conception and range between 2 and 6 mg/dL throughout pregnancy. These levels are associated with a decrease in fetal sequelae (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011). High maternal phenylalanine levels are associated with microcephaly, cognitive impairment, and congenital heart defects in their children (Aminoff, 2009; Cunningham, Leveno, Bloom, et al., 2010). Ultrasound examinations are used for fetal surveillance beginning in the first trimester. A spontaneous vaginal birth is anticipated.

Women with PKU should be advised against breastfeeding because their milk will contain a high concentration of phenylalanine (Aminoff, 2009). If these women choose to breastfeed despite the risk, their phenylalanine blood levels must be monitored closely

(Lawrence and Lawrence, 2005). Infants diagnosed with PKU can usually be breastfed safely because human breast milk is a relatively low phenylalanine food (Feillet and Agostoni, 2010). If infants with PKU are breastfed, the amount of human breast milk ingested daily may be monitored so phenylalanine levels do not get too high. Another strategy that may be implemented is to alternate human breast milk feedings with products that contain little or no phenylalanine (Feillet and Agostoni, 2010).

CARDIOVASCULAR DISORDERS

During a normal pregnancy the maternal cardiovascular system undergoes many changes that place a physiologic strain on the heart. The major cardiovascular changes that occur during a normal pregnancy and affect the woman with cardiac disease are increased intravascular volume, decreased systemic vascular resistance, cardiac output changes occurring during labor and birth, and the intravascular volume changes that occur just after childbirth. The strain is present during pregnancy and continues after birth. The normal heart can compensate for the increased workload so pregnancy, labor, and birth are generally well tolerated; but the diseased heart is hemodynamically challenged.

If the cardiovascular changes are not well tolerated, cardiac failure can develop during pregnancy, labor, or the postpartum period. In addition, if myocardial disease develops, valvular disease exists, or a congenital heart defect is present, cardiac decompensation (inability of the heart to maintain a sufficient cardiac output) may occur. Fever and infection are the major causes of cardiac decompensation during pregnancy (Easterling and Stout, 2012).

From 0.5% to 4% of pregnancies are complicated by heart disease. Cardiac disorders are one of the most important nonobstetric causes of maternal mortality (Gaddipati and Troiano, 2013). The rate of rheumatic fever, once responsible for the vast majority of cardiac disease in pregnancy, is now declining (Gilbert, 2011). Currently cardiomyopathy and congenital heart disease are the major causes of cardiac disease in pregnant women (Gaddipati and Troiano, 2013). Thanks to better management of congenital heart disease in childhood, pregnancy outcomes for women with these conditions are generally positive. However, cardiac disease accounts for 15% of maternal mortality during pregnancy (Gilbert, 2011). Box 11-2 lists maternal cardiac disease risk groups and their related mortality rates. Pregnancy is not advised in women who have several cardiac conditions, including pulmonary hypertension, Marfan syndrome with aortic involvement, and Eisenmenger syndrome, because the associated maternal mortality rate is extremely high, up to 50% (Easterling and Stout, 2012; Gaddipati and Troiano, 2013).

The degree of disability experienced by the woman with cardiac disease is often more important in the treatment and prognosis during pregnancy than the diagnosis of the type of cardiovascular disease. The New York Heart Association (NYHA) functional classification of heart disease is a widely accepted standard:

- Class I: Asymptomatic without limitation of physical activity
- Class II: Symptomatic with slight limitation of activity
- Class III: Symptomatic with marked limitation of activity
- Class IV: Symptomatic with inability to carry on any physical activity without discomfort

No classification of heart disease can be considered rigid or absolute, but the NYHA classification offers a basic practical guide for treatment, assuming that frequent prenatal visits, good patient cooperation, and appropriate obstetric care occur. Medical therapy is conducted by a team approach and includes the cardiologist, the obstetrician, and nurses. The functional classification may change for the pregnant woman because of the hemodynamic changes that occur in the cardiovascular system. A 30% to 45% increase in cardiac output occurs compared with nonpregnancy resting values, with most of the increase in the first trimester and the peak at 20 to 26 weeks of gestation (Blanchard and Shabetai, 2009). The functional classification of the disease is determined at 3 months and again at 7 or 8 months of gestation. Pregnant women may progress from class I or II to class III or IV during the pregnancy as cardiac output increases and more stress is placed on the heart.

Miscarriage and stillbirth both occur more often in the pregnant woman with cardiac problems than in healthy women. In addition, IUGR is common, probably because of low oxygen pressure in the mother (Blanchard and Shabetai, 2009).

A diagnosis of cardiac disease depends on the history, physical examination, radiographic and electrocardiographic findings, Holter monitoring, echocardiography, and if indicated ultrasonographic results. Most diagnostic studies are noninvasive and can be performed safely during pregnancy. The differential diagnosis of heart disease also involves ruling out respiratory problems and other potential causes of chest pain.

BOX 11-2 MATERNAL CARDIAC DISEASE RISK GROUPS

Group I (Mortality Rate <1%)
- Atrial septal defect
- Ventricular septal defect (uncomplicated)
- Patent ductus arteriosus
- Pulmonic and tricuspid disease
- Biosynthetic valve prosthesis (porcine and human allograft)
- Tetralogy of Fallot (corrected)
- Mitral stenosis (New York Heart Association [NYHA] class I and II)

Group II (Mortality Rate 5%-15%)
- Mitral stenosis NYHA class III and IV or with atrial fibrillation
- Aortic stenosis
- Coarctation of aorta (uncomplicated)
- Uncorrected tetralogy of Fallot
- Previous myocardial infarction
- Marfan syndrome with normal aorta
- Artificial heart valve

Group III (Mortality Rate 25%-50%)
- Pulmonary hypertension
- Coarctation of the aorta (complicated)
- Endocarditis
- Marfan syndrome with aortic involvement
- Eisenmenger syndrome

Data from Gaddipati S, Troiano NH: Cardiac disorders in pregnancy. In Troiano NH, Harvey CJ, Chez BF, editors: *AWHONN's high risk and critical care obstetrics*, ed 3, Philadelphia, 2013, Lippincott Williams and Wilkins.

Congenital Cardiac Diseases

Atrial Septal Defect

Atrial septal defect (ASD) is an abnormal opening between the atria. It is one of the causes of a left-to-right shunt and one of the most common congenital defects seen during pregnancy (Gaddipati and Troiano, 2013). This defect may go undetected because the woman is usually asymptomatic. The pregnant woman with an ASD usually

has an uncomplicated pregnancy. However, some women may develop congestive heart failure or arrhythmias as the pregnancy progresses as a result of increased plasma volume. Another possible complication is the development of emboli (blood clots) (Gaddipati and Troiano, 2013).

Ventricular Septal Defect

Ventricular septal defect (VSD), an abnormal opening between the right and left ventricles, is another cause of a left-to-right shunt. It may occur as a single lesion or in combination with other cardiac anomalies such as tetralogy of Fallot. The defect is usually diagnosed and corrected early in life. As a result a VSD is not very common in pregnancy. Women with small, uncomplicated VSDs usually do not have pregnancy complications. For women with a large VSD, there is a higher risk for congestive heart failure or pulmonary hypertension. Medical management includes administration of anticoagulants if indicated, along with rest and decreased physical activity (Gaddipati and Troiano, 2013).

Coarctation of the Aorta

Coarctation of the aorta is a localized narrowing of the aorta near the insertion of the ductus. Patients with this lesion have hypertension in their upper extremities but hypotension in the lower extremities. Coarctation of the aorta is an example of an acyanotic congenital heart lesion. If at all possible, the lesion should be corrected surgically before pregnancy. However, pregnancy is usually relatively safe for the woman with uncomplicated, uncorrected coarctation. The maternal mortality rate is approximately 3% (Blanchard and Shabetai, 2009). Complications that can occur include hypertension, congestive heart failure, cerebrovascular accident (stroke), aortic dissection, and rupture of associated aneurysms (Blanchard and Shabetai, 2009; Easterling and Stout, 2012). The mainstays of treatment for uncorrected coarctation of the aorta during pregnancy are rest and antihypertensive medications, preferably beta-adrenergic blocking agents. Some authorities recommend cesarean birth to prevent blood pressure elevations during second-stage labor that could possibly lead to rupture of the aorta or cerebral blood vessels. However, vaginal birth is usually recommended, with cesarean birth performed only for obstetric indications. If bacteremia is suspected, antibiotic prophylaxis is given during labor and birth (Cunningham, Leveno, Bloom, et al., 2010).

Tetralogy of Fallot

Tetralogy of Fallot is by far the most common cyanotic heart disease observed during pregnancy (Blanchard and Shabetai, 2009). Components of tetralogy of Fallot include a VSD; pulmonary stenosis; overriding aorta; and right ventricular hypertrophy, leading to a right-to-left shunt. Women with tetralogy of Fallot are encouraged to have surgical repair preconceptionally because pregnancy does not cause a significant risk once the VSD and pulmonary stenosis have been repaired (Gaddipati and Troiano, 2013). On the other hand, women with uncorrected tetralogy of Fallot experience more right-to-left shunting during pregnancy, resulting in reduced blood flow through the pulmonary circulation and increasing hypoxemia, which can cause syncope or death (Gaddipati and Troiano, 2013). Maintenance of venous return in women with uncorrected tetralogy of Fallot is critical. Therefore the most dangerous time for these women is the late third trimester of pregnancy and the early postpartum period, when venous return is reduced by the large pregnant uterus and peripheral venous pooling after birth. Use of pressure-graded support hose is recommended. Blood loss during birth may also adversely affect venous return; thus blood volume must be adequately maintained. Prophylactic antibiotics should be given during the intrapartum period (Blanchard and Shabetai, 2009).

Acquired Cardiac Diseases

Mitral Valve Prolapse

Mitral valve prolapse (MVP) is a fairly common, usually benign, condition. Recently more specific echocardiographic diagnostic criteria have resulted in significantly reduced prevalence estimates for MVP (perhaps 1% of the female population) than previously thought (Blanchard and Shabetai, 2009). In MVP the mitral valve leaflets prolapse into the left atrium during ventricular systole, allowing some backflow of blood. Midsystolic click and late systolic murmur are hallmarks of this syndrome. Most cases are asymptomatic. A few women have atypical chest pain (sharp and located in the left side of the chest) that occurs at rest and does not respond to nitrates. They may also have anxiety, palpitations, dyspnea on exertion, and syncope. If women are symptomatic, beta-blocking drugs are given to relieve chest pain and palpitations and reduce the risk of life-threatening arrhythmias (Cunningham, Leveno, Bloom, et al., 2010). If symptoms are unusually severe, thyroid function should also be checked (Blanchard and Shabetai, 2009). Pregnancy and its associated hemodynamic changes may change or alleviate the murmur and click of MVP and its symptoms. Pregnancy is generally well tolerated unless bacterial endocarditis occurs. Antibiotic prophylaxis is often given before birth to prevent bacterial endocarditis (Cunningham, Leveno, Bloom, et al.; Easterling and Stout, 2012).

Mitral Stenosis

Mitral stenosis is almost always caused by rheumatic heart disease (RHD), a consequence of rheumatic fever (Easterling and Stout, 2012). Rheumatic fever develops suddenly, often several symptom-free weeks after an inadequately treated group A beta-hemolytic streptococcal throat infection. Episodes of rheumatic fever create an autoimmune reaction in the heart tissue, leading to permanent damage of heart valves (usually the mitral valve) and the chordae tendineae cordis. This damage is classified as RHD. RHD may be evident during acute rheumatic fever or discovered years later. Recurrences of rheumatic fever are common, each with the potential to increase the severity of heart damage.

Mitral stenosis is a narrowing of the opening of the mitral valve caused by stiffening of valve leaflets, which obstructs blood flow from the atrium to the ventricle. As the mitral valve narrows, dyspnea worsens, occurring first on exertion and eventually at rest. A tight stenosis plus the increase in blood volume and cardiac output of normal pregnancy may cause pulmonary edema, atrial fibrillation, right-sided heart failure, infective endocarditis, pulmonary embolism, and massive hemoptysis (Blanchard and Shabetai, 2009; Cunningham, Leveno, Bloom, et al., 2010). Approximately 25% of women with mitral valve stenosis may become symptomatic for the first time during pregnancy. Maternal mortality is related to functional capacity. Almost all maternal deaths related to mitral stenosis occur in women who are classified as NYHA class III or IV (Cunningham, Leveno, Bloom, et al., 2010).

Women with a history of RHD who are at risk for exposure to streptococcal infection should receive prophylaxis with daily oral penicillin G or monthly benzathine penicillin (Bicillin) injections. Pregnant women are usually considered at high risk for exposure because they generally live around groups of children (Easterling and Stout, 2012). In addition, women with mitral stenosis may require diuretics such as furosemide (Lasix) to prevent pulmonary edema and beta blockers or calcium channel blockers to prevent tachycardia (Easterling and Stout, 2012). Cardioversion may be

needed for new-onset atrial fibrillation, a complication associated with mitral stenosis. Women who have chronic atrial fibrillation may need digoxin or beta blockers to control the heart rate. In addition, anticoagulant therapy may be needed to prevent embolism (Blanchard and Shabetai, 2009).

The care of the woman with mitral stenosis is typically managed by reducing her activity, restricting dietary sodium, and increasing bed rest, in addition to the pharmacologic management discussed previously (Cunningham, Leveno, Bloom, et al., 2010). The pregnant woman with mitral stenosis should be monitored clinically for symptoms and with echocardiograms to assess the atrial and ventricular size and heart valve function. Prophylaxis for intrapartum endocarditis and pulmonary infections may be given to women at high risk (Blanchard and Shabetai, 2009; Easterling and Stout, 2012).

During labor adequate pain control is required to prevent tachycardia. Epidural analgesia for labor is preferred (Easterling and Stout, 2012). Encourage the woman to labor and give birth in the lateral decubitus position and avoid the supine and lithotomy positions. Shortening the second stage of labor by vacuum- or forceps-assisted birth is also important to decrease the cardiac workload. Cesarean birth should be performed only for obstetric indications. Aggressive diuresis is initiated immediately after birth because fluid shifts can place the woman at risk for pulmonary edema (Blanchard and Shabetai, 2009; Easterling and Stout, 2012).

For women with NYHA class III or IV cardiac disease, surgical intervention may be necessary. Valve replacement and open commissurotomy have been performed successfully during pregnancy. Currently balloon valvotomy is likely to be the procedure of choice. Surgical intervention should be considered only when symptoms cannot be controlled by medical therapy (Easterling and Stout, 2012).

Aortic Stenosis

Aortic stenosis is a narrowing of the opening of the aortic valve leading to an obstruction to left ventricular ejection. It is rarely encountered as a complication of pregnancy because most women who develop this condition do so after their childbearing years are over. In the past the maternal mortality rate was reported to be as high as 17%, but it has decreased over the last several decades (Easterling and Stout, 2012). Medical management is similar to that for mitral stenosis.

Ischemic Heart Disease

Myocardial Infarction

Myocardial infarction (MI), an acute ischemic event, rarely occurs in women of childbearing age. It is estimated to occur in only 1 of 10,000 pregnancies (Blanchard and Shabetai, 2009). However, authorities anticipate that the incidence will rise, considering the number of women who delay childbearing until later in life (Gaddipati and Troiano, 2013). Frequently women with coronary artery disease have classic risk factors such as diabetes, hypertension, cigarette smoking, hyperlipidemia, and obesity (Cunningham, Leveno, Bloom, et al., 2010). The cardiac changes that normally occur in a pregnant woman may provoke symptoms for the first time. It is also possible for women with a history of MI to become pregnant (Gaddipati and Troiano, 2013).

MI occurs most frequently in the last trimester of pregnancy and in women older than 33 years. The maternal mortality rate from an MI during pregnancy is approximately 20%. Women are most likely to die at the time of the infarction or during labor and birth (Blanchard and Shabetai, 2009). The risk of maternal death increases if women give birth within 2 weeks of an MI (Easterling and Stout, 2012).

Medical management for pregnant women with MI is the same as that for nonpregnant women and includes the administration of morphine, nitrates, lidocaine, beta blockers, aspirin, magnesium sulfate, and calcium antagonists (Easterling and Stout, 2012). Thrombolytic agents such as urokinase, streptokinase, and tissue plasminogen activator (tPA) do not appear to cross the placenta. However, their use is considered to be relatively contraindicated in pregnancy because of the risk for subsequent maternal and fetal hemorrhage (Gaddipati and Troiano, 2013). Because pain can lead to tachycardia and increased cardiac demands, pain control during labor is crucial. The side-lying position is preferred to prevent pressure on the vena cava. Vaginal birth is preferable, with avoidance of maternal pushing and a vacuum- or forceps-assisted birth (Easterling and Stout, 2012).

Other Cardiac Diseases and Conditions

Primary Pulmonary Hypertension

Women with primary pulmonary hypertension (PPH) have constriction of the arteriolar vessels in the lungs, leading to an increase in the pulmonary artery pressure. As a result of this pathology, there is right ventricular hypertension, right ventricular hypertrophy and dilation, and finally right ventricular failure with tricuspid regurgitation and systemic congestion. The major physiologic difficulty in PPH is maintaining blood flow to the lungs. Any event that significantly decreases venous return to the heart such as hypotension impairs the ability of the right ventricle to pump blood through the pulmonary vessels with their high, fixed vascular resistance. Because hypotension can occur quickly and is often unresponsive to medical therapy, it must be avoided at all costs (Blanchard and Shabetai, 2009).

Symptoms may be nonspecific such as fatigue and shortness of breath. Dyspnea on exertion is the most common symptom (Cunningham, Leveno, Bloom, et al., 2010).

PPH is diagnosed by electrocardiography. The diagnosis is confirmed by right-sided cardiac catheterization, which may be deferred during pregnancy (Cunningham, Leveno, Bloom, et al., 2010). Mortality rates reported during pregnancy are as high as 50%; thus pregnancy is not advised in women with this condition (Blanchard and Shabetai, 2009). The most dangerous times for these women are the intrapartum and early postpartum periods because of increases in cardiac output and fluid shifts.

Medical management of PPH during pregnancy includes limiting activity and avoiding supine positioning. Diuretics, supplemental oxygen, and vasodilator medications are also ordered. During labor and birth hypotension must be avoided by carefully establishing epidural analgesia and preventing blood loss (Cunningham, Leveno, Bloom, et al., 2010).

Peripartum Cardiomyopathy

Peripartum cardiomyopathy (PCM) is congestive heart failure with cardiomyopathy. The classic criteria for the diagnosis of PCM include development of congestive heart failure during the last month of pregnancy or within the first 5 postpartum months; absence of heart disease before the last month of pregnancy; a left ventricular ejection fraction of less than 45%; and, most important, lack of another cause for heart failure. The cause of the disease is unknown (Blanchard and Shabetai, 2009). Theories that have been suggested include autoimmune mechanisms or nutritional deficiencies (Easterling and Stout, 2012; Gaddipati and Troiano, 2013). At one time viral infections were considered to be a possible cause, but

the prevalence of antibodies to echovirus and Coxsackie virus has not been found to be greater in women with cardiomyopathy than in those who do not have the disease (Easterling and Stout, 2012). The incidence of PCM is 1 in 1300 to 1 in 15,000 live births in the United States (Gaddipati and Troiano, 2013).

Associated risk factors include maternal age older than 30 years, multiparity, African descent, obesity, tocolytic use, preeclampsia, and chronic hypertension. Clinical findings are those of congestive heart failure (left ventricular failure). Clinical manifestations include dyspnea, fatigue, edema, and radiologic findings of cardiomegaly (Gaddipati and Troiano, 2013).

Medical management of PCM includes a regimen used for congestive heart failure: diuretics, sodium and fluid restriction, afterload-reducing agents, and digoxin. Anticoagulation may be necessary if the cardiac chambers are significantly dilated and contract poorly because of the increased risk for clot formation. Angiotensin-converting enzyme inhibitors, often prescribed to achieve afterload reduction, can be used only in the postpartum period because they are associated with fetal renal dysfunction. During labor epidural anesthesia is often used for pain control to decrease the cardiac workload and reduce tachycardia. Cesarean birth should be performed only for obstetric indications (Easterling and Stout, 2012).

In one half of all women with PCM left ventricular dysfunction resolves within 6 months. These women generally do well. However, if left ventricular dysfunction does not resolve within 6 months, approximately 85% of women with PCM will die in the next 4 to 5 years. Death is usually the result of progressive congestive heart failure, arrhythmia, or thromboembolism (Easterling and Stout, 2012). The recurrence rate for cardiomyopathy in a subsequent pregnancy is high, anywhere from 20% to 50%. The risk of recurrence is increased in women who did not completely recover left ventricular function after the initial episode of PCM (Blanchard and Shabetai, 2009).

Infective Endocarditis

Infective endocarditis, or inflammation of the innermost lining (endocardium) of the heart caused by invasion of microorganisms, is an uncommon disorder during pregnancy. It may be seen in women taking street drugs intravenously, although people who have had corrective surgery for congenital heart disease are at greatest risk to develop infective endocarditis (Cunningham, Leveno, Bloom, et al., 2010). Bacterial endocarditis, leading to incompetence of heart valves and thus congestive heart failure and cerebral emboli, can result in death. Treatment is with antibiotics.

Eisenmenger Syndrome

Eisenmenger syndrome is a right-to-left or bidirectional shunting that can be at either the atrial or the ventricular level of the heart and is combined with elevated pulmonary vascular resistance. It is associated with an underlying structural cardiac defect, either a VSD (most common) or a patent ductus arteriosus (Blanchard and Shabetai, 2009). Eisenmenger syndrome is associated with high mortality (50% in mothers and 50% in fetuses). Because of the poor pregnancy outcomes, pregnancy should be avoided by women with the syndrome. Termination may be recommended if pregnancy occurs (Gaddipati and Troiano, 2013). Although sudden death can occur at any time, the intrapartum and early postpartum periods seem to be the most dangerous (Blanchard and Shabetai, 2009). Maternal morbidity is associated with right ventricular failure and associated cardiogenic shock (Cunningham, Leveno, Bloom, et al., 2010).

In women who continue pregnancy despite the risks, management includes measures to maintain pulmonary blood flow. Physical activity is strictly limited. Other interventions include the use of pressure-graded elastic support hose and oxygen therapy. Antepartal hospitalization may be necessary to provide optimal care (Blanchard and Shabetai, 2009). During labor and birth narcotic-based regional anesthesia provides pain relief without causing excessive hemodynamic instability. Hypotension must be prevented at all costs because it results in more right-to-left shunting, thereby increasing hypoxemia, increasing pulmonary vascular resistance, and worsening the shunt. Volume overload or excessive systemic resistance must also be prevented because it further stresses the failing right side of the heart. Cesarean birth should be performed only for obstetric indications and avoided whenever possible (Easterling and Stout, 2012).

Marfan Syndrome

Marfan syndrome is an autosomal dominant disorder characterized by generalized weakness of the connective tissue, resulting in the characteristic feature of the disease, aortic root dilation. Other signs and symptoms associated with Marfan syndrome include dislocation of the optic lens, deformity of the anterior thorax, scoliosis, long limbs, joint laxity, and arachnodactyly. Diagnosis is usually based on family history and physical examination, including ocular, cardiovascular, and skeletal features (Easterling and Stout, 2012).

The majority of deaths from Marfan syndrome are caused by aortic dissection and rupture. Excruciating chest pain is the most common symptom of aortic dissection. Aortic dissection most often occurs in the third trimester of pregnancy or after birth. Overall the maternal mortality rate associated with Marfan's syndrome is greater than 50%. However, it is significantly increased if the aortic root diameter measures more than 4 cm (Easterling and Stout, 2012).

Preconception counseling for women with Marfan syndrome is essential to make women aware of the risks of pregnancy with this disease. An accurate assessment of the aortic root using noninvasive imaging with transesophageal echocardiography, computed tomography, or magnetic resonance imaging must be obtained to assess the woman's specific risk and make management recommendations. Elective repair of the aorta is recommended when the aortic root diameter measures 5.5 to 6 cm. Therefore women with an aortic root diameter greater than 5.5 cm should be counseled to have it repaired before becoming pregnant. On the other hand, women with an aortic root diameter less than 4 cm can attempt pregnancy with only modest risk (Easterling and Stout, 2012). Because the condition is inherited, each child born to a woman with Marfan syndrome has a 50% chance of having the disorder (Gaddipati and Troiano, 2013).

Management during pregnancy includes restricted activity and use of beta blockers to maintain a resting heart rate of approximately 70 beats/min. Tachycardia should also be prevented during labor. Women with aortic root diameters less than 4 cm can give birth vaginally, reserving cesarean birth for obstetric indications. Some authorities believe that women with larger aortic root diameters should give birth by elective cesarean because of concerns about increased pressure in the aorta during labor. However, data do not exist to make this a firm recommendation (Blanchard and Shabetai, 2009; Easterling and Stout, 2012).

Heart Transplantation

Increasing numbers of heart recipients are completing pregnancies successfully. Before conception the woman should be assessed for quality of ventricular function and potential rejection of the transplant. She should also be considered to be stabilized on her immunosuppressant regimen. Women who have no evidence of rejection

and have normal cardiac function at the beginning of the pregnancy appear to do well during pregnancy, labor, and birth. Research has shown that the transplanted heart responds normally to pregnancy-related changes. Complications that are common in women who have had a heart transplant include hypertension and at least one episode of rejection (Cunningham, Leveno, Bloom, et al., 2010). Conception should be postponed for at least 1 year after transplantation to prevent acute rejection episodes (Blanchard and Shabetai, 2009).

CARE MANAGEMENT

The presence of cardiac disease is a significant influencing factor in the decision-making process for or against becoming pregnant. Couples planning a pregnancy must understand the risks involved in their situation. If the pregnancy is unplanned, the nurse should explore the couple's desire to continue it in light of the risks involved. Pregnancy termination is one option, depending on the severity of the cardiac defect. The family may need further information to make an informed decision regarding the future of the pregnancy.

The pregnant woman with a cardiac disorder is in a high risk situation. Her care is provided by a multidisciplinary team, including a cardiologist, obstetrician, perinatologist, and registered nurse experienced in the care of women with high risk pregnancies. If she chooses to continue the pregnancy, the woman's condition may be assessed as often as weekly. For additional information on cardiac disease, visit the American Heart Association website at www.americanheart.org.

Antepartum

Therapy for the pregnant woman with heart disease is focused on minimizing stress on the heart, which intensifies as cardiac output increases. Cardiac output begins to rise significantly early in pregnancy and probably peaks somewhere between 25 and 30 weeks of gestation (Gordon, 2012). Factors that increase the risk of cardiac decompensation are avoided. The workload of the cardiovascular system is reduced by appropriate treatment of any coexisting emotional stress, hypertension, anemia, hyperthyroidism, or obesity.

Signs and symptoms of cardiac decompensation are taught at the first prenatal visit and reviewed at each subsequent visit (Box 11-3 and Patient Teaching box).

Infections are treated promptly because respiratory, urinary, or gastrointestinal (GI) tract infections can complicate the condition by accelerating the heart rate and by direct spread of organisms (e.g., streptococci) to the heart structure. As previously mentioned, infections are a major cause of cardiac decompensation during pregnancy. The woman should notify her health care provider at the first sign of infection or exposure to an infection. Vaccination against influenza and pneumococci can be given (Easterling and Stout, 2012).

Nutrition counseling is necessary, optimally with the woman's family present. The pregnant woman needs a well-balanced diet with iron and folic acid supplementation, high protein levels, and adequate calories to gain weight. Iron supplements tend to cause constipation; thus the woman should increase her intake of fluids and fiber. A stool softener may also be prescribed. It is important that the woman with a cardiac disorder avoid straining during defecation, thus causing the **Valsalva maneuver** (forced expiration against a closed airway, which when released, causes blood to rush to the heart and overload the cardiac system). Sodium restriction may be necessary. The woman's intake of potassium may be monitored to prevent hypokalemia, especially if she is taking diuretics.

BOX 11-3 SIGNS OF POTENTIAL COMPLICATIONS: CARDIAC DECOMPENSATION

Pregnant Woman: Subjective Symptoms

- Increasing fatigue or difficulty breathing, or both, with her usual activities
- Feeling of smothering
- Frequent cough
- Palpitations; feeling that her heart is "racing"
- Generalized edema: Swelling of face, feet, legs, fingers (e.g., rings do not fit anymore)

Nurse: Objective Signs

- Irregular, weak, rapid pulse (≥100 beats/min)
- Progressive, generalized edema
- Crackles at base of lungs after two inspirations and exhalations that do not clear after coughing
- Orthopnea; increasing dyspnea
- Rapid respirations (≥25 breaths/min)
- Moist, frequent cough
- Cyanosis of lips and nail beds

PATIENT TEACHING

The Pregnant Woman at Risk for Cardiac Decompensation

Instruct woman to:

- Watch for and immediately report signs of cardiac decompensation or congestive heart failure: generalized edema; distention of neck veins; dyspnea; frequent, moist cough; or palpitations.
- Watch for and immediately report signs of thromboembolism: pain, redness, tenderness, or swelling in extremities or chest pain.
- Avoid constipation and thus straining with bowel movements (Valsalva maneuver) by taking in adequate fluids and fiber. A stool softener may also be helpful.

Teach importance of:

- Daily weighing. Sudden weight gain indicates fluid retention.
- Keeping all prenatal visit appointments, although they will be scheduled more frequently than for "normal" pregnant women.
- Limiting activity (depending on classification of her heart disease). Patients with class I or II cardiac disease need 10 hours of sleep every night and 30 minutes of rest after meals. Patients with class III or IV cardiac disease usually need bed rest for most of each day.

Modified from Gilbert ES: *Manual of high risk pregnancy and delivery*, ed 5, St Louis, 2011, Mosby.

Depending on the specific cardiac condition, some women may be limited in their total daily fluid intake. A referral to a registered dietitian may be necessary for a nutritional plan of care.

Cardiac medications are prescribed as needed, with attention to fetal well-being. The hemodynamic changes that occur during pregnancy such as increased plasma volume and increased renal clearance of drugs can alter the amount of medication needed to establish and maintain a therapeutic drug level (Blanchard and Shabetai, 2009). Therefore monitoring drug levels during pregnancy is crucial to maintain effective therapy for the woman while minimizing risk to the fetus.

Anticoagulant therapy may be prescribed during pregnancy for several conditions such as recurrent venous thrombosis, pulmonary

embolus, RHD, prosthetic valves, or cyanotic congenital heart defects. If anticoagulant therapy is required during pregnancy, unfractionated heparin or low-molecular-weight heparin (Lovenox) is most commonly prescribed. Heparin, a large-molecule drug, is safe for use during pregnancy because it does not cross the placenta and has no teratogenic effects associated with its use. Warfarin (Coumadin), another popular anticoagulant, does cross the placenta (Gilbert, 2011). It can cause fetal bone and eye anomalies and cognitive impairment when taken early in pregnancy. Eye anomalies and cognitive impairment can occur in exposed fetuses even when the drug is taken only after the first trimester has ended (Niebyl and Simpson, 2012). Therefore warfarin is generally not prescribed during pregnancy. However, it is sometimes used from the second trimester until close to birth in women who have mechanical heart valves because of the increased risk of venous thromboembolism in these patients when heparin is used (Gilbert, 2011).

Tests for fetal maturity and well-being and placental sufficiency may be necessary. Other therapy is directly related to the functional classification of heart disease. The nurse must reinforce the need for close medical supervision.

Intrapartum

For all pregnant women the intrapartum period is the one that evokes the most apprehension in patients and caregivers. The woman with impaired cardiac function has additional reasons to be anxious because labor and giving birth place an additional burden on her already compromised cardiovascular system.

Assessments include the routine assessments for all laboring women and those for cardiac decompensation. In addition, arterial blood gases (ABGs) may be needed to assess for adequate oxygenation. A pulmonary artery catheter may be inserted to monitor hemodynamic status accurately during labor and birth. Electrocardiograph (ECG) monitoring and continuous monitoring of blood pressure and oxygen saturation **(pulse oximetry)** are usually instituted for the woman, and continuous fetal monitoring is used to monitor the fetus.

! NURSING ALERT

A pulse rate above 100 beats/min or a respiratory rate greater than 24 breaths/min, particularly when associated with dyspnea, may indicate impending ventricular failure (Cunningham, Leveno, Bloom, et al., 2010).

Nursing care during labor and birth focuses on the promotion of cardiac function. Minimize anxiety by maintaining a calm atmosphere. Provide anticipatory guidance by keeping the woman and her family informed of labor progress and events that are likely to occur and answering any questions they have. Support the woman's childbirth preparation method to the degree that it is feasible for her cardiac condition. Nursing techniques that promote comfort such as back massage are also used.

Cardiac function is supported by keeping the woman's head and shoulders elevated and body parts resting on pillows. The side-lying position usually facilitates positive hemodynamics during labor. Discomfort is relieved with medication and supportive care. Physiologically the ideal labor for a woman with heart disease is one that is short and pain free. Therefore use of epidural analgesia is encouraged, although care must be taken to avoid hypotension, a common side effect of regional anesthesia (Easterling and Stout, 2012; Gaddipati and Troiano, 2013).

Beta-adrenergic agents such as terbutaline (Brethine) are associated with various side effects, including tachycardia, irregular pulse, myocardial ischemia, and pulmonary edema. Therefore these medications should not be used in women with known or suspected heart disease (Gilbert, 2011; Iams, Romero, and Creasy, 2009; Simhan, Iams, and Romero, 2012).

Spontaneous or induced (with a favorable cervix) labor followed by vaginal birth is preferred for women with cardiac disease. If no obstetric problems exist, vaginal birth may be accomplished with the woman in the side-lying position to facilitate uterine perfusion. The supine position should be avoided but, if it is used, place a pad under one hip to displace the uterus laterally and minimize the danger of supine hypotension. Have the woman flex her knees and place her feet flat on the bed. To prevent compression of popliteal veins and an increase in blood volume in the chest and trunk as a result of the effects of gravity, do not use stirrups. Open-glottis pushing is recommended. The woman should avoid the Valsalva maneuver when pushing in the second stage of labor because it reduces diastolic ventricular filling and obstructs left ventricular outflow. Mask oxygen is important. Episiotomy and vacuum extraction or outlet forceps are often used to decrease the length of the second stage of labor and the workload of the heart during that time. Cesarean birth is not routinely recommended for women who have cardiovascular disease because of the risks of dramatic fluid shifts, sustained hemodynamic changes, and increased blood loss.

Routine intrapartum antibiotic prophylaxis for the prevention of bacterial endocarditis is not recommended by the American Heart Association, but it is optional in high risk patients who give birth vaginally. Because bacteremia is common during both vaginal and cesarean birth, many practitioners routinely give antibiotic prophylaxis to all high risk patients. Ampicillin (vancomycin for women who are allergic to penicillin) and gentamicin are the medications recommended for prophylaxis (Easterling and Stout, 2012; Gaddipati and Troiano, 2013). Oxytocin is usually given immediately after birth to prevent hemorrhage. Ergot products (e.g., methylergonovine [Methergine]) should not be used because they increase blood pressure. Fluid balance should be maintained, and blood loss replaced. If tubal sterilization is desired, it is best to delay surgery until the woman is hemodynamically near normal, afebrile, nonanemic, and able to ambulate normally (Cunningham, Leveno, Bloom, et al., 2010).

Postpartum

Monitoring for cardiac decompensation in the postpartum period is essential. The first 24 to 48 hours after birth are the most hemodynamically difficult for the woman. Hemorrhage or infection or both may worsen the cardiac condition. The woman with a cardiac disorder may continue to require a pulmonary artery catheter and ABG monitoring.

! NURSING ALERT

The immediate postbirth period is hazardous for a woman whose heart function is compromised. Cardiac output increases rapidly as extravascular fluid is remobilized into the vascular compartment. At the moment of birth, intraabdominal pressure is reduced drastically; pressure on veins is removed, the splanchnic vessels engorge, and blood flow to the heart is increased.

Care in the postpartum period is tailored to the woman's functional capacity. Postpartum assessment of the woman with cardiac disease includes vital signs, oxygen saturation levels, lung and heart auscultation, presence and degree of edema, amount and character of bleeding, uterine tone and fundal height, urinary output, pain

(especially chest pain), the activity-rest pattern, dietary intake, mother-infant interactions, and emotional state. The head of the bed is elevated, and the woman is encouraged to lie on her side. Bed rest may be ordered, with or without bathroom privileges. Progressive ambulation may be permitted as tolerated. The nurse or family members may need to help the woman with her grooming and hygiene needs and other activities. Bowel movements without stress or strain are promoted with stool softeners, diet, and fluids.

The woman may need a family member to help in the care of the infant. Breastfeeding is not contraindicated, but some women with heart disease (particularly those with life-threatening disease) may be unable to breastfeed. The woman who chooses to breastfeed needs the support of her family and the nursing staff to be successful. For example, she may need assistance in positioning herself and/or the infant for feeding. To further conserve the woman's energy, the infant can be brought to her and taken from her after the feeding. Most medications used to manage cardiac disorders are compatible with breastfeeding. However, thiazide diuretics may suppress lactation (Blanchard and Shabetai, 2009). Because diuretics can cause neonatal diuresis that can lead to dehydration, lactating women must be monitored closely to determine if medication doses can be reduced and still be effective. Neonatal nurses should be alerted to watch for voiding patterns and amounts and to monitor the infant closely for signs of dehydration.

If the woman is unable to breastfeed and her energies do not allow her to bottle-feed the infant, the baby can be kept at the bedside so she can look at and touch her baby to establish an emotional bond with a low expenditure of energy. The infant should be held at the mother's eye level near her lips and brought to her fingers. At the same time, involving the mother passively in her infant's care helps her feel vitally important—as she is—to the infant's well-being (e.g., "You can offer something no one else can: you can provide your baby with your sounds, touch, and rhythms that are so comforting"). Perhaps the woman can be encouraged to make a tape recording of her talking, singing, or whispering, which can be played for the baby in the nursery to help the infant feel her presence and be in contact with her voice. This also enhances maternal-infant bonding.

Preparation for discharge is planned carefully with the woman and family. Provision of help for the woman in the home by relatives, friends, and others must be addressed. If necessary, the nurse refers the family to community resources (e.g., for assistance with household activities). Rest and sleep periods, activity, and diet must be planned. The couple may need information about reestablishing sexual relations and contraception or sterilization.

Women with congenital heart disease should be offered contraceptive counseling. In general, for women with congenital heart disease the complications associated with pregnancy are usually greater than the risks associated with any form of contraception (Easterling and Stout, 2012). Women at particular risk for thromboembolism should avoid combined estrogen-progestin oral contraceptives, but progestin-only pills may be used. Parenteral progestins (e.g., medroxyprogesterone [Depo-Provera]) are safe and effective for women with cardiac disease. However, they cause irregular bleeding, which may be problematic for women on anticoagulant therapy. An IUD may be used by women with congenital heart lesions (Easterling and Stout, 2012).

Monitoring for cardiac decompensation continues through the first few weeks after birth because of hormonal shifts that affect hemodynamics. Little data are available regarding how quickly cardiac output returns to normal after giving birth. Older studies suggested that this occurred by 8 to 10 weeks postpartum. However, a longitudinal study that followed women before, during, and after pregnancy found that both nulliparous and multiparous women had significantly higher cardiac outputs above their prepregnancy values even at 1 year after giving birth (Katz, 2012).

Men and women with a congenital heart defect are at increased risk for having children who also have a defect. The risk for affected mothers is greater, approximately 2 to more than 3 times that of affected fathers. Children born with a congenital heart defect to parents with congenital heart defects appear to inherit the risk for cardiac maldevelopment in general rather than a specific defect because they often do not have the same defect as the parent (Easterling and Stout, 2012). Therefore preconception and genetic counseling before a subsequent pregnancy are essential.

OTHER MEDICAL DISORDERS IN PREGNANCY

Anemia

Anemia is a common medical disorder of pregnancy, affecting from 20% to 60% of pregnant women (Kilpatrick, 2009). It results in a reduction of the oxygen-carrying capacity of the blood; thus the heart tries to compensate by increasing the cardiac output. This effort increases the workload of the heart and stresses ventricular function. Therefore anemia that occurs with any other complication (e.g., preeclampsia) may result in congestive heart failure.

An indirect index of the oxygen-carrying capacity is the packed RBC volume, or hematocrit level. The normal hematocrit range in nonpregnant women is 37% to 47%. However, normal values for pregnant women with adequate iron stores may be as low as 33%. According to the Centers for Disease Control and Prevention (CDC), anemia in pregnancy is defined as hemoglobin less than 11 g/dL in the first and third trimesters and less than 10.5 g/dL in the second trimester (Kilpatrick, 2009). A hemoglobin level less than 6 to 8 mg/dL is considered severe anemia (Blackburn, 2013).

When a woman has anemia during pregnancy, the loss of blood at birth, even if minimal, is not well tolerated. She is at an increased risk for requiring blood transfusions. Women with anemia have a higher incidence of postpartum complications such as infection than pregnant women with normal hematologic values.

Care of the anemic pregnant woman requires that the health care provider distinguish between the normal physiologic anemia of pregnancy and disease states. The majority of cases of anemia in pregnancy are caused by iron deficiency. The other types include a considerable variety of acquired and hereditary anemias such as folic acid deficiency, sickle cell anemia, and thalassemia.

Iron Deficiency Anemia

Iron deficiency anemia is by far the most common anemia of pregnancy, accounting for approximately 75% of cases. It is diagnosed by checking the woman's serum ferritin level in addition to her hemoglobin and hematocrit levels. The serum ferritin level reflects iron reserves (Samuels, 2012). Serum ferritin levels below 12 mcg/L along with a low hemoglobin level indicate iron deficiency anemia (Blackburn, 2013). An association appears to exist between maternal iron deficiency anemia, especially severe anemia, and preterm birth and low-birth-weight infants, although whether these poor pregnancy outcomes are caused by iron deficiency anemia is uncertain (Samuels, 2012). Usually even the fetus of an anemic woman receives adequate iron stores from the mother at the cost of further depleting the mother's iron level (Blackburn, 2013).

Generally iron deficiency anemia is preventable or easily treated with iron supplements. Because of the increased amounts of iron needed for fetal development and maternal stores, pregnant women

are often encouraged to take prophylactic iron supplementation (Blackburn, 2013; Gilbert, 2011). Most women with iron deficiency anemia can absorb as much iron as they need by taking one 325-mg tablet of ferrous sulfate twice each day (Samuels, 2012). Some pregnant women cannot tolerate the prescribed oral iron because of nausea and vomiting associated with the pregnancy and as a side effect of iron therapy. In such cases the woman may receive parenteral iron therapy such as an iron-dextran complex (Imferon). This medication can be given either by intravascular or intramuscular injection, although the intramuscular injection is very painful. Women who are severely anemic may require blood transfusions (Samuels, 2012).

Teach the importance of iron supplements for preventing or treating iron deficiency anemia (see Patient Teaching box on p. 245). In addition, teach dietary ways to increase the oral intake of iron-rich foods and decrease the GI side effects of iron therapy.

Folic Acid Deficiency Anemia

Folate is a water-soluble vitamin found naturally in dark green leafy vegetables, citrus fruits, eggs, legumes, and whole grains. Even in well-nourished women, folate deficiency is common. Poor diet, cooking with large volumes of water, and increased alcohol use may contribute to folate deficiency. During pregnancy the need for folate increases, both because of fetal demands and because folate is less well absorbed from the GI tract during gestation.

Folic acid is the form of the vitamin used in vitamin supplements. The recommended daily intake of folic acid for nonpregnant women is 400 mcg. Pregnant women need 50% more, or 600 mcg/day (Otten, Helwig, and Meyers, 2006). Since 1998 the FDA has required the addition of folic acid to cereals, pasta, breads, and other food that are labeled "enriched." However, the amount added is small, and most pregnant women need a supplement. Both prescription and nonprescription prenatal vitamins contain more than the recommended daily intake of folic acid and should be sufficient to prevent and treat folate deficiency. Women at particular risk for folate deficiency include those who have significant hemoglobinopathies, take anticonvulsant medication, are pregnant with a multifetal gestation, or have frequent pregnancies. These women require larger than usual doses of folic acid (Samuels, 2012).

Folate deficiency is the most common cause of megaloblastic anemia during pregnancy, but a vitamin B_{12} deficiency must also be considered. Vitamin B_{12} deficiency in pregnant women is seen much more often now than in the past because of the increasing numbers of women who become pregnant after undergoing bariatric surgery (Samuels, 2012). Megaloblastic anemia rarely occurs before the third trimester of pregnancy (Kilpatrick, 2009; Samuels, 2012). Women with megaloblastic anemia caused by folic acid deficiency have the usual presenting symptoms and signs of anemia: pallor; fatigue; lethargy; and glossitis and skin roughness, which are associated specifically with megaloblastic anemia (Kilpatrick, 2009). Folate deficiency usually improves rapidly with folic acid therapy. It rarely occurs in the fetus and is not a significant cause of perinatal morbidity. Iron deficiency often occurs along with folate deficiency (Samuels, 2012).

Sickle Cell Hemoglobinopathy

Sickle cell hemoglobinopathy is a disease caused by the presence of abnormal hemoglobin in the blood. Sickle cell trait (SA hemoglobin pattern) is sickling of the RBCs but with a normal RBC life span. Most people with sickle cell trait are asymptomatic. Approximately 1 in 12 African-American adults in the United States have sickle cell trait (Samuels, 2012). Women with sickle cell trait require genetic counseling and partner testing to determine their risk of producing children with sickle cell trait or disease.

Women with sickle cell trait usually do well in pregnancy. However, they are at increased risk for preeclampsia, intrauterine fetal death, preterm birth and low-birth-weight infants, and postpartum endometritis. They are also at increased risk for UTIs and may be deficient in iron (Kilpatrick, 2009; Samuels, 2012).

Sickle cell anemia (sickle cell disease) is a recessive, hereditary, familial hemolytic anemia that affects persons of African or Mediterranean ancestry. These individuals usually have abnormal hemoglobin types (SS or SC). The average life span of RBCs in a person with sickle cell anemia is only 5 to 10 days compared to the 120-day life span of a normal RBC. Sickle cell anemia occurs in 1 in 708 African-Americans in the United States (Samuels, 2012). People with sickle cell anemia have recurrent attacks (crises) of fever and pain, most often in the abdomen, joints, or extremities, although virtually all organ systems can be affected. These attacks are attributed to vascular occlusion when RBCs assume a characteristic sickled shape. Crises are usually triggered by dehydration, hypoxia, or acidosis (Samuels, 2012).

Women with sickle cell anemia require genetic counseling before pregnancy. All children born to a woman with sickle cell anemia will be affected in some way by the disease. The woman's partner must be tested to determine the couple's risk of producing children with sickle cell disease rather than sickle cell trait. Women with sickle cell anemia are at risk for poor pregnancy outcomes, including miscarriage, IUGR, and stillbirth. Although maternal mortality is rare, maternal morbidity is significant and includes an increased risk for preeclampsia and infection, particularly in the urinary tract and the lungs. The frequency of painful crises also appears to be increased during pregnancy (Samuels, 2012) (see Critical Thinking Case Study).

The woman is monitored carefully during pregnancy for the development of UTI or preeclampsia. In addition, she has serial ultrasound examinations to monitor fetal growth and will likely have antepartum fetal testing performed regularly during the third trimester. Infections are treated aggressively with antibiotics. If crises occur they are managed with analgesia, oxygen, and hydration. Some authorities still recommend prophylactic transfusions, which replace the woman's sickle cells with normal RBCs, to improve oxygen-carrying capacity and suppress the synthesis of sickle

CRITICAL THINKING CASE STUDY

Sickle Cell Hemoglobinopathy

Latasha is a 23-year-old G1 P0 with sickle cell anemia who is hospitalized with a crisis at 16 weeks of gestation. She says, "I've been in and out of the hospital all my life because of my sickle cell disease. I sure hope my baby won't have it!"

1. Evidence—Is there sufficient evidence to counsel Latasha regarding her baby's chance of having sickle cell disease?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. The chance that Latasha's baby will inherit either sickle cell trait or sickle cell disease
   b. Pregnancy risks related to sickle cell disease
   c. Usual pregnancy management in women with sickle cell disease
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

hemoglobin. However, most clinicians believe that prophylactic transfusions do not improve fetal or neonatal outcome and are not worth the associated risks of isosensitization, viral infection, transfusion reactions, and hemochromatosis (Samuels, 2012).

SAFETY ALERT

Women with sickle cell anemia are not iron deficient. Therefore routine iron supplementation, even that found in prenatal vitamins, should be avoided because these women can develop iron overload (Samuels, 2012).

If no complications occur, pregnancy can continue until term. Intrapartum women with sickle cell disease should be encouraged to labor in a side-lying position. They may require supplemental oxygen. Adequate hydration should be maintained while preventing fluid overload. Conduction anesthesia (e.g., epidural or combined spinal epidural anesthesia) is recommended because it provides excellent pain relief. Vaginal birth is preferred. Cesarean birth should be performed only for obstetric indications (Samuels, 2012).

Thalassemia

Thalassemia is a relatively common anemia in which an insufficient amount of hemoglobin is produced to fill the RBCs. It is a hereditary disorder that involves the abnormal synthesis of the alpha or beta chains of hemoglobin. Beta thalassemia is the more common variety in the United States and usually occurs in persons of Mediterranean, North African, Middle Eastern, and Asian descent (Kilpatrick, 2009).

Beta thalassemia minor is the heterozygous form of this disorder. People with heterozygous beta thalassemia are carriers of the disorder and are usually asymptomatic (Samuels, 2012). They may be mildly anemic but are usually healthy otherwise. Women whose pregnancies are complicated by beta thalassemia minor generally do not experience associated maternal or infant complications if their condition is stable (Blackburn, 2013) and do not require antepartum fetal testing (Samuels, 2012). Iron therapy should only be prescribed for women who are iron deficient, although folic acid supplementation is recommended for all women with beta thalassemia minor (Samuels, 2012).

The homozygous form of beta thalassemia is known as thalassemia major, or Cooley's anemia. Persons with this form of the disease usually have hepatosplenomegaly and bone deformities caused by massive marrow tissue expansion. These individuals usually die of infection or cardiovascular complications fairly early in life. If women live to reach childbearing age, infertility is common. If women with this disorder do become pregnant, they usually experience severe anemia and congestive heart failure, although successful full-term pregnancies have been reported. Women with beta thalassemia major are managed much like those with sickle cell anemia during pregnancy (Samuels, 2012).

Pulmonary Disorders

As pregnancy advances and the enlarged uterus presses on the thoracic cavity, any pregnant woman may experience increased respiratory difficulty. This difficulty is compounded by pulmonary disease.

Asthma

Asthma is a chronic inflammatory disorder involving the tracheobronchial airways, with increased airway responsiveness to a variety of stimuli. It is characterized by periods of exacerbations and remissions. Exacerbations are triggered by allergens, marked change in ambient temperature, or emotional tension. In many cases the actual cause may be unknown, although a family history of allergy is common. In response to stimuli, narrowing of the hyperreactive airways is widespread, causing difficulty with breathing; however, the condition is reversible. The clinical manifestations are expiratory wheezing, productive cough, thick sputum, dyspnea, or any combination.

Asthma may be the most common potentially serious medical condition to complicate pregnancy. It affects 8% of all pregnancies. The prevalence and morbidity rates are increasing, although the asthma-related mortality has dropped in recent years (Whitty and Dombrowski, 2012).

The effect of pregnancy on asthma is unpredictable. The severity of the disease is unchanged in one third, improved in one third, and worsened in one third of pregnant women. If asthma worsens, the more severe symptoms usually occur between 17 and 24 weeks of gestation (Gilbert, 2011). Asthma appears to be associated with preeclampsia, low birth weight or IUGR, preterm birth, and perinatal mortality (Whitty and Dombrowski, 2012).

The ultimate goal of asthma therapy in pregnancy is maintaining adequate oxygenation of the fetus by preventing hypoxic episodes in the mother. Achieving this goal requires monitoring lung function objectively (e.g., peak expiratory flow rate and forced expiratory volume in one second), avoiding or controlling asthma triggers (e.g., dust mites, animal dander, pollen, wood smoke), educating patients about the importance of controlling asthma during pregnancy, and drug therapy. Current drug therapy for asthma emphasizes treatment of airway inflammation to decrease airway hyperresponsiveness and prevent asthma symptoms. Decreasing airway inflammation with inhaled corticosteroids is currently the preferred treatment for managing persistent asthma during pregnancy (Whitty and Dombrowski, 2009).

During pregnancy women with moderate-to-severe, poorly controlled asthma need ultrasound examinations to assess fetal growth and date the pregnancy. Repeat ultrasound examinations should be performed after an asthma exacerbation to evaluate fetal activity and growth (Whitty and Dombrowski, 2012). Women with moderate or severe asthma will probably begin antepartum fetal testing by 32 weeks of gestation (Whitty and Dombrowski, 2009). Acute exacerbations may require albuterol, steroids, aminophylline, beta-adrenergic agents, and oxygen. Women with severe exacerbations unresponsive to treatment may require intubation and mechanical ventilation (Whitty and Dombrowski, 2012). Although asthma attacks during labor are rare, medications for asthma are continued during labor and the postpartum period. Women who have received systemic corticosteroids during the previous 4 weeks should be given stress doses of corticosteroids during labor and for the first 24 hours after birth (Whitty and Dombrowski, 2012). Pulse oximetry should be instituted during labor. Epidural anesthesia reduces oxygen consumption and is recommended for pain relief. Fentanyl, a nonhistamine-releasing narcotic, may also be used for pain control and is not associated with bronchospasm (Cunningham, Leveno, Bloom, et al., 2010; Whitty and Dombrowski, 2009).

During the postpartum period women who have asthma are at increased risk for hemorrhage. If excessive bleeding occurs, prostaglandin (PG)E_2 or E_1 can be given, although the patient's respiratory status should be monitored (Whitty and Dombrowski, 2012). Because carboprost (15-methyl $PGF_{2\alpha}$ [Hemabate]) and ergonovine and methylergonovine (Methergine) can cause bronchospasm, their use should be avoided (Cunningham, Leveno, Bloom, et al., 2010). In general, only small amounts of asthma medications enter breast milk; therefore their use is not considered a contraindication to breastfeeding. However, in sensitive individuals theophylline in

breast milk can cause vomiting, feeding difficulties, jitteriness, and cardiac arrhythmias in neonates (Whitty and Dombrowski, 2012). The woman usually returns to her prepregnancy asthma status within 3 months after giving birth.

Cystic Fibrosis

Cystic fibrosis is a common autosomal recessive genetic disorder in which the exocrine glands produce excessive viscous secretions, which causes problems with both respiratory and digestive functions. Most people with cystic fibrosis have chronic obstructive pulmonary disease, pancreatic exocrine insufficiency, and elevated sweat electrolytes. Morbidity and mortality are usually caused by progressive chronic bronchial pulmonary disease (Whitty and Dombrowski, 2009).

Since the gene for cystic fibrosis was identified in 1989, data can be collected for the purposes of genetic counseling for couples regarding carrier status. In the United States approximately 4% of the Caucasian population are carriers of the cystic fibrosis gene. Cystic fibrosis occurs in 1 in 3000 live Caucasian births. People with cystic fibrosis now live much longer than they did in the past because of earlier diagnosis of the disease and advances in antibiotic therapy and nutritional support. Currently over 45% of all individuals in the United States with cystic fibrosis are more than 18 years old. Men tend to live a little longer (median age of survival is 29.6 years) compared to women, whose median age of survival is 27.3 years. Although most men with cystic fibrosis are infertile, women with the disease are often fertile and thus able to become pregnant (Whitty and Dombrowski, 2012).

In women with good nutrition, mild obstructive lung disease, and minimal lung impairment, pregnancy is tolerated well (Whitty and Dombrowski, 2012). In women with severe disease the pregnancy is often complicated by chronic hypoxemia and frequent pulmonary infections. Risk factors that may predict a poor pregnancy outcome are poor prepregnancy nutritional status, significant pulmonary disease with hypoxemia, pulmonary hypertension, liver disease, and diabetes mellitus (Whitty and Dombrowski, 2009). Increased maternal and perinatal mortality is related to severe pulmonary infection. The incidence of preterm birth, IUGR, and uteroplacental insufficiency is increased (Whitty and Dombrowski, 2009).

Care of the pregnant woman with cystic fibrosis requires a team effort. Ideally the woman should reach 90% of her ideal body weight before becoming pregnant. A weight gain of 11 to 12 kg (24 to 26 lbs) is recommended during pregnancy. Women who are unable to achieve the recommended weight gain through oral supplements may require nasogastric tube feedings at night. Pancreatic insufficiency may put the woman at risk for malnutrition because she cannot meet the increased nutritional requirements of pregnancy. If malnutrition is severe, parenteral hyperalimentation may be necessary. Fat-soluble vitamins may not be well absorbed, resulting in deficiency in those nutrients. Throughout pregnancy frequent monitoring of the woman's weight, blood glucose, hemoglobin, total protein, serum albumin, prothrombin time, and fat-soluble vitamins A and E is suggested. Pancreatic enzymes should be adjusted as necessary (Whitty and Dombrowski, 2012).

Baseline pulmonary function tests ideally should be completed before pregnancy and continued as needed during pregnancy. Inhaled recombinant human deoxyribonuclease I may be given to improve lung function by decreasing sputum viscosity. Inhaled 7% saline is also beneficial in this regard (Cunningham, Leveno, Bloom, et al., 2010). Early detection and treatment of infection are critical. Management of infection includes IV antibiotics along with chest physical therapy and bronchial drainage (Whitty and Dombrowski, 2012).

Fetal assessment is essential, given that the fetus is at risk for uteroplacental insufficiency, which can result in IUGR. Maternal nutritional status and weight gain during pregnancy significantly affect fetal growth. Fundal height should be measured routinely, and ultrasound examinations performed to evaluate fetal growth and amniotic fluid volume. Fetal movement counts are often recommended, starting at 28 weeks of gestation. NSTs should be initiated at 32 weeks of gestation or sooner if evidence of fetal compromise exists (Whitty and Dombrowski, 2012).

During labor increased cardiac output stresses the cardiovascular system and can lead to cardiopulmonary failure in the woman with pulmonary hypertension or cor pulmonale. These women are also more likely to develop right-sided heart failure. Epidural or local analgesia is the preferred analgesic for birth, with vaginal birth recommended. Cesarean birth should be reserved for obstetric indications. If general anesthesia is needed for cesarean birth, anticholinergic medications should not be given before surgery because they tend to promote airway drying (Whitty and Dombrowski, 2012).

Breastfeeding appears to be safe as long as the sodium content of the milk is not abnormal. Pumping and discarding the milk are continued until the sodium content has been determined. Milk samples should be tested periodically for sodium, chloride, and total fat; and the infant's growth pattern should be monitored (Lawrence and Lawrence, 2005).

Integumentary Disorders

Dermatologic disorders induced by pregnancy include melasma (chloasma), vascular "spiders," palmar erythema, and striae gravidarum. A number of chronic skin disorders may complicate pregnancy. These disorders may be present before pregnancy or appear for the first time during pregnancy. Their course varies during pregnancy. For example, acne may improve. Psoriasis improves in 40% of women, remains unchanged in 40% of women, and worsens in 20% of women during pregnancy. Lesions from neurofibromatosis may increase in size and number during pregnancy (Cunningham, Leveno, Bloom, et al., 2010). Explanation, reassurance, and commonsense measures should suffice for normal skin changes. In contrast, disease processes during and soon after pregnancy may be extremely difficult to diagnose and treat.

SAFETY ALERT

Isotretinoin (Accutane), commonly prescribed for cystic acne, is highly teratogenic. There is a risk for craniofacial, cardiac, and CNS malformations in exposed fetuses. This drug should not be taken during pregnancy.

Pruritus is a major symptom in several pregnancy-related skin diseases. *Pruritus gravidarum,* generalized itching without the presence of a rash, develops in up to 14% of pregnant women. It is often limited to the abdomen and is usually caused by skin distention and development of striae. Pruritus gravidarum is not associated with poor perinatal outcomes. It is treated symptomatically with skin lubrication, topical antipruritics, and oral antihistamines. Ultraviolet light and careful exposure to sunlight decrease itching. Pruritus gravidarum usually disappears shortly after birth but can recur in approximately half of all subsequent pregnancies (Rapini, 2009).

Pruritic Urticarial Papules and Plaques of Pregnancy

Another common pregnancy-specific cause of pruritus is pruritic urticarial papules and plaques of pregnancy (PUPPP) (Fig. 11-5),

FIG 11-5 Woman with pruritic urticarial papules and plaques of pregnancy. Lesions also are present on her arms, back, abdomen, and buttocks. (Courtesy Shannon Perry, Phoenix, AZ.)

also known as *polymorphic eruption of pregnancy*. PUPPP classically appears in primigravidas during the mid to late third trimester and occurs a bit more frequently in women carrying male fetuses. The disorder is much more commonly seen in multiple gestations than in singletons (Kroumpouzos, 2012). The abdomen is usually affected, but lesions can spread to the arms, thighs, back, and buttocks. PUPPP almost always causes pruritus, and the itching is severe in 80% of cases. However, it is not associated with poor maternal or fetal outcomes. Therefore the goal of therapy is simply to relieve maternal discomfort. Antipruritic topical medications, topical steroids, and oral antihistamines usually provide relief. Women with severe symptoms may require oral prednisone. PUPPP usually resolves before birth or within several weeks after birth. However, on rare occasions it may persist or even begin after birth. PUPPP does not usually recur in subsequent pregnancies (Kroumpouzos, 2012; Rapini, 2009).

Intrahepatic Cholestasis of Pregnancy

Intrahepatic cholestasis of pregnancy (ICP) is a liver disorder unique to pregnancy that is characterized by generalized pruritus. The itching usually begins during the third trimester, most severely affects the palms and soles, and is worse at night (Cappell, 2012). ICP occurs more frequently during the winter months. A geographic variance in the prevalence of the disease has also been noted. It occurs most often in Southeast Asia, Chile, Bolivia, and Scandinavia; although it is seen less frequently now in Chile and Scandinavia than in the past (Cappell, 2012; Williamson and Mackillop, 2009).

No skin lesions are present. Women with ICP have elevated serum bile acids and liver function tests. Jaundice may or may not be present. As many as one half of women with ICP develop dark urine and light-colored stools. The cause of ICP is unknown, but approximately half of women have a family history of the disorder. Other risk factors for ICP are multiple gestations and a history of ICP in a previous pregnancy (Cappell, 2012).

Poor fetal outcomes, including meconium ileus, preterm birth, and stillbirth, are associated with ICP. The cause of these complications is likely related to increased levels of fetal serum bile levels. Treatment consists of medication, usually ursodeoxycholic acid, which effectively controls the pruritus and laboratory abnormalities associated with ICP, and continued monitoring of liver function tests and bile acids (Cappell, 2012; Williamson and Mackillop, 2009). If fetal complications do not occur, birth should be considered at or near term after lung maturity has been documented. Symptoms generally disappear quickly after birth, and usually there are no long-term sequelae. However, postpartum hemorrhage is more likely in women who had ICP, and they are also at risk to develop cholelithiasis after birth. ICP recurs in about two thirds of subsequent pregnancies (Cappell, 2012).

Neurologic Disorders

The pregnant woman with a neurologic disorder must deal with potential teratogenic effects of prescribed medications, changes of mobility during pregnancy, and impaired ability to care for the baby. The nurse should be aware of all medications the woman is taking and the associated potential for producing congenital anomalies. As the pregnancy progresses, the woman's center of gravity shifts and causes balance and gait changes. The nurse should advise the woman of these expected changes and suggest safety measures as appropriate. Family and community resources may be needed to help provide infant care for the neurologically impaired woman.

Epilepsy

Epilepsy (often called *seizure disorder)* is a disorder of the brain that causes recurrent seizures and is the most common major neurologic disorder accompanying pregnancy. Less than 1% of all pregnant women have a seizure disorder (Aminoff, 2009). Seizure disorders are either acquired (less than 15% of all cases) or idiopathic (more than 85% of all cases), which means that a specific cause for the seizures cannot be identified. The majority of women with a seizure disorder who become pregnant have an uneventful pregnancy with an excellent outcome (Samuels and Niebyl, 2012).

Women with epilepsy should receive preconception counseling if at all possible. A detailed history of medication use and seizure frequency should be obtained. If the woman has frequent seizures before conception, she is likely to continue this pattern during pregnancy; therefore achieving effective seizure control is extremely important before conception, even if changing medications is required (Samuels and Niebyl, 2012).

Infants born to women taking anticonvulsant medications have an increased incidence of congenital anomalies, including cleft lip and palate, congenital heart disease, and neural tube defects (NTDs). These anomalies are related to the dose, type, and number of anticonvulsant medications taken, not to epilepsy itself (Samuels and Niebyl, 2012).

SAFETY ALERT

Carbamazepine (Tegretol) and valproate (Depakote) should be avoided if possible during pregnancy, especially during the first trimester, because their use is associated with NTDs in the fetus.

Several new anticonvulsant medications have been developed for use within the last decade. More information is needed regarding the fetal effects of these medications. However, any anticonvulsant medication required to achieve good seizure control in a woman with epilepsy should be used, regardless of the increased risk of fetal anomalies, because the most important goal during pregnancy is the prevention of seizures (Samuels and Niebyl, 2012).

Pregnant women with epilepsy are advised to take a folic acid supplement of 4 mg daily, which may decrease the incidence of NTDs. They are also encouraged to take a prenatal vitamin containing vitamin D daily because anticonvulsant medications can interfere with production of the active form of this vitamin (Cunningham, Leveno, Bloom, et al., 2010; Samuels and Niebyl, 2012).

If possible, only one anticonvulsant medication—at the lowest dose level that is effective at keeping the woman seizure free—should be prescribed during pregnancy. The increase in plasma volume that is a normal pregnancy change can affect drug metabolism and distribution. Therefore blood levels of anticonvulsant medications should be checked, and drug dosages adjusted as necessary. With patient cooperation and close monitoring, most women with epilepsy should experience no change or even have fewer seizures during pregnancy. An increase in seizure frequency is usually related either to noncompliance with taking prescribed anticonvulsant medications or with sleep deprivation (Samuels and Niebyl, 2012). If an increase in seizure activity does occur during pregnancy, it is usually in women who had frequent seizures (more than one per month) before pregnancy (Aminoff, 2009).

In addition to congenital anomalies, the fetus of a woman with epilepsy is also at risk for IUGR. Determining an accurate gestational age as early as possible is important. This information decreases any confusion later in pregnancy regarding fetal growth issues. If the patient's weight gain and fundal height appear appropriate, serial ultrasounds for fetal weight assessment may not be necessary. Maternal serum screening around 16 weeks of gestation and ultrasound examination at 18 to 22 weeks of gestation should be performed to assess for the presence of an NTD or other fetal anomalies. Nonstress testing later in pregnancy is not necessary unless the woman has other medical or obstetric factors that increase the risk for stillbirth (Samuels and Niebyl, 2012).

Management of anticonvulsant therapy during prolonged labor is challenging. During labor absorption of medications given orally is unpredictable, especially if vomiting occurs. Women who are maintained on phenytoin (Dilantin) or phenobarbital may be given these medications parenterally during labor. No parenteral form of carbamazepine has been developed. Oral administration of carbamazepine may be attempted; but, if the woman experiences a seizure or a preseizure aura, she may be given phenytoin intravenously instead to carry her through labor. Vaginal birth is preferred (Samuels and Niebyl, 2012).

After birth the levels of anticonvulsant medications must be monitored frequently for the first few weeks because they can rise rapidly. If medication dose levels were increased during pregnancy, they need to be reduced quickly to prepregnancy levels. All of the major anticonvulsant medications are found in breast milk, but the use of these medications is not a contraindication to breastfeeding. However, topiramate has been associated with neonatal weight loss; thus it probably should not be prescribed if the woman is breastfeeding (Samuels and Niebyl, 2012).

During the neonatal period infants exposed in utero to phenobarbital, phenytoin, and primidone, which cause a vitamin K deficiency, can hemorrhage. However, infants who receive vitamin K at birth have not been shown to have an increased risk of bleeding. This problem is now rare, because most infants routinely receive an intramuscular injection of vitamin K immediately after birth. In addition, phenobarbital and primidone are almost never prescribed, and phenytoin is used to treat epilepsy much less often now than in the past (Samuels and Niebyl, 2012).

All methods of contraception can be used by women with an idiopathic seizure disorder. However, commonly prescribed anticonvulsant medications such as carbamazepine and phenytoin (also topiramate and oxcarbazepine at higher doses) reduce the effectiveness of oral contraceptives. Women taking low-dose oral contraceptives especially may have more breakthrough bleeding and be at risk for an unplanned pregnancy (Cunningham, Leveno, Bloom, et al., 2010; Samuels and Niebyl, 2012). Lamotrigine, zonisamide, gabapentin, tiagabine, valproate, and levetiracetam have not been reported to cause oral contraceptive failure (Aminoff, 2009; Samuels and Niebyl).

In terms of planning for future childbearing, couples should be informed that children born to women with a seizure disorder of unknown cause have a 4 times greater chance (risk of 2% to 4%) for an idiopathic seizure disorder compared to the general population. Epilepsy in the father does not appear to increase a child's risk for developing a seizure disorder (Samuels and Niebyl, 2012).

Multiple Sclerosis

Multiple sclerosis (MS), a patchy demyelinization of the spinal cord and CNS, may be a viral disorder. It occurs equally in men and women. Onset of symptoms, which include weakness of one or both lower extremities, visual complaints, and loss of coordination, is subtle and usually occurs between the ages of 20 and 40 years. The disease is characterized by exacerbations and remissions. Pregnancy does not seem to worsen the disease (Samuels and Niebyl, 2012).

Remissions during pregnancy are common. If an exacerbation occurs, it is more likely to do so during the third trimester of pregnancy or postpartum. Treatment may include corticosteroids and immunosuppressive agents. Several new drugs and biopharmaceuticals are available for treating MS. Their use in pregnancy has been limited; thus few data and no controlled studies are available. However, many consist of molecules that are too large to cross the placenta. Therefore they may be acceptable for use during pregnancy. They do not appear to be associated with anomalies (Samuels and Niebyl, 2012). Interferon is also sometimes used to treat MS relapses during pregnancy and postpartum. Its safety for use during pregnancy has not been established, although in theory it should not cross the placenta because of its large molecular size (Stuart and Bergstrom, 2011).

Women who have become paraplegic with MS are more likely to develop UTIs during pregnancy but may feel no symptoms. Therefore they should be screened routinely. Women who have become paraplegic or have lumbosacral lesions as a result of MS may have little pain during labor. Determining when labor begins may be difficult for them. Uterine contractions occur normally, but these women may have difficulty pushing effectively during the second stage of labor. Therefore, vacuum- or forceps-assisted birth may be necessary (Samuels and Niebyl, 2012). Epidural anesthesia can be used during labor (Stuart and Bergstrom, 2011).

Depression is common among women with MS; thus they should be assessed frequently for evidence of postpartum depression. Breastfeeding is encouraged, although medications that are Lactation Risk Category L5 should not be prescribed. IV immunoglobulin (IVIG) is considered safe for use during lactation; no adverse effects in infants have been reported. All hormonal contraceptives may be used by women with MS (Stuart and Bergstrom, 2011).

Bell Palsy

Bell palsy is an acute idiopathic facial paralysis. The cause is unknown, but it may be related to the reactivation of herpesvirus infection or acute human immunodeficiency virus type 1 (HIV-1) retroviral infections. Bell palsy occurs fairly often, especially in women of reproductive age. Women are affected 2 to 4 times more often than men (Cunningham, Leveno, Bloom, et al., 2010). An association between Bell palsy and pregnancy was first cited by Bell in 1830. Pregnant women are affected 3 to 4 times more often than nonpregnant women. The incidence usually peaks during the third trimester and the puerperium. Women who develop Bell palsy

during pregnancy have an increased risk for gestational hypertension as well (Cunningham, Leveno, Bloom, et al., 2010).

The clinical manifestations of Bell palsy include the sudden development of a unilateral facial weakness, with maximum weakness within 48 hours after onset, pain surrounding the ear, difficulty closing the eye on the affected side, hyperacusis (abnormal acuteness of the sense of hearing), and occasionally a loss of taste (Aminoff, 2009; Cunningham, Leveno, Bloom, et al., 2010).

No effects of maternal Bell palsy have been observed in infants. Maternal outcome is generally good unless a complete block in nerve conduction occurs. Steroid therapy may improve outcome, although its benefits have not always been proven in past research studies. To be effective, steroids should be administered within the first 5 to 6 days after the paralysis develops (Aminoff, 2009). Supportive care includes prevention of injury to the constantly exposed cornea, facial muscle massage, careful chewing and manual removal of food from inside the affected cheek, and reassurance. Although 80% of affected men and nonpregnant women recover to a satisfactory level within a year, only approximately half of women who develop the disorder during pregnancy do so (Cunningham, Leveno, Bloom, et al., 2010).

Autoimmune Disorders

Autoimmune disorders, also called *collagen vascular diseases,* make up a large group of conditions that disrupt the function of the immune system of the body. In these types of disorders the immune system is unable to distinguish "self" from "nonself." As a result, antibodies develop that attack its normally present antigens, causing tissue damage. Autoimmune disorders can occur during pregnancy because a large percentage of women with an **autoimmune disease** are women of childbearing age (Gilbert, 2011). Common autoimmune diseases include systemic lupus erythematosus, myasthenia gravis, antiphospholipid syndrome, rheumatoid arthritis, and systemic sclerosis (Chin and Branch, 2012; Cunningham, Leveno, Bloom, et al., 2010).

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic, multisystem inflammatory disease that affects the skin, joints, kidneys, lungs, serous membranes, nervous system, liver, and heart. The exact cause of the disease is unknown but probably involves the interaction of several factors, including immunologic, environmental, hormonal, and genetic factors. SLE is the most common serious autoimmune disease affecting women of reproductive age. It occurs 2 to 4 times more often in African-American and Hispanic women than in Caucasian women and is 7 to 15 times more common in women than in men. Most cases of SLE occur in adolescence or young adulthood. Recently the incidence of SLE has nearly tripled, probably because of increased diagnosis (Chin and Branch, 2012; Gilbert, 2011).

Common symptoms, including myalgias, fatigue, weight change, and fevers, occur in nearly all women with SLE at some time during the course of the disease. Although a diagnosis of SLE is suspected based on clinical signs and symptoms, it is confirmed by laboratory testing that demonstrates the presence of circulating autoantibodies. As is the case with other autoimmune diseases, SLE is characterized by a series of exacerbations (flares) and remissions (Chin and Branch, 2012).

Authorities have conflicting opinions as to whether pregnancy increases the likelihood of SLE flares. However, it appears that disease activity at the beginning of pregnancy is an important predictor of exacerbations during pregnancy. Therefore women are advised to wait until they have been in remission for at least 6 months before attempting to become pregnant (Chin and Branch, 2012; Gilbert, 2011). In addition to exacerbations, other maternal risks include an increased rate of miscarriage, nephritis, preeclampsia, possible need to give birth at a preterm gestation, and an increased risk of cesarean birth. Fetal risks include stillbirth, IUGR, and preterm birth (Chin and Branch, 2012).

Medical therapy during pregnancy is kept to a minimum in women who are in remission or who have a mild form of SLE. Immunosuppressive medications should be discontinued before conception. Nonsteroidal antiinflammatory drugs and aspirin are ordinarily the most commonly used antiinflammatory drugs, but they are not recommended for use during pregnancy. Aspirin should not be used after 24 weeks of gestation because of an increased risk of premature closure of the fetal ductus arteriosus (Cunningham, Leveno, Bloom, et al., 2010). Glucocorticoids such as prednisone are often used to treat SLE during pregnancy, as either maintenance therapy or short-term treatment for flares. There is a small risk for fetal cleft lip and palate if glucocorticoids are used during early pregnancy. Prolonged use of this group of medications also increases the risks for bone demineralization, gestational diabetes, preeclampsia, premature rupture of membranes (PROM) and IUGR. Given the significant risks associated with long-term glucocorticoid use, hydroxychloroquine, an antimalarial drug, may be the best medication for maintenance SLE therapy during pregnancy. It significantly reduces SLE disease activity but appears to cause no adverse effects on the fetus (Chin and Branch, 2012).

Prenatal care otherwise focuses on close monitoring to detect common pregnancy complications such as hypertension, proteinuria, and IUGR. Ultrasound examinations are performed frequently to monitor fetal growth. Fetal assessment tests, including daily fetal movement counts and weekly or twice-weekly NSTs and amniotic fluid volume assessments or biophysical profiles, likely begin at 30 to 32 weeks of gestation (see Chapter 10). More frequent ultrasound examinations and fetal testing are necessary if the woman develops an SLE flare, antiphospholipid syndrome, hypertension, proteinuria, or evidence of IUGR (Chin and Branch, 2012).

Women with SLE can develop an exacerbation during labor. Any maintenance medications should be continued throughout the intrapartum period or resumed immediately postpartum at the last pregnancy dose. Even if a flare does not occur, all women who have received chronic glucocorticoid therapy (20 mg or more of prednisone daily for at least 3 weeks) need larger (stress) doses of steroids during labor (Chin and Branch, 2012). Vaginal birth is preferred, but cesarean birth is common because of maternal and fetal complications.

Close monitoring of all women with SLE should continue after birth. Women who have more severe SLE manifestations or who had an SLE exacerbation during pregnancy are at greatest risk to experience a postpartum flare (Chin and Branch, 2012).

Women with SLE and chronic vascular or renal disease should limit their number of pregnancies because of maternal complications associated with the illness and increased adverse perinatal outcomes (Cunningham, Leveno, Bloom, et al., 2010). If desired, the safest time for tubal sterilization is during the postpartum period or when the disease is in remission. Estrogen-containing oral contraceptives may increase the risk of thromboembolism (Gilbert, 2011). Progestin-only implants and injections provide effective contraception with no known effects on lupus flares (Cunningham, Leveno, Bloom, et al., 2010). Barrier methods, in addition to progestin-only contraceptive options, are the least risky forms of contraception for women with SLE (Gilbert, 2011). Evidence does not support concerns regarding an increased risk of infection when IUDs

are prescribed for women receiving immunosuppressive therapy (Cunningham, Leveno, Bloom, et al., 2010).

Myasthenia Gravis

Myasthenia gravis (MG), an autoimmune motor (muscle) end-plate disorder that involves acetylcholine use, affects the motor function at the myoneural junction. Muscle weakness, particularly of the eyes, face, tongue, neck, limbs, and respiratory muscles, results. In addition, women may experience ptosis, diplopia, and dysphagia. Women are affected twice as often as men, and the incidence peaks between the ages of 20 and 30 years (Porter and Branch, 2006). Because the greatest period of risk is during the first year after diagnosis, pregnancy should probably be avoided until symptomatic improvement occurs (Cunningham, Leveno, Bloom, et al., 2010). The response of women with MG to pregnancy is unpredictable; remission, exacerbation, or continued stability during pregnancy can occur.

Pregnancy does not appear to affect the overall course of MG, but as the uterus enlarges respirations may be compromised. In addition, the normal fatigue experienced by many pregnant women may be tolerated poorly by those with MG (Cunningham, Leveno, Bloom, et al., 2010). Treatment during pregnancy is the same as for nonpregnant women. Usual medications include glucocorticoids and acetylcholinesterase inhibitors. Monitoring blood glucose values is important because hyperglycemia may result from corticosteroid therapy. Thymectomy may result in remission of the disease but is best performed before or after pregnancy if at all possible. For severe weakness plasmapheresis or IVIG therapy may be needed.

Because MG does not affect smooth muscle, most women tolerate labor well. Vaginal birth is desired, but vacuum or forceps assistance may be required because of muscle weakness. Oxytocin may be given, but medications that cause muscular relaxation should be avoided if at all possible. Narcotics must be used cautiously because they may cause respiratory depression, and women with MG are already at risk for respiratory muscle weakness. Regional analgesia is preferred (Aminoff, 2009; Cunningham, Leveno, Bloom, et al., 2010). After birth women must be supervised carefully because relapses often occur during the puerperium.

SAFETY ALERT

Magnesium sulfate must not be administered to women with MG because it inhibits the release of acetylcholine and can trigger myasthenic crisis.

Approximately 10% to 15% of neonates born to women with MG develop neonatal myasthenia. This transient disorder results from the transfer of maternal antibody against acetylcholine receptors across the placenta. Symptoms, including a poor cry, respiratory difficulties, weakness in suckling, a weak Moro reflex, and feeble limb movements, usually appear within the first 72 hours after birth. Neonatal myasthenia can be treated with anticholinesterase medications and usually resolves by 6 weeks after birth (Aminoff, 2009).

SUBSTANCE ABUSE

Abuse of both legal and illegal substances (alcohol and drugs), whether by pregnant women or other people, can result in addiction. In 2011 the American Society of Addiction Medicine (ASAM) published a short definition of addiction, in which they state the following:

> Addiction is a primary, chronic disease of brain reward, motivation, memory and related circuitry. Dysfunction in these circuits leads to characteristic biological, psychological, social and spiritual manifestations … .Like other chronic diseases, addiction often involves cycles of relapse and remission. Without treatment or engagement in recovery activities, addiction is progressive and can result in disability or premature death" (ASAM, 2011).

Dual diagnosis, which is very common, is the coexistence of substance abuse and another psychiatric disorder. Mood and anxiety disorders are the psychiatric disorders that are most commonly seen along with substance abuse in women. The psychiatric illness usually occurs before substance use begins (Wisner, Sit, Altemus, et al., 2012).

The damaging effects of alcohol and illicit drugs on pregnant women and their unborn babies are well documented (Gilbert, 2011; Wisner, Sit, Altemus, et al., 2012). Alcohol and other drugs easily pass from a mother to her baby through the placenta. Smoking during pregnancy has serious health risks, including bleeding complications, miscarriage, stillbirth, prematurity, low birth weight, and sudden unexplained infant death (Gilbert, 2011; Wisner, Sit, Altemus, et al., 2012). Congenital anomalies have occurred in infants of mothers who have taken drugs. With one exception the safest pregnancy is one in which the woman is drug and alcohol free. For women addicted to opioids, methadone maintenance treatment is the current standard of care during pregnancy (Wisner, Sit, Altemus, et al., 2012).

Because many pregnant women are reluctant to reveal their use of substances or the extent of their use, data on prevalence are highly variable. Approximately 15% of all pregnant women have a substance-abuse problem (Gilbert, 2011). Blinded urine drug screens conducted at hospitals across the United States revealed that similar rates of substance use during pregnancy occurred in women of different ages, races, and social classes, although the specific substances used differed by race and social class. African-American and poor women were more likely to use illicit substances, particularly cocaine, whereas Caucasian and educated women were more likely to use alcohol, although polysubstance abuse was common (Wisner, Sit, Altemus, et al., 2012).

Less than 10% of pregnant women who are substance abusers receive treatment for their addictions. Social stigma, labeling, and guilt are significant barriers (Brady and Ashley, 2005). Women often do not seek help because of the fear of losing custody of their child or children or criminal prosecution. Pregnant women who abuse substances commonly have little understanding of the ways in which these substances affect them, their pregnancies, and their babies. In many instances pregnant mothers who use psychoactive substances receive negative feedback from society and health care providers, who not only may condemn them for endangering the life of the fetus but may also even withhold support as a result. Barriers within the drug treatment system may also deter these women from receiving the help they need. Traditionally substance-abuse treatment programs have not addressed issues that affect pregnant women such as concurrent need for obstetric care and child care for other children. Long waiting lists and lack of health insurance present further barriers to treatment. Pregnant women with co-occurring substance abuse and psychiatric disorders face unique barriers because of the social stigma attached to both conditions and insufficient knowledge and training to manage coexisting disorders (Brady and Ashley, 2005).

Because of the risks to the unborn children and financial concerns, pregnant women who abuse substances can now face criminal charges under expanded interpretations of child abuse and drug trafficking statutes (Guttmacher Institute, 2010). See Chapter 3 for additional discussion of this issue.

BOX 11-4 SCREENING WITH THE *4Ps* PLUS

***P**arents:* Did either of your parents ever have a problem with alcohol or drugs?
***P**artner:* Does your partner have a problem with alcohol or drugs?
***P**ast:* Have you ever had any beer or wine or liquor?
***P**regnancy:* In the month before you knew you were pregnant, how many cigarettes did you smoke? In the month before you knew you were pregnant, how much beer, wine, or liquor did you drink?

LEGAL TIP: Drug Testing During Pregnancy
There is no requirement in the United States for a health care provider to test either the pregnant woman or the newborn for the presence of drugs. However, nurses need to know the practices of the states in which they are working. In some states a woman whose urine drug screen is positive at the time of labor and birth must be referred to child protective services. If the mother is not in a drug treatment program or is judged unable to provide care, the infant may be placed in foster care. The U.S. Supreme Court has ruled that in all states it is unlawful to test for drug use without the pregnant woman's permission (Harris and Paltrow, 2003).

CARE MANAGEMENT

Screening

Screening questions for alcohol and drug abuse should be included in the overall assessment at the first prenatal visit of all women. Information about drug use should be obtained by first asking about the woman's intake of over-the-counter and prescribed medications. Next her use of legal drugs such as caffeine, nicotine, and alcohol should be determined. Finally she should be questioned about her use of illicit drugs such as cocaine, heroin, and marijuana. The approximate frequency and amount should be documented for each drug used (Seidel, Ball, Dains, et al., 2011).

The *4 Ps Plus* is a screening tool designed specifically to identify pregnant women who need in-depth assessment (Box 11-4). It consists of five questions and takes less than a minute to complete. Because women frequently deny or greatly underreport usage when asked about drug or alcohol consumption during pregnancy, asking about substance use before pregnancy is often an effective screening method (Wisner, Sit, Altemus, et al., 2012).

Urine toxicologic testing is often performed to screen for illicit drug use. Drugs may be found in urine days to weeks after ingestion, depending on how quickly they are metabolized and excreted from the body. Meconium (from the neonate) and hair can also be analyzed to determine past drug use over a longer period (Gilbert, 2011).

Because substance-abusing pregnant women are at risk for a variety of infections and medical conditions, a comprehensive medical history should be obtained, and a complete physical examination performed. Laboratory assessments likely include screening for syphilis, hepatitis B and C, and HIV. A complete blood count and a skin test to screen for tuberculosis may also be ordered. In addition, the woman may be tested for other common sexually transmitted infections such as gonorrhea and chlamydia (Wisner, Sit, Altemus, et al., 2012). Initial and serial ultrasound studies are usually performed to determine gestational age because the woman may have had amenorrhea as a result of her drug use or have no idea when her last menstrual period occurred.

Initial Care

Intervention with the pregnant substance abuser begins with education about specific effects on pregnancy, the fetus, and the newborn for each drug used. Consequences of perinatal drug use should be clearly communicated, and abstinence recommended as the safest course of action unless the woman is abusing opioids. Women are often more receptive to making lifestyle changes during pregnancy than at any other time in their lives. The casual, experimental, or recreational drug user is frequently able to achieve and maintain sobriety when she receives education, support, and continued monitoring throughout the remainder of the pregnancy. Periodic screening throughout pregnancy of women who have admitted to drug use may help them to continue abstinence.

Treatment for substance abuse is individualized for each woman, depending on the type of drug used and the frequency and amount of use. Women are more likely to attempt to stop smoking during pregnancy than at any other time in their lives. Quitting before conception is ideal, but even quitting before 16 weeks of gestation significantly decreases the adverse risks. Smoking-cessation programs during pregnancy are effective and should be offered to all pregnant smokers. These programs should continue throughout the postpartum period as well, because many women resume smoking after the birth. Many smoking cessation resources are available, both in print and online (Gilbert, 2011; Wisner, Sit, Altemus, et al., 2012). For more information on smoking cessation, visit the American Lung Association website at www.lungusa.org or the CDC website at www.cdc.gov/tobacco/quit_smoking/index.htm. In addition, see Box 3-5 for smoking cessation resources provided by the ACOG.

Detoxification, short-term inpatient or outpatient treatment, long-term residential treatment, aftercare services, and self-help support groups are all possible options for alcohol and drug abuse. Women for Sobriety may be a more helpful organization for women than Alcoholics Anonymous or Narcotics Anonymous, which were originally developed for male substance abusers. In general long-term treatment of any sort is becoming increasingly difficult to obtain, particularly for women who lack insurance coverage. Although some programs allow a woman to keep her children with her at the treatment facility, far too few of them are available to meet the demand.

Pregnant women requiring withdrawal from alcohol should be admitted for inpatient management. Alcohol withdrawal treatment during pregnancy consists of the administration of benzodiazepines. Chlordiazepoxide (Librium), diazepam (Valium), lorazepam (Ativan), and oxazepam (Serax) are benzodiazepines that are commonly used. Disulfiram (Antabuse) is teratogenic; therefore its use in aversion therapy is contraindicated during pregnancy. Currently there are four medications approved by the FDA for the treatment of alcohol dependence, but their use during pregnancy has been very limited. Acute management of alcohol withdrawal also includes thiamine replacement and maintenance of adequate hydration and electrolyte balance (Wisner, Sit, Altemus, et al., 2012).

Methadone maintenance treatment (MMT) is currently considered the standard of care for pregnant women who are dependent on heroin or other narcotics. Buprenorphine (Subutex or Suboxone) is another medication approved for opioid addiction treatment that is being used increasingly during pregnancy. Opioid replacement therapy has been shown to decrease opioid and other drug abuse; reduce criminal activity; improve individual functioning; and

decrease rates of infections such as hepatitis B and C, HIV, other sexually transmitted infections, and tuberculosis. In addition, opioid replacement therapy is associated with reduced fetal exposure to illicit drug use and improved neonatal outcomes. However, 30% to 80% of infants exposed to opioids, including methadone or buprenorphine, in utero require treatment for neonatal abstinence syndrome (NAS). Neither the incidence nor the severity of NAS correlates directly with the maternal medication dose at birth (Wisner, Sit, Altemus, et al., 2012).

Pregnant women who use cocaine should be advised to stop using immediately. These women need a great deal of assistance such as an alcohol and drug treatment program, individual or group counseling, and participation in self-help support groups to accomplish this major lifestyle change successfully.

Methamphetamines are stimulants with vasoconstrictive characteristics similar to those of cocaine and are used similarly. As is the case with cocaine users, methamphetamine users are urged to immediately stop all use during pregnancy. Unfortunately, because methamphetamine users are extremely psychologically addicted, the rate of relapse is very high.

Although substance abusers may be difficult to care for at any time, they are often particularly challenging during the intrapartum and postpartum periods because of manipulative and demanding behavior. Typically these women display poor control over their behavior and a low threshold for pain. Increased dependency needs and poor parenting skills may also be apparent.

Nurses must understand that substance abuse is an illness and that these women deserve to be treated with patience, kindness, consistency, and firmness when necessary (Box 11-5). Even women who are actively abusing drugs experience pain during labor and after giving birth and may need both pain medication and nonpharmacologic interventions. Developing a standardized plan of care so patients have limited opportunities to play staff members against one another is helpful. Mother-infant attachment should be promoted by identifying the woman's strengths and reinforcing positive maternal feelings and behaviors. Staffing should be sufficient to ensure strict surveillance of visitors and prevent unsupervised drug use.

Advice regarding breastfeeding must be individualized. Although all abused substances appear in breast milk, some in greater amounts than others (Lawrence and Lawrence, 2005), breastfeeding is definitely contraindicated in women who use amphetamines, alcohol, cocaine, heroin, or marijuana. However, methadone use is not a contraindication to breastfeeding. The baby's nutrition and safety needs are of primary importance in this consideration. For some women a desire to breastfeed may provide strong motivation to achieve and maintain sobriety.

Smoking can interfere with the let-down reflex. Women who smoke in the postpartum period and breastfeed should avoid smoking for 2 hours before a feeding to minimize the nicotine in the milk and improve the let-down reflex. All smokers should be discouraged from smoking in the same room with the infant because exposure to secondhand smoke can increase the likelihood that the infant will experience behavioral and respiratory health problems (Lawrence and Lawrence, 2005).

BOX 11-5 DEALING WITH PREGNANT SUBSTANCE ABUSERS

- Realize that the decision to become and remain sober can *only* be made by the substance abuser.
- Understand that nurses do not have the power to cure anyone. They are only cheerleaders and supporters!
- Educate yourself about the effects of drug use in general and its effect on pregnancy and the newborn specifically.
- Treat substance abusers with the same respect and consideration that you show other people.
- Become familiar with your local treatment centers. Learn which of them accept pregnant women. Keep an up-to-date list of groups meeting in your community.
- Remember that there are no "hopeless cases." It is never too late to quit!
- Practice patience and persistence. It may take months or years to see the effects of your work.

Follow-up Care

Before a known substance abuser is discharged with her baby, the home situation must be assessed to determine that the environment is safe and that someone will be available to meet the infant's needs if the mother is unable to do so. The social services department of the hospital is usually involved in interviewing the mother before discharge to ensure that the infant's needs will be met. Family members or friends are sometimes asked to become actively involved with the mother and infant after discharge. A home care or public health nurse may be asked to make home visits to assess the mother's ability to care for the baby and provide guidance and support. If serious questions about the infant's well-being exist, the case is likely to be referred to the state child protective services agency for further action.

KEY POINTS

- Careful monitoring of blood glucose levels, insulin, or oral hypoglycemic medication administration when necessary and dietary counseling are used to create a normal intrauterine environment for fetal growth and development in the pregnancy complicated by pregestational diabetes or GDM.
- Poor maternal glycemic control before conception and during pregnancy may be responsible for fetal congenital malformations and maternal complications such as miscarriage, infection, and dystocia (difficult labor) caused by macrosomia.
- Maternal insulin requirements increase as the pregnancy progresses and may quadruple by term as a result of insulin resistance created by placental hormones, insulinase, and cortisol.
- Thyroid dysfunction during pregnancy requires close monitoring of thyroid hormone levels to regulate therapy and prevent fetal insult.
- High levels of phenylalanine in the maternal bloodstream cross the placenta and are teratogenic to the fetus. Damage can be prevented or minimized by dietary restriction of phenylalanine.
- The stress of the normal maternal adaptations to pregnancy on a heart the functions of which are already taxed may cause cardiac decompensation.
- Anemia is a common medical disorder of pregnancy, affecting at least 20% of pregnant women.

- Asthma may be the most common potentially serious medical condition to complicate pregnancy. The prevalence and morbidity rates are increasing, although the asthma-related mortality has dropped in recent years.
- A pregnant woman with epilepsy should take only one anticonvulsant medication, at the lowest dose level that is effective at keeping her seizure free if at all possible.
- Many autoimmune disorders (e.g., SLE and MG) are often diagnosed in women during their reproductive years; therefore they may occur during pregnancy.
- Support from a variety of sources, including family and friends, health care providers, and the recovery community, is needed to help perinatal substance abusers achieve and maintain sobriety.

CHAPTER

12

High Risk Perinatal Care: Gestational Conditions

Kitty Cashion

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Differentiate among gestational hypertension, preeclampsia, and chronic hypertension.
- Describe etiologic theories and pathophysiology of preeclampsia.
- Compare care management of women with mild gestational hypertension or preeclampsia versus severe gestational hypertension or preeclampsia.
- Discuss the preconception, antepartum, intrapartum, and postpartum management of the woman with chronic hypertension.
- Explain the effects of hyperemesis gravidarum on maternal and fetal well-being.
- Differentiate among causes, signs and symptoms, possible complications, and management of miscarriage, ectopic pregnancy, cervical insufficiency, and hydatidiform mole.
- Compare and contrast placenta previa and placental abruption in relation to signs and symptoms, complications, and management.
- Discuss the diagnosis and management of disseminated intravascular coagulation.
- Discuss signs and symptoms, effects on pregnancy, and management of urinary tract infections.
- Explain the basic principles of care for a pregnant woman undergoing abdominal surgery.
- Discuss implications of trauma on mother and fetus during pregnancy.
- Identify priorities in assessment and stabilization measures for the pregnant trauma victim.

Some women experience significant problems during the months of gestation that can greatly affect pregnancy outcome. Some of these conditions develop as a result of the pregnant state; others are problems that can happen to anyone at any time of life but occur in this case during pregnancy. This chapter discusses a variety of disorders that did not exist before pregnancy, all of which have at least one thing in common: their occurrence in pregnancy puts the woman and fetus at risk. Hypertension in pregnancy, hyperemesis gravidarum, hemorrhagic complications of early and late pregnancy, urinary tract infection (UTI), surgery during pregnancy, and trauma are discussed. For each problem, management throughout the entire perinatal period (antepartum, intrapartum, and postpartum) is included in this chapter; thus all the information for each condition is located in one place in the text.

HYPERTENSION IN PREGNANCY

Significance and Incidence

Hypertensive disorders are some of the most common medical complications of pregnancy, occurring in approximately 5% to 10% of all pregnancies. The incidence varies among hospitals, regions, and countries. Hypertensive disorders are a major cause of maternal and perinatal morbidity and mortality worldwide (Sibai, 2012). In the United States and Canada they are one of the top causes of maternal morbidity and mortality (Harvey and Sibai, 2013). The four most common types of hypertensive disorders occurring in pregnancy are: (1) gestational hypertension, (2) preeclampsia-eclampsia, (3) chronic hypertension, and (4) preeclampsia superimposed on chronic hypertension (Gilbert, 2011; Harvey and Sibai, 2013).

Classification

The classification of hypertensive disorders in pregnancy is confusing because not all health care providers consistently use standard definitions. The classification system most commonly used in the United States is based on reports from the American College of Obstetricians and Gynecologists (ACOG, 2002) and the National High Blood Pressure Education Program (2000). This classification system is summarized in Table 12-1.

TABLE 12-1 CLASSIFICATION OF HYPERTENSIVE STATES OF PREGNANCY

TYPE	DESCRIPTION
Gestational Hypertensive Disorders	
Gestational hypertension	Development of hypertension after week 20 of pregnancy in previously normotensive woman without proteinuria
Preeclampsia	Development of hypertension and proteinuria in previously normotensive woman after 20 weeks of gestation or in early postpartum period; in presence of trophoblastic disease preeclampsia can develop before 20 weeks of gestation
Eclampsia	Development of convulsions or coma not attributable to other causes in preeclamptic woman
Chronic Hypertensive Disorders	
Chronic hypertension	Hypertension in pregnant woman present before pregnancy or diagnosed before 20 weeks of gestation and persistent after 12 weeks postpartum
Superimposed preeclampsia or eclampsia	In women with hypertension before 20 weeks of gestation, new-onset proteinuria In women with both hypertension and proteinuria before 20 weeks of gestation: worsening hypertension or proteinuria

Data from American College of Obstetricians and Gynecologists (ACOG): *Diagnosis and management of preeclampsia and eclampsia,* AGOG Practice Bulletin No. 33, Washington DC, 2002, ACOG; Harvey C, Sibai B: Hypertension in pregnancy. In Troiano NH, Harvey CJ, Chez BF, editors: *AWHONN's high risk and critical care obstetrics*, ed 3, Philadelphia, 2013, Lippincott Williams & Wilkins.

BOX 12-1 BLOOD PRESSURE MEASUREMENT

- Measure blood pressure with the woman seated (ambulatory) or in the lateral recumbent position with the arm at heart level. Neither the woman nor the health care provider should talk while the blood pressure is being measured.
- After positioning allow the woman at least 10 minutes of quiet rest before blood pressure measurement to encourage relaxation.
- Instruct the woman to refrain from tobacco or caffeine use 30 minutes before blood pressure measurement.
- Use the right arm each time.
- Support the arm in a horizontal position at heart level.
- Use the proper-size cuff (cuff should cover approximately 80% of the upper arm or be 1½ times the length of the upper arm).
- Maintain a slow, steady deflation rate.
- Take the average of two readings at least 6 hours apart to minimize recorded blood pressure variations across time.
- Use Korotkoff phase V (disappearance of sound) for recording the diastolic value.
- Use accurate equipment. The mercury sphygmomanometer is the most accurate device.
- If interchanging manual and electronic devices, use caution in interpreting different blood pressure values.

Gestational Hypertension

Gestational hypertension is the onset of hypertension without proteinuria after week 20 of pregnancy (ACOG, 2002; National High Blood Pressure Education Program, 2000). Hypertension is defined as a systolic blood pressure (BP) greater than 140 mm Hg or a diastolic BP greater than 90 mm Hg. The hypertension should be recorded on at least two separate occasions at least 4 to 6 hours apart but within a maximum of a 1-week period (ACOG, 2002; Harvey and Sibai, 2013; National High Blood Pressure Education Program, 2000). Only one pressure (either systolic or diastolic) needs to be elevated to meet the definition of hypertension (Harvey and Sibai, 2013). Both the National High Blood Pressure Education Program and the American Heart Association (AHA) have published extensive recommendations for accurately measuring BP (Pickering, Hall, Appel, et al., 2005; National High Blood Pressure Education Program, 2000). Box 12-1 provides detailed instructions for measurement.

Gestational hypertension is further classified as either mild or severe. The definitions of mild and severe gestational hypertension are the same as the definitions for BP readings for mild and severe preeclampsia (Table 12-2). Gestational hypertension does not persist longer than 12 weeks postpartum and usually resolves during the first postpartum week (Harvey and Sibai, 2013). Some women who initially are thought to have gestational hypertension will eventually be diagnosed with chronic hypertension. Others will develop proteinuria, thereby changing their diagnosis to preeclampsia.

Preeclampsia

Preeclampsia is a pregnancy-specific condition in which hypertension and proteinuria develop after 20 weeks of gestation in a woman who previously had neither condition. It occurs in approximately 2% to 7% of healthy nulliparous pregnant women and much more frequently in women with multifetal gestation, a history of preeclampsia, chronic hypertension, and preexisting diabetes (Sibai, 2012). Preeclampsia is a vasospastic, systemic disorder and is usually categorized as mild or severe for purposes of management (ACOG, 2002; National High Blood Pressure Education Program, 2000). Table 12-2 lists criteria for mild and severe preeclampsia, and Table 12-3 gives common laboratory changes that occur in both.

Eclampsia

Eclampsia is the onset of seizure activity or coma in a woman with preeclampsia who has no history of preexisting pathology that can result in seizure activity (Harvey and Sibai, 2013; Roberts and Funai, 2009). Eclamptic seizures can occur before, during, or after birth. Approximately one third of eclamptic seizures occur after birth, almost always within the first 48 hours after birth (Roberts and Funai, 2009).

Chronic Hypertensive Disorders

Chronic Hypertension. **Chronic hypertension** is defined as hypertension that is present before the pregnancy or develops before 20 weeks of gestation. Hypertension initially diagnosed during pregnancy that persists longer than 12 weeks postpartum is also classified as chronic hypertension (Harvey and Sibai, 2013; Roberts and Funai, 2009). Chronic hypertension is further classified as mild or severe based on systolic and diastolic BPs. Most women with mild chronic hypertension experience uncomplicated pregnancies. However,

TABLE 12-2 DIFFERENTIATION BETWEEN MILD AND SEVERE PREECLAMPSIA

	MILD PREECLAMPSIA	SEVERE PREECLAMPSIA
Maternal Effects		
Blood pressure (BP)	BP reading ≥140/90 mm Hg × 2, at least 4-6 hr apart but within a maximum of a 1-wk period	Rise to ≥160/110 mm Hg on two occasions at least 6 hr apart
Proteinuria		
Qualitative dipstick	≥1+ on dipstick on two random urine samples collected at least 4-6 hr apart	≥3+ on dipstick on two random urine samples collected at least 4 hr apart
Quantitative 24-hr analysis	Proteinuria of ≥300 mg in a 24-hr specimen	Proteinuria of ≥5 g in a 24-hr specimen
Urine output	≥25-30 mL/hr	<500 mL/24 hr
Headache	Absent or transient	Persistent or severe
Visual problems	Absent	Blurred, photophobia
Irritability or changes in affect	Transient	May be severe
Epigastric or right upper quadrant pain, nausea, and vomiting	Absent	May be present
Thrombocytopenia	Absent	May be present
Impaired liver function	Normal	May be present
Pulmonary edema	Absent	May be present
Fetal Effects		
Placental perfusion	Reduced	Decreased perfusion expressing as IUGR in fetus; abnormal fetal status on antepartum testing

Data from American College of Obstetricians and Gynecologists (ACOG): *Diagnosis and management of preeclampsia and eclampsia,* ACOG Practice Bulletin No. 33, Washington DC, 2002, ACOG; Harvey C, Sibai B: Hypertension in pregnancy. In Troiano NH, Harvey CJ, Chez BF, editors: *AWHONN's high risk and critical care obstetrics*, ed 3, Philadelphia, 2013, Lippincott Williams & Wilkins.
IUGR, Intrauterine growth restriction.

those with severe chronic hypertension have an increased risk of perinatal mortality (Gilbert, 2011).

Chronic Hypertension with Superimposed Preeclampsia. Women with chronic hypertension may develop superimposed preeclampsia, which increases the morbidity for mother and fetus. A diagnosis of chronic hypertension with superimposed preeclampsia is made with the following findings (Harvey and Sibai, 2013):

- In women with hypertension before 20 weeks of gestation
- New-onset proteinuria
  - In women with both hypertension and proteinuria before 20 weeks of gestation
  - Significant worsening of hypertension or proteinuria

PREECLAMPSIA

Etiology

Preeclampsia is a condition unique to human pregnancy. Signs and symptoms develop only during pregnancy and disappear soon after birth of the fetus and expulsion of the placenta. Common risk factors associated with the development of preeclampsia are listed in Box 12-2. The strongest risk factors are a first pregnancy when the woman is younger than 19 or older than 40 years of age, a first pregnancy with a new partner, and a history of severe preeclampsia (Gilbert, 2011).

The cause of preeclampsia is unknown. Many theories have been suggested to explain its etiology. Current theories that are still being considered include abnormal trophoblast invasion, immunologic response to partially foreign genetic placental and fetal tissue, stimulation of the inflammatory system by cardiovascular changes of pregnancy, various dietary deficiencies, and genetic abnormalities (Harvey and Sibai, 2013).

Pathophysiology

Preeclampsia can progress along a continuum from mild-to-severe preeclampsia to eclampsia. Current thought is that the pathologic changes that occur in the woman with preeclampsia are caused by disruptions in placental perfusion and endothelial cell dysfunction (Gilbert, 2011; Harvey and Sibai, 2013; Sibai, 2012). These changes are present long before the clinical diagnosis of preeclampsia is made (Roberts and Funai, 2009). Normally in pregnancy the spiral arteries in the uterus widen from thick-walled muscular vessels to thinner, saclike vessels with much larger diameters. This change increases the capacity of the vessels, allowing them to handle the increased blood volume of pregnancy. Because this vascular remodeling does not occur or only partially develops in women with preeclampsia, decreased placental perfusion and hypoxia result (Harvey and Sibai, 2013). Placental ischemia is thought to cause endothelial cell dysfunction by stimulating the release of a substance that is toxic to endothelial cells. This anomaly causes generalized vasospasm, which results in poor tissue perfusion in all organ systems, increased peripheral resistance and BP, and increased endothelial cell permeability, leading to intravascular protein and fluid loss and ultimately to less plasma volume. The main pathogenic factor is not an increase in BP but poor perfusion as a result of vasospasm and reduced plasma volume (Fig. 12-1) (Gilbert, 2011; Roberts and Funai, 2009). Fig. 12-2 demonstrates how endothelial cell dysfunction causes many of the common signs and symptoms of preeclampsia.

Reduced kidney perfusion decreases the glomerular filtration rate and can lead to degenerative glomerular changes and oliguria. Pathologic changes in the endothelial cells of the glomeruli (glomerular endotheliosis) are uniquely characteristic of preeclampsia. Protein, primarily albumin, is lost in the urine. Uric acid clearance is decreased, but serum uric acid levels increase. Sodium and water are retained. Acute tubular necrosis and renal failure may occur (Gilbert, 2011; Roberts and Funai, 2009).

Plasma colloid osmotic pressure decreases as serum albumin levels decrease. Intravascular volume is reduced as fluid moves out of the intravascular compartment, resulting in hemoconcentration,

TABLE 12-3 COMMON LABORATORY CHANGES IN PREECLAMPSIA

	NORMAL NONPREGNANT	PREECLAMPSIA	HELLP
Hemoglobin, hematocrit	12-16 g/dL, 37%-47%	May ↑	↓
Platelets (cells/mm^3)	150,000-400,000/mm^3	Unchanged or <100,000/mm^3	<100,000/mm^3
Prothrombin time (PT), partial thromboplastin time (PTT)	12-14 sec, 60-70 sec	Unchanged	Unchanged
Fibrinogen	200-400 mg/dL	300-600 mg/dL	↓
Fibrin split products (FSPs)	Absent	Absent or present	Present
Blood urea nitrogen (BUN)	10-20 mg/dL	↑	↑
Creatinine	0.5-1.1 mg/dL	>1.2 mg/dL	↑
Lactate dehydrogenase (LDH)*	45-90 units/L	↑	↑ (>600 units/L)
Aspartate aminotransferase (AST)	4-20 units/L	Elevated	↑ (>70 units/L)
Alanine aminotransferase (ALT)	3-21 units/L	Elevated	↑
Creatinine clearance	80-125 mL/min	130-180 mL/min	↓
Burr cells or schistocytes	Absent	Absent	Present
Uric acid	2-6.6 mg/dL	>5.9 mg/dL	>10 mg/dL
Bilirubin (total)	0.1-1 mg/dL	Unchanged or ↑	↑ (>1.2 mg/dL)

Data from American College of Obstetricians and Gynecologists (ACOG): *Diagnosis and management of preeclampsia and eclampsia,* ACOG Practice Bulletin No. 33, Washington DC, 2002, ACOG; Cunningham F, Leveno K, Bloom S, et al, editors: *Williams obstetrics*, ed 23, New York, 2010, McGraw-Hill; Dildy G: Complications of preeclampsia. In Dildy G, Belfort M, Saade G, et al, editors: *Critical care obstetrics,* ed 4, Malden, MA, 2004, Blackwell Science; Harvey C, Sibai B: Hypertension in pregnancy. In Troiano NH, Harvey CJ, Chez BF, editors: *AWHONN's high risk and critical care obstetrics*, ed 3, Philadelphia, 2013, Lippincott Williams & Wilkins.
*LDH values differ according to the test or assays being performed.

BOX 12-2 COMMON RISK FACTORS FOR PREECLAMPSIA

- Primigravida younger than 19 or older than 40 years old
- Severe preeclampsia in a previous pregnancy
- Family history (mother or sister) of preeclampsia
- Paternal history (partner previously fathered a preeclamptic pregnancy in another woman)
- African descent
- Multifetal gestation
- Maternal infection/inflammation in current pregnancy (i.e., urinary tract infection, periodontal disease)
- Preexisting medical or genetic conditions
  - Chronic hypertension
  - Renal disease
  - Pregestational diabetes mellitus
  - Connective tissue disease (i.e., systemic lupus erythematosus, rheumatoid arthritis)
  - Thrombophilia (i.e., antiphospholipid antibody syndrome, protein C or S deficiency, factor V Leiden mutation)
  - Obesity

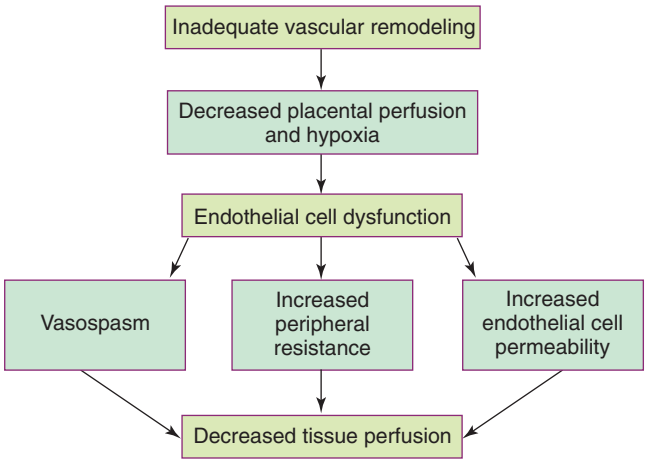

FIG 12-1 Etiology of preeclampsia: disruptions in placental perfusion and endothelial cell dysfunction.

increased blood viscosity, and tissue edema. The hematocrit value increases as fluid leaves the intravascular space. Arteriolar vasospasm can lead to endothelial damage and increased capillary permeability, predisposing the woman to pulmonary edema (see Fig. 12-2) (Gilbert, 2011; Roberts and Funai, 2009).

Decreased liver perfusion can lead to impaired liver function and elevated liver enzyme levels. If hepatic edema and subcapsular hemorrhage develop, the woman may complain of epigastric or right upper quadrant pain. Hemorrhagic necrosis in the liver can result in a subcapsular hematoma, which is a rare occurrence (Gilbert, 2011). Rupture of a subcapsular hematoma is a life-threatening complication and a surgical emergency (see Fig. 12-2).

Neurologic complications associated with preeclampsia include cerebral edema and hemorrhage and increased central nervous system (CNS) irritability. CNS irritability manifests as headaches, hyperreflexia, positive ankle clonus, and seizures. Arteriolar vasospasms and decreased blood flow to the retina can lead to visual disturbances such as scotoma (dim vision or blind or dark spots in

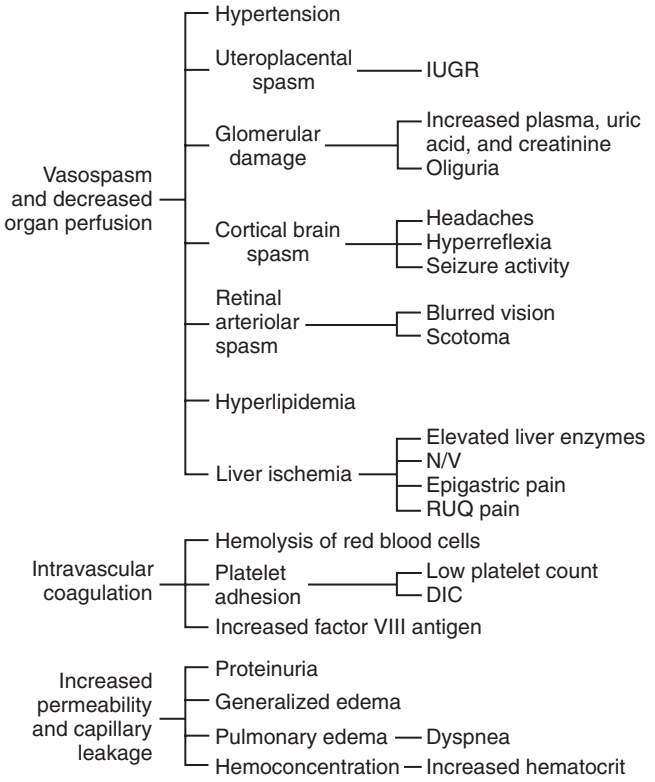

FIG 12-2 Consequences of endothelial cell dysfunction. *DIC,* Disseminated intravascular coagulation; *IUGR,* intrauterine growth restriction; *N/V,* nausea/vomiting; *RUQ,* right upper quadrant. (From Gilbert ES: *Manual of high risk pregnancy and delivery*, ed 5, St Louis, 2011.)

the visual field) and blurred or double vision (Gilbert, 2011; Roberts and Funai, 2009).

Traditionally preeclampsia was considered to affect the woman primarily, causing hypertension, proteinuria, and perhaps associated multisystem dysfunction. However, currently it is recognized that it can also primarily affect the fetus, resulting in fetal growth restriction, decreased amniotic fluid volume, abnormal fetal oxygenation, low birth weight, and preterm birth (Sibai, 2012).

HELLP Syndrome

HELLP syndrome is a laboratory diagnosis for a variant of severe preeclampsia that involves hepatic dysfunction, characterized by hemolysis *(H),* elevated liver enzymes *(EL),* and low platelet count *(LP).* It is not a separate illness. Specific laboratory findings are needed to diagnose HELLP syndrome and distinguish it from other serious diseases that share the same signs and symptoms. HELLP syndrome occurs in 0.5% to 0.9% of all pregnancies. Ten to twenty percent of women with severe preeclampsia develop it (Harvey and Sibai, 2013). Table 12-3 lists laboratory changes that occur in HELLP syndrome. Traditionally it was not diagnosed unless all three laboratory abnormalities were present. Recently, however, women who develop only one or two of the diagnostic laboratory values are being diagnosed with incomplete HELLP, partial HELLP, or the ELLP syndrome (Harvey and Sibai, 2013).

The pathophysiologic changes of HELLP syndrome occur as a result of arteriolar vasospasm, endothelial cell dysfunction with fibrin deposits, and adherence of platelets in blood vessels. Red blood cells are damaged as they pass through narrowed blood vessels and become hemolyzed, resulting in a decreased red blood cell and platelet count and hyperbilirubinemia. Endothelial damage and fibrin deposits in the liver lead to impaired liver function and can cause hemorrhagic necrosis. Liver enzymes are elevated when hepatic tissue is damaged (Gilbert, 2011).

HELLP syndrome usually develops during the antepartum period. The clinical presentation is often nonspecific. Most women with the disorder report a history of malaise, influenza-like symptoms, and epigastric or right upper quadrant abdominal pain. Symptoms tend to worsen at night and improve during the daytime. HELLP syndrome can progress rapidly (Harvey and Sibai, 2013).

! NURSING ALERT

An extremely important point to understand is that many women with HELLP syndrome may not have signs or symptoms of severe preeclampsia. For example, although most women have hypertension, BP may be only mildly elevated in 15% to 50% of cases. Proteinuria may be absent. As a result, women with HELLP syndrome are often misdiagnosed with a variety of other medical or surgical disorders (Sibai, 2012).

HELLP syndrome appears to occur more frequently in Caucasian women than women of other races. A diagnosis of HELLP syndrome is associated with an increased risk for maternal death and adverse perinatal outcomes, including pulmonary edema, acute renal failure, disseminated intravascular coagulopathy (DIC), placental abruption, liver hemorrhage or failure, acute respiratory distress syndrome (ARDS), sepsis, and stroke (Sibai, 2012). The reported perinatal mortality rate ranges from 7.4% to 34%, with a maternal mortality rate of approximately 1% (Sibai, 2012). The rate of preterm birth in women with HELLP syndrome is approximately 70%, with 15% of these occurring before 28 weeks of gestation. Most of the perinatal deaths occur before 28 weeks of gestation in association with placental abruption or severe fetal growth restriction (Sibai, 2012).

CARE MANAGEMENT

Identifying and Preventing Preeclampsia

Numerous clinical trials have examined various interventions to prevent preeclampsia, including protein or salt restriction; zinc, magnesium, fish oil, or vitamins C and E supplementation; use of diuretics or other antihypertensive medications; and use of heparin or low dose aspirin. All of these interventions demonstrated minimal to no benefit in preventing or reducing the severity of preeclampsia (Sibai, 2012).

No reliable test that can be used as a routine screening tool for predicting preeclampsia has yet been developed. However, the search for biomarkers that can identify individual women who will develop hypertension during pregnancy is ongoing (Harvey and Sibai, 2013). For example, the tyrosine kinase (sFLt) and serum placental growth factor (PIGF) ratio at 22 to 26 weeks of gestation was shown in one study to be highly predictive of early-onset preeclampsia (Gilbert, 2011). An abnormal uterine artery Doppler velocimetry in the first or second trimester of pregnancy has also been suggested as a good screening test to predict preeclampsia (Gilbert, 2011).

Although research offers future promise, much work remains before a screening test for preeclampsia is available for widespread clinical use. Nurses should be aware of what strategies are being studied and use the most valid results so they can counsel pregnant women about interventions that are evidence based. Meanwhile the

best preeclampsia prevention methods include early prenatal care for the identification of women at risk and early detection of the disease.

Physical Examination

Accurate measurement of BP is essential in the early detection of hypertensive disorders. Personnel caring for pregnant women need to be consistent in taking and recording BP measurements in a standardized manner (see Box 12-1).

Assessment for edema is another component of the physical examination, although the presence of edema is no longer included in the definition of preeclampsia. Edema is assessed for distribution, degree, and pitting. Dependent edema is edema of the lowest or most dependent parts of the body, where hydrostatic pressure is greatest. If a pregnant woman is ambulatory, the edema may first be evident in the feet and ankles. If she is confined to bed, it is more likely to occur in the sacral region. Pitting edema leaves a small depression or pit after finger pressure is applied to the swollen area (Fig. 12-3). The pit, which is caused by movement of fluid to adjacent tissue away from the point of pressure, normally disappears within 10 to 30 seconds. Although the amount of edema is difficult to quantify, the method shown in Fig. 12-4 may be used to record relative degrees of edema formation.

Deep tendon reflexes (DTRs) reflect the balance between the cerebral cortex and spinal cord. They are evaluated as a baseline and to detect any changes. The biceps and patellar reflexes are assessed, and the findings recorded (Fig. 12-5 and Table 12-4). To elicit the biceps reflex, the examiner strikes a downward blow over the thumb, which is situated over the biceps tendon (see Fig. 12-5, *A*). Normal response is flexion of the arm at the elbow, described as a 2+ response. The patellar reflex is elicited with the woman's legs hanging freely over the end of the examining table or with the woman lying on her side with the knee slightly flexed (see Fig. 12-5, *D*). The patellar tendon (inferior to the patella) is tapped with a percussion hammer. Normal response is the extension or kicking out of the leg.

To assess for hyperactive reflexes (clonus) at the ankle joint, the examiner supports the leg with the knee flexed (see Fig. 12-5, *F*). With one hand the examiner sharply dorsiflexes the foot, maintains

FIG 12-3 Pitting edema. (Courtesy Shannon Perry, Phoenix, AZ.)

(From Seidel H, Ball J, Dains J, et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

the position for a moment, and then releases it. Normal (negative clonus) response is elicited when no rhythmic oscillations (jerks) are felt while the foot is held in dorsiflexion. When the foot is released, no oscillations are seen as the foot drops to the plantar-flexed position. Abnormal (positive clonus) response is recognized by rhythmic oscillations of one or more "beats" felt when the foot is in dorsiflexion and seen as the foot drops to the plantar-flexed position.

The presence of *proteinuria* is determined from dipstick testing on a clean-catch or catheterized urine specimen or evaluation of a 24-hour urine collection. Proteinuria is defined as a concentration at or greater than 30 mg/dL (≥1+ on dipstick measurement) in at least two random urine specimens collected at least 6 hours apart. In a 24-hour specimen proteinuria is defined as a concentration at or greater than 300 mg/24 hours. A diagnosis of severe preeclampsia requires a concentration of ≥5 g protein in a 24-hour urine collection or a value of ≥3+ on dipstick (Harvey and Sibai, 2013). Because a 24-hour collection to measure the quantity of protein and creatinine clearance is more reflective of true renal status, it is preferred over dipstick testing. Alkaline, concentrated, or dilute urine can yield a false reading. Urine contaminated with bacteria, blood, and amniotic fluid also can yield a false positive for proteinuria. Therefore, to ensure accurate results, proteinuria should be determined using only a urine specimen that has been collected by either a thorough clean-catch, midstream technique or catheterization (Gilbert, 2011).

During the examination the woman is evaluated for signs and symptoms of severe preeclampsia such as severe headaches (usually frontal); epigastric pain (heartburn); right upper quadrant abdominal pain; or visual disturbances such as scotoma, photophobia, or double vision. The signs and symptoms of mild versus severe preeclampsia are summarized in Table 12-2.

Mild Gestational Hypertension and Mild Preeclampsia

The goals of therapy for women with mild gestational hypertension and mild preeclampsia are to ensure maternal safety and have the woman give birth to a healthy newborn as close to term as possible. At 37 weeks or more of gestation, the plan of care for a woman with mild gestational hypertension or mild preeclampsia is most likely to be the induction of labor, preceded, if necessary, by cervical ripening (Sibai, 2012). When mild gestational hypertension or mild preeclampsia is suspected before 37 weeks of gestation, close observation of maternal and fetal status is necessary. Women with mild gestational hypertension and mild preeclampsia can be managed safely at home, provided they have frequent maternal and fetal evaluation (Gilbert, 2011; Sibai, 2012).

TABLE 12-4 ASSESSING DEEP TENDON REFLEXES

GRADE	DEEP TENDON REFLEX RESPONSE
0	No response
1+	Sluggish or diminished
2+	Active or expected response
3+	More brisk than expected, slightly hyperactive
4+	Brisk, hyperactive, with intermittent or transient clonus

From Seidel HM, Ball JW, Dains JE, et al: *Mosby's guide to physical examination*, ed 7, St Louis, 2011, Mosby.

Criteria for home care include BP less than 150/100; proteinuria less than 500 mg/day; normal platelet count, liver enzymes, and creatinine levels; normal fetal status; no signs or symptoms of severe preeclampsia; and a reliable, compliant patient (Gilbert, 2011; Sibai, 2012). Successful home care requires the woman to be well educated about preeclampsia and highly motivated to follow the plan of care (see Patient Teaching box). All teaching should include the woman and her family; and time must be allowed for them to absorb information, ask questions, and voice concerns. Methods for enhancing learning include visual aids, DVDs or Internet videos, handouts, and demonstrations with return demonstrations. Furthermore, the effects of illness, language, age, cultural beliefs, and support systems must be considered.

Maternal and Fetal Assessment. Initial maternal laboratory evaluation includes measurement of serum creatinine, platelet count, liver enzymes, and a 24-hour urine protein assessment. Thereafter the platelet count, liver enzymes, and serum creatinine are usually assessed once each week. Women are also evaluated for signs or symptoms of worsening preeclampsia such as severe headaches, blurred or double vision, mental confusion, right upper quadrant or epigastric pain, nausea or vomiting, shortness of breath, and decreased urinary output (Sibai, 2012). Fetal evaluation generally includes daily fetal movement counts and nonstress testing or a biophysical profile (BPP) once or twice weekly until birth. (See Chapter 10 for more information on fetal assessment tests.) Ultrasound evaluation of amniotic fluid status and determination of estimated fetal weight are performed at the time mild preeclampsia is diagnosed and serially thereafter, depending on findings (Sibai, 2012).

Activity Restriction. Complete or partial bed rest for the duration of the pregnancy is still recommended frequently. However, no evidence has been found that this practice improves pregnancy outcome. Moreover, prolonged bed rest is known to increase the risk of thrombophlebitis (Sibai, 2012). Other adverse physiologic outcomes related to complete bed rest include cardiovascular deconditioning; diuresis with accompanying fluid, electrolyte, and weight loss; muscle atrophy; and psychologic stress. These changes begin

PATIENT TEACHING

Assessing and Reporting Clinical Signs of Preeclampsia

- Take your blood pressure as directed. Use your right arm in a sitting position each time for consistent and accurate readings. Support the arm on a table in a horizontal position at heart level.
- Report to your health care provider immediately any increase in your blood pressure.
- Dipstick test your clean-catch urine sample as directed to assess proteinuria.
- Report to your health care provider if proteinuria is 2+ or more or if you have a decrease in urine output.
- Assess your baby's activity daily. Decreased activity (four or fewer movements per hour) may indicate fetal compromise and should be reported.
- Be sure to keep your scheduled prenatal appointments so any changes in your or your baby's condition can be detected.
- Keep a daily log or diary of your assessments for your home health care nurse or bring it with you to your next prenatal visit.
- Report to your health care provider immediately any headache, dizziness, or blurring of vision.

on the first day of bed rest and continue for the duration of therapy. Therefore restricted activity rather than complete bed rest is recommended (Sibai, 2012).

Women with mild preeclampsia generally feel reasonably well; therefore boredom from activity restriction is common. Diversionary activities, including television and computer or smart phone use, visits from friends, and creation of a comfortable and convenient environment are ways to cope with the boredom. Participation in online prenatal classes may also be possible. Gentle exercise (e.g., range-of-motion exercises, stretching, Kegel exercises, pelvic tilts) is important in maintaining muscle tone, blood flow, regularity of bowel function, and a sense of well-being (see Patient Teaching box).

A high risk pregnancy can be very stressful for the woman and her family. Family stressors include separation from family members when hospitalized, need for activity restriction, financial concerns, ability to manage the household, family activities, and child care. The family needs to use coping mechanisms and support systems to help them through this crisis. An excellent Internet-based support group for pregnant women on bed rest is Sidelines (www.sidelines.org) (Gilbert, 2011). Relaxation techniques can also help to reduce stress and prepare the woman for labor and birth.

Diet. Women with mild preeclampsia can have a regular diet with adequate protein (60 to 70 g), calcium (1200 mg), 600 mcg of folic acid, and adequate zinc (11 to 12 mg) and sodium (1.5 g) (Gilbert, 2011; Otten, Helwig, and Meyers, 2006). Adequate fluid intake (six to eight 8-ounce glasses of water per day) is encouraged to enhance renal perfusion and bowel function (Gilbert, 2011) (see Patient Teaching box on p. 310).

Severe Gestational Hypertension and Severe Preeclampsia

Women with severe gestational hypertension are at greater risk for pregnancy complications than are women with mild preeclampsia. Therefore these women should be managed as if they have severe preeclampsia. Women diagnosed with severe gestational hypertension or severe preeclampsia should be hospitalized immediately for a thorough evaluation of maternal-fetal status (Sibai, 2012). These women are placed on magnesium sulfate on admission to prevent eclamptic seizures. Maternal assessments include monitoring BP;

PATIENT TEACHING

Coping with Activity Restriction

At Home

- Clarify with your health care provider: What is bed rest? Question your activity level, positioning, bathroom privileges, children's visits, activities, personal hygiene, mobility, diet, and visitors.
- Have your computer or smart phone available at your bedside. Both devices can be used for communication with friends, to conduct business, and to shop as necessary. Also use your computer or smart phone to communicate with Internet support groups and obtain information.
- Have a television and DVD player to watch television programs or movies and a radio, CD player, or MP3 player to listen to music.
- Delegate responsibilities to family members or friends as much as possible (i.e., attend to the laundry, pick up groceries, drop off and pick up dry cleaning, meet repair people, attend to child care, organize meals).
- Have these available for use on your bed or couch:
  - Egg crate mattress
  - Pillows and more pillows (body pillow)
- Keep a big trash basket near your bed and daytime resting place.
- Place a box or crate near the bed/sofa to store items such as:
  - Post-it notes
  - Cups with lids and flexible straws
  - Paper plates
  - Plastic forks, spoons, and knives
  - Baby monitor or walkie-talkies
  - Wet wipes
  - Notebook to record questions for providers, telephone numbers, to-do lists
  - Envelopes and stationery
  - Take-out menus
  - Reading materials
  - Books
  - Audio books
  - Magazines
- Stock mini-refrigerator or cooler with water or other beverages or healthy snacks.
- Plan for family time—visits and interaction, particularly with small children (see the Patient Teaching box: Activities for Children of Women on Activity Restriction on p. 447).
- Explore your interest in a new hobby.
  - Work crossword or jigsaw puzzles.
  - Learn to embroider, smock, crochet, or knit.
  - Do mending or sewing.
- Do craft projects; make something for the baby.
- Identify relaxation exercises and activities (music) and implement.
- Arrange to have a facial, manicure/pedicure, neck massage, or other special treat when you need a lift.

In the Hospital

- Clarify with your health care provider: What is bed rest? Question your activity level, positioning, bathroom privileges, children's visits, activities, personal hygiene, mobility, diet, and visitors.
- In addition to survival tips for the home, the following may be useful in the hospital setting:
  - Bring your own pillow, shampoo, and conditioner.
  - Have a wheelchair for outside visits or visiting other antepartal women if allowed.
  - If possible bring a laptop computer so you can watch movies or television programs if Internet access is available.
  - Ask friends to bring healthy food and snacks rather than flowers when visiting.
  - Explore your interest in handheld games.
  - Work with staff regarding scheduling (e.g., obstetric provider examinations, vital signs, nursing assessments).
  - Bring earplugs to block the hospital noise.
  - Ask for a room with a view.
  - Have a large calendar and clock for easy viewing. Record significant events on the calendar.

PATIENT TEACHING

Diet for Preeclampsia

- Eat a nutritious, balanced diet (60 to 70 g protein, 1200 mg calcium, 600 mcg of folic acid, 11 to 12 mg of zinc, and 1.5 g of sodium). Consult with registered dietitian on the diet best suited for you as an individual.
- Salt foods to taste. Limiting excessively salty foods (luncheon meats, pretzels, chips, pickles, and sauerkraut) will likely be necessary to meet the recommended sodium intake of 1.5 g/day.
- Eat foods with roughage (whole grains, raw fruits, and vegetables).
- Drink six to eight 8-ounce glasses of water per day.
- Avoid alcohol and tobacco and limit caffeine intake.

BOX 12-3 HOSPITAL PRECAUTIONARY MEASURES FOR WOMEN WITH PREECLAMPSIA

- Environment:
  - Quiet
  - Nonstimulating
  - Lighting subdued
- Seizure precautions:
  - Suction equipment tested and ready to use
  - Oxygen administration equipment tested and ready to use
  - Call button within easy reach
- Emergency medications available on the unit:
  - Hydralazine
  - Labetalol
  - Nifedipine
  - Magnesium sulfate
  - Calcium gluconate or calcium chloride
- Emergency birth pack easily accessible

urine output; cerebral status; and the presence of epigastric pain, tenderness, labor, or vaginal bleeding (Sibai, 2012). Laboratory evaluation includes a platelet count, liver enzymes, and serum creatinine (see Table 12-3). Fetal assessment includes continuous electronic fetal heart rate monitoring, a BPP, and ultrasound evaluation of fetal growth and amniotic fluid (Sibai, 2012).

After this initial assessment period a multidisciplinary plan of care is developed with the woman and her family. The goals of care management are to ensure maternal safety, assess the degree of maternal and fetal risk, formulate a plan for giving birth, and prevent eclampsia and other serious complications. If the pregnancy is 34 weeks of gestation or greater, birth will likely be accomplished promptly, either as cesarean or after labor induction. By 34 weeks of gestation, the risks of continuing the pregnancy are considered greater than the risks of preterm birth (Sibai, 2012).

Expectant Management

Women who are between 24 0/7 and 32 6/7 weeks of gestation and have no indication for giving birth immediately may be candidates for expectant management. These women should be hospitalized at a tertiary care facility that is able to provide both maternal and neonatal intensive care. Care-management decisions should be made in consultation with a maternal fetal medicine **(perinatologist)** specialist, and patient and family counseling by a neonatologist should be provided (Sibai, 2012).

Expectant management includes the use of oral antihypertensive medications as needed to maintain the systolic BP between 140 and 155 mm Hg and the diastolic BP between 90 and 105 mm Hg. Management also includes ongoing maternal and fetal assessment for indicators of worsening condition (Sibai, 2012). Corticosteroids (betamethasone) are ordered to enhance fetal lung maturation. The dose is 12.5 mg intramuscularly, repeated in 24 hours. Optimal benefit begins 24 hours after the first dose is administered and lasts for 7 days (Gilbert, 2011; Sibai, 2012). Most women managed expectantly develop a maternal or fetal indication for giving birth within 2 weeks, although some are able to continue their pregnancies safely for several more weeks. Immediate birth is indicated if eclampsia, pulmonary edema, placental abruption, DIC, or renal dysfunction develops (Sibai, 2012).

Intrapartum Care

Intrapartum nursing care is directed toward the early identification of fetal heart rate (FHR) abnormalities and the prevention of maternal complications. Continuous FHR and uterine contraction monitoring are initiated, and the woman is assessed for signs of placental abruption such as uterine tachysystole or vaginal bleeding. Maternal evaluation also includes assessment of the central nervous, cardiovascular, pulmonary, and renal systems. Vital signs and assessments are performed as ordered and per hospital policy (see Nursing Care Plan). Patient and family education and supportive measures are also initiated (Gilbert, 2011; Simpson and Creehan, 2008).

The woman with severe preeclampsia is maintained on bed rest with the side rails up in a quiet, darkened environment. Emergency drugs, oxygen, and suction equipment should be checked and readily available (Box 12-3). To reduce the risk of pulmonary edema, total intravenous (IV) and oral fluids should not exceed 125 mL/hr. Intensive hemodynamic monitoring is not a routine standard of care and is indicated only in the presence of pulmonary edema or oliguria unresponsive to fluid challenge or severe hypertension unresponsive to medications. A pulmonary artery (Swan-Ganz) catheter can be inserted to evaluate central venous and pulmonary artery pressures (Gilbert, 2011; Simpson and Creehan, 2008).

Magnesium Sulfate. Magnesium sulfate is the drug of choice in the prevention and treatment of seizure activity (eclampsia) caused by severe preeclampsia (see Evidence-Based Practice box). It is almost always administered intravenously as a secondary infusion (piggyback) by a volumetric infusion pump. Per protocol or health care provider's order, an initial loading dose of 4 to 6 g of magnesium sulfate is infused over 15 to 30 minutes. This dose is followed by a maintenance dose of magnesium sulfate that is diluted in an IV solution (e.g., 40 g of magnesium sulfate in 1000 mL of lactated Ringer's solution [1 g = 25 mL]) and administered by an infusion pump at 2 g/hr. This dose should maintain a therapeutic serum magnesium level of 4 to 7 mEq/L. After the loading dose, transient lowering of the arterial BP may occur secondary to relaxation of smooth muscle (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011).

Magnesium sulfate is rarely given intramuscularly because the absorption rate cannot be controlled, injections are painful, and tissue necrosis may occur. However, the intramuscular (IM) route may be used in low-resource settings or with some women who are being transported to a tertiary care center. The IM dose is a 10-g loading dose (administered as two separate injections of 5 g in each buttock). The maintenance dosage is 5 g administered every 4 hours in alternating buttocks (Harvey and Sibai, 2013). Local anesthetic can be added to the solution to reduce injection pain. The Z-track technique should be used for the deep IM injection, followed by gentle massage at the site.

NURSING CARE PLAN

Severe Preeclampsia

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
Risk for Injury to woman and fetus related to CNS irritability (seizures)	Woman will show diminished signs of CNS irritability (e.g., DTRs ≤2+, absence of clonus) and have no seizure activity.	Establish baseline data (e.g., DTRs, clonus).	To use as basis for evaluating effectiveness of treatment
		Administer IV magnesium sulfate per physician's orders.	To decrease hyperreflexia and minimize risk of seizure activity
		Monitor maternal vital signs, level of consciousness, FHR, urine output, DTRs, IV flow rate, and serum levels of magnesium sulfate.	To assess for and prevent magnesium sulfate toxicity (e.g., drowsiness, lethargy, slurred speech, loss of DTRs, depressed respirations, cardiac arrest)
		Have calcium gluconate or calcium chloride on the unit.	To be available if needed as an antidote for magnesium sulfate toxicity
		Maintain a quiet, darkened environment.	To avoid stimuli that may precipitate seizure activity
Ineffective Tissue Perfusion related to preeclampsia secondary to arteriolar vasospasm	Woman will exhibit signs of adequate tissue perfusion (i.e., adequate urine output and normal FHR tracing).	Administer IV magnesium sulfate per physician order.	To relax vasospasms and increase renal perfusion
		Place woman on bed rest in side-lying position.	To maximize uteroplacental blood flow, reduce blood pressure, and promote diuresis
		Monitor fetal heart for rate, baseline variability, and absence of late decelerations.	To assess for evidence of adequate uteroplacental oxygenation
Other Possible Nursing Diagnoses			
Risk for Excess Fluid Volume related to increased sodium retention secondary to administration of magnesium sulfate	Woman will exhibit signs of normal fluid volume (i.e., balanced intake and output, normal serum creatinine levels, normal breath sounds), adequate oxygenation (i.e., normal respirations; full orientation to person, time, and place), normal range of cardiac output (i.e., normal pulse rate and rhythm), and fetal well-being (i.e., adequate fetal movement, normal FHR).	Monitor woman for signs of fluid volume excess (increased edema, decreased urine output, elevated serum creatinine level, weight gain, dyspnea, crackles).	To detect potential complications
Risk for Impaired Gas Exchange related to pulmonary edema secondary to increased vascular resistance		Monitor woman for signs of impaired gas exchange (increased respirations, dyspnea, altered blood gases, hypoxemia).	To detect potential complications
Risk for Decreased Cardiac Output related to use of antihypertensive drugs		Monitor woman for signs of decreased cardiac output (altered pulse rate and rhythm).	To detect potential complications
Risk for Injury to Fetus related to uteroplacental insufficiency secondary to use of antihypertensive medications		Monitor fetus for abnormal signs (decreased fetal activity, abnormal FHR or pattern).	To prevent complications
		Record findings and report signs of increasing problems to physician.	To enable timely interventions

CNS, Central nervous system; *DTR,* deep tendon reflex; *FHR,* fetal heart rate; *IV,* intravenous.

NURSING ALERT

High serum levels of magnesium can cause relaxation of smooth muscle such as the uterus. However, when administered as a 4- to 6-g loading dose followed by a 1- to 2-g/hr maintenance dose, magnesium sulfate has not been shown to significantly affect the need for oxytocin (Pitocin) stimulation of labor. Other than a brief period of uterine muscle relaxation during and immediately after administration of the loading dose, no evidence of decreased uterine contractility has been observed (Cunningham, Leveno, Bloom, et al., 2010).

It is unclear how magnesium sulfate works to prevent and treat eclamptic seizures. It may cause vasodilation in the peripheral and cerebral circulation, prevent or decrease cerebral edema, or function as a central anticonvulsant (Harvey and Sibai, 2013). Because magnesium is excreted in the urine, accurate recordings of maternal urine output must be obtained. If renal function declines, not all of the magnesium sulfate will be excreted adequately, resulting in magnesium toxicity. Common side effects of magnesium sulfate are a feeling of warmth, flushing, diaphoresis, and burning at the IV site. Symptoms of mild toxicity include lethargy, muscle weakness, decreased or absent DTRs, double vision, and slurred speech.

EVIDENCE-BASED PRACTICE

Common Treatments for Eclampsia and Preeclampsia

Ask the Question

For women whose pregnancies are complicated by eclampsia or preeclampsia, are the treatments commonly used today evidence based and cost-effective?

Search for the Evidence

Search Strategies

English research-based publications on preeclampsia, eclampsia, HELLP, magnesium, calcium, and corticosteroids were included.

Databases Used

Cochrane Collaborative Database, National Guideline Clearinghouse (AHRQ), CINAHL, PubMed, UpToDate, and the professional websites for AWHONN and SOGC

Critically Analyze the Evidence

- Severe preeclampsia (hypertension plus proteinuria) is an inflammatory disease of pregnancy associated with maternal risks for stroke, renal or liver failure, and clots. Eclampsia (seizure) is associated with increased risk for maternal and fetal death and preterm birth and low birth weight.
- Magnesium sulfate ($MgSO_4$) is commonly used for treatment of preeclampsia and eclampsia but not for hypertension without proteinuria. A systematic review found that using $MgSO_4$ for eclampsia was associated with lower risks for maternal death, recurrent seizure, and major morbidity (McDonald, Lutsiv, Dzaja, et al., 2012).
- A meta-analysis found that, when compared to placebo or no treatment, $MgSO_4$ given to preeclamptic women halved the risk of eclampsia, decreased the risk for placental abruption, and probably decreased maternal death (Duley, Gulmezoglu, Henderson-Smart, et al., 2010). Although the risk for cesarean birth was increased, there were no differences in severe maternal morbidity or perinatal or infant death up to 1 year.
- Calcium supplements are often recommended to prevent preeclampsia. A systematic review found that calcium supplements in pregnancy reduced the risk of preeclampsia to half that of placebo or no treatment, especially for populations with lower baseline calcium intake (Hofmeyr, Lawrie, Atallah, et al., 2010). The risk of preterm birth decreased with calcium, although overall perinatal death was unchanged. A slight paradoxical increase in the incidence of hemolysis, elevated liver enzymes, and low platelets (HELLP) was puzzling but did not change the overall recommendation for calcium supplementation in pregnancy.
- In the presence of HELLP, corticosteroids have commonly been used to decrease the inflammatory process; but a systematic analysis found that, although corticosteroid use improved platelet counts, it did not change maternal mortality or severe morbidity or perinatal death (Woudstra, Chandra, Hofmeyr, et al., 2010).

Apply the Evidence: Nursing Implications

- As a muscle relaxer $MgSO_4$ has many uses in the maternal hospital setting: the treatment of preeclampsia and eclampsia, the treatment of preterm labor, and as prophylactic neuroprotection against cerebral palsy for a fetus at risk for preterm birth. The nurse must understand the difference and be able to communicate each of these uses to the patient and family.
- $MgSO_4$ is associated with a higher cesarean birth rate and maternal adverse effects such as flushing, decreased urinary output, toxicity, respiratory depression, and hyporeflexia.
- For women at risk for preeclampsia, especially women with low baseline calcium such as low-income and lactose-intolerant populations, calcium supplements are an evidence-based preventive therapy, well accepted, readily available, and low-cost.
- Blood pressure can be expected to peak at 3 to 6 days postpartum.
- Preconception and postpartum teaching for women at greater risk for preeclampsia should include attaining and keeping a healthy body mass index, ideal pregnancy intervals of >2 years and <10 years, and monitoring for other cardiovascular risk factors.
- Corticosteroids do not appear to alter the outcomes of HELLP, although improved platelet counts may prevent excessive bleeding.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Describe how the strength and relevance of available evidence influence the choice of interventions in providing patient-centered care.

Calcium supplements in pregnancy decrease the risk of preeclampsia.

Skills

Read original research and evidence reports related to area of practice.

Systematic analyses confirm the benefits of $MgSO_4$ for improving outcomes for women with eclampsia and preeclampsia.

Attitudes

Value the need for continuous improvement in clinical practice based on new knowledge.

Synthesize the best preventive evidence for patient preconception and postpartum teaching.

BOX 12-4 CARE OF THE WOMAN WITH PREECLAMPSIA RECEIVING MAGNESIUM SULFATE

Patient and Family Teaching

- Explain technique, rationale, and reactions to expect:
  - Route and rate
  - Purpose of "piggyback" infusion
- Reasons for use:
  - Tailor information to woman's readiness to learn.
  - Explain that magnesium sulfate is used to prevent disease progression.
  - Explain that magnesium sulfate is used to prevent seizures, *not* to decrease blood pressure.
- Reactions to expect from medication:
  - Initially the woman appears flushed and feels hot, sedated, and nauseated. She may experience burning at the IV site, especially during the bolus.
  - Sedation continues.
- Monitoring to anticipate:
  - *Maternal:* Blood pressure, pulse, respiratory rate, DTRs, level of consciousness, urine output (indwelling catheter), presence of headache, visual disturbances, epigastric pain
  - *Fetal:* FHR and activity

Administration

- Verify physician's order.
- Position woman in side-lying position.
- Prepare solution and administer with an infusion control device (pump).
- Piggyback solution of 40 g of magnesium sulfate in 1000 mL lactated Ringer's solution with infusion control device at the ordered rate: loading dose—initial bolus of 4 to 6 g over 15 to 30 min; maintenance dose—2 g/hr, according to unit protocol or specific physician's order.

Maternal and Fetal Assessments

Vital signs and assessments are performed as ordered by the health care provider and per hospital protocol.

- Monitor blood pressure, pulse, respiratory rate every 15 to 30 minutes, depending on woman's condition.
- Monitor FHR and contractions continuously.
- Monitor intake and output, proteinuria, DTRs, presence of headache, visual disturbances, level of consciousness, and epigastric pain at least hourly.
- Restrict hourly fluid intake to a total of no more than 125 mL/hr; urinary output should be at least 25 to 30 mL/hr.

Reportable Conditions

- Blood pressure: systolic ≥160 mm Hg or diastolic ≥110 mm Hg
- Respiratory rate: <12 breaths/min
- Urinary output: <25 to 30 mL/hr
- Presence of headache, visual disturbances, decrease in level of consciousness, or epigastric pain
- Increasing severity or loss of DTRs, increasing edema, proteinuria
- Any abnormal laboratory values (magnesium level, platelet count, creatinine clearance, levels of uric acid, AST, ALT, prothrombin time, partial thromboplastin time, fibrinogen, fibrin split products)
- Any other significant change in maternal or fetal status

Emergency Measures

- Keep emergency drugs and intubation equipment immediately available.
- Keep side rails up.
- Keep lights dimmed and maintain a quiet environment.

Documentation

- All of the above

ALT, Alanine aminotransferase; *AST,* aspartate aminotransferase; *DTR,* deep tendon reflex; *FHR,* fetal heart rate; *IV,* intravenous.

Increasing toxicity may be indicated by maternal hypotension, bradycardia, bradypnea, and cardiac arrest (Gilbert, 2011). Blood can be drawn to determine precisely the serum magnesium level if mild or severe toxicity is suspected (Box 12-4).

MEDICATION ALERT

If magnesium toxicity is suspected, prompt actions are needed to prevent respiratory or cardiac arrest. The magnesium infusion should be discontinued immediately. Calcium gluconate or calcium chloride (antidotes for magnesium sulfate) can be given intravenously (Cunningham, Leveno, Bloom, et al., 2010).

Magnesium sulfate does not seem to affect the FHR in a healthy term fetus. Doses of magnesium sulfate that prevent maternal seizures have been determined to be safe for the fetus. Neonatal serum magnesium levels approximate the levels of the mother (Roberts and Funai, 2009).

MEDICATION ALERT

Magnesium sulfate is considered a high-alert medication because it can cause patient harm when administered incorrectly. Measures to improve the safe use of this medication include developing detailed policies, procedures, protocols, and standing orders and thorough assessment and documentation. *Never* abbreviate magnesium sulfate as $MgSO_4$ anywhere in the medical record (Institute for Safe Medication Practices [ISMP], 2012).

Control of Blood Pressure. Antihypertensive medications are indicated when the systolic BP exceeds 160 mm Hg or the diastolic BP exceeds 110 mm Hg. Maternal risks associated with severe hypertension include left ventricular failure, cerebral hemorrhage, and placental abruption. To maintain uteroplacental perfusion, antihypertensive therapy must not decrease the arterial pressure too much or too rapidly. Hydralazine, labetalol, and nifedipine are effective drugs for treating hypertension intrapartum. They may also be used during pregnancy or in the postpartum period for BP control (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011; Harvey and Sibai, 2013). Table 12-5 compares antihypertensive agents often used to treat hypertension in pregnancy.

Postpartum Care

Throughout the postpartum period the woman needs careful monitoring of her vital signs, intake and output, DTRs, and level of consciousness. The magnesium sulfate infusion is continued after birth for seizure prophylaxis as ordered, usually for 12 to 24 hours. Assessments for effects and side effects continue until the medication is discontinued. Given that magnesium sulfate potentiates the action of narcotics, CNS depressants, and calcium channel blockers, these medications must be administered with caution.

Most women with gestational hypertension become normotensive during the first week after giving birth. On the other hand, hypertension may take longer to resolve in women with preeclampsia. Women with severe gestational hypertension or severe

TABLE 12-5 PHARMACOLOGIC CONTROL OF HYPERTENSION IN PREGNANCY

ACTION	TARGET TISSUE	MATERNAL EFFECTS	FETAL EFFECTS	NURSING ACTIONS
Hydralazine (Apresoline, Neopresol)				
Arteriolar vasodilator	Peripheral arterioles: to decrease muscle tone, decrease peripheral resistance; hypothalamus and medullary vasomotor center for minor decrease in sympathetic tone	Headache, flushing, palpitations, tachycardia, some decrease in uteroplacental blood flow, increase in heart rate and cardiac output, increase in oxygen consumption, nausea and vomiting	Tachycardia; late decelerations and bradycardia if maternal diastolic pressure <90 mm Hg	Assess for effects of medication; alert woman (family) to expected effects of medication; assess blood pressure frequently because precipitous drop can lead to shock and perhaps placental abruption; if giving multiple doses, wait at least 20 minutes after the first dose is given to administer an additional dose to allow time to assess the effects of the initial dose; assess urinary output; maintain bed rest in lateral position with side rails up; use with caution in presence of maternal tachycardia.
Labetalol Hydrochloride (Normodyne, Trandate)				
Combined alpha- and beta-blocking agent causing vasodilation without significant change in cardiac output	Peripheral arterioles (see hydralazine)	Minimal: flushing, tremulousness, orthostatic hypotension; minimal change in pulse rate	Minimal, if any	See hydralazine; less likely to cause excessive hypotension and tachycardia; less rebound hypertension than hydralazine. Do not use in women with asthma or heart failure. Do not exceed 80 mg in a single dose.
Methyldopa (Aldomet)				
Maintenance therapy if needed: 250-500 mg orally every 8 hr (α_2-receptor agonist)	Postganglionic nerve endings: interferes with chemical neurotransmission to reduce peripheral vascular resistance; causes CNS sedation	Sleepiness, postural hypotension, constipation; rare: drug-induced fever in 1% of women and positive Coombs' test result in 20% of women	After 4 months of maternal therapy, positive Coombs' test result in infant	See hydralazine.
Nifedipine (Adalat, Procardia)				
Calcium channel blocker	Arterioles: to reduce systemic vascular resistance by relaxation of arterial smooth muscle	Headache, flushing; may interfere with labor	Minimal	See hydralazine. Avoid concurrent use with magnesium sulfate because skeletal muscle blockade can result. Do not administer sublingually.

CNS, Central nervous system.

preeclampsia are frequently discharged from the hospital on an antihypertensive medication such as labetalol or nifedipine. If this is the case, the BP needs to be checked frequently either at home or at the health care provider's office. Within a few weeks after birth antihypertensive medications often can be discontinued.

Remember, too, that severe preeclampsia or severe gestational hypertension may develop for the first time after birth. The nurse should assess the postpartum woman regularly for any symptoms of preeclampsia such as headaches, visual disturbances, or epigastric pain. Women should be taught to contact their health care provider or return to the hospital immediately if they notice any of these symptoms after discharge (Sibai, 2012).

Future Health Care

Women with severe preeclampsia have a significantly increased risk of developing severe preeclampsia in a future pregnancy. This risk is especially likely in women who initially developed it earlier (during the second trimester) in pregnancy (Sibai, 2012). Even if these women remain normotensive in a subsequent pregnancy, they may have a greater likelihood of an adverse pregnancy outcome such

as preterm birth, small-for-gestational-age infant, and perinatal death (Sibai, 2012).

Women with preeclampsia (especially early-onset and severe preeclampsia) also have an increased risk of developing chronic hypertension and cardiovascular disease later in life. These women are also more likely to have underlying renal disease (Sibai, 2012). The postpartum period provides an excellent opportunity to educate women about lifestyle changes that may decrease their risk for developing future health problems (Gilbert, 2011; Sibai, 2012).

Eclampsia

Eclampsia is usually preceded by premonitory signs and symptoms, including persistent headache, blurred vision, severe epigastric or right upper quadrant abdominal pain, and altered mental status. However, convulsions can appear suddenly and without warning in a seemingly stable woman with only minimal BP elevations (Sibai, 2012). The convulsions that occur in eclampsia are frightening to observe. Tonic contraction of all body muscles (seen as arms flexed, hands clenched, legs inverted) precedes the tonic-clonic convulsion. During this stage muscles alternately relax and contract. Respirations are halted and then begin again with long, deep, stertorous inhalations. Hypotension follows; and muscular twitching, disorientation, and amnesia persist for a while after the convulsion. The woman may also vomit or be incontinent of urine or stool.

Immediate Care

Nursing actions during a convulsion are directed toward ensuring a patent airway and patient safety (see Emergency box).

It is important to note the time of onset and duration of the seizure. Call for help but do not leave the bedside. Make certain that the side rails on the bed are raised; pad them with a folded blanket or pillow if possible. Women with eclampsia have been known to sustain fractures from falling out of bed during the seizure. Immediately after the convulsion, lower the head of the bed and turn the woman onto her side. This helps prevent aspiration of vomitus (Gilbert, 2011).

Nursing actions after a convulsion are directed toward maternal stabilization. First assess the status of the woman's airway, breathing, and pulse. Suction secretions from her glottis to clear the airway, insert an oral airway, and administer oxygen at 10 L/min by nonrebreather face mask. If an IV infusion is not in place, start one with an 18-gauge needle. If an IV line was in place before the seizure, it may have infiltrated and will need to be restarted immediately. As soon as IV access is obtained, administer magnesium sulfate as ordered (Gilbert, 2011).

If eclampsia develops after initiating magnesium sulfate therapy, additional magnesium sulfate should be administered. Magnesium sulfate is the drug of choice for treating eclamptic seizures and preventing repeated seizures. One of the advantages of magnesium sulfate over other antiseizure medications such as diazepam (Valium) is that it reduces the risk of aspiration because it does not depress the gag reflex (Harvey and Sibai, 2013).

A rapid assessment of uterine activity, cervical status, and fetal status is performed after the convulsion. During a convulsion the uterus becomes hypercontractile and hypertonic. As a result, the membranes may have ruptured, or the cervix may have dilated rapidly, and birth may be imminent. The FHR tracing may demonstrate bradycardia, late decelerations, minimal baseline variability, or any combination. These findings usually resolve soon after the convulsion ends and the woman's hypoxia is corrected (Sibai, 2012). Help the woman with hygiene and a change of linens and gown if needed.

EMERGENCY

Eclampsia

Tonic-Clonic Convulsion Signs

- Stage of invasion: 2-3 seconds, eyes fixed, twitching of facial muscles
- Stage of contraction: 15-20 seconds, eyes protrude and are bloodshot, all body muscles in tonic contraction
- Stage of convulsion: Muscles relax and contract alternately (clonic), respirations halted and then begin again with long, deep, stertorous inhalation; coma ensues

Intervention

- Keep airway patent: turn head to one side, place pillow under one shoulder or back if possible.
- Call for assistance. Do not leave bedside.
- Protect with padded side rails up.
- Observe and record convulsion activity.

After Convulsion

- Do not leave unattended until fully alert.
- Observe for postconvulsion confusion, coma, incontinence.
- Use suction as needed.
- Administer oxygen via nonrebreather face mask at 10 L/min.
- Start intravenous fluids and monitor for potential fluid overload.
- Give magnesium sulfate or other anticonvulsant drug as ordered.
- Insert indwelling urinary catheter.
- Monitor blood pressure, pulse, and respirations frequently until stabilized.
- Monitor fetal and uterine status.
- Expedite laboratory work as ordered to monitor kidney function, liver function, coagulation system, and drug levels.
- Provide hygiene and a quiet environment.
- Support and keep woman and family informed.
- Be prepared to assist with birth when woman is in stable condition.

NURSING ALERT

Immediately after a seizure a woman may be very confused and can be combative. Restraints may be necessary temporarily. Several hours may be needed for the woman to regain her usual level of mental functioning.

After stabilization of the woman and fetus, a decision is made regarding timing and method of birth. Eclampsia alone is not an indication for immediate cesarean birth. The route of birth (induction of labor versus cesarean birth) depends on maternal and fetal condition, fetal gestational age, presence of labor, and the cervical Bishop score. Regional anesthesia is not recommended for eclamptic women with coagulopathy or a platelet count less than 50,000/mm^3 (Sibai, 2012).

Chronic Hypertension

An increasing number of women who give birth have chronic hypertension, which affects approximately 4% to 5% of all pregnancies (Gilbert, 2011). Non-Hispanic black women are much more likely to have a pregnancy complicated by chronic hypertension than are women of other races or ethnicities. In 2010 the rate of chronic hypertension in non-Hispanic black women who gave birth (28.1) was more than double the rate of that reported in women of all races who gave birth (13.6) (Martin, Hamilton, Sutton, et al., 2012). In addition to race, other risk factors for chronic hypertension in

pregnancy are older age and obesity. As more women delay childbearing and are obese, the number of pregnancies complicated by chronic hypertension can be expected to increase (Sibai, 2012).

More than 90% of women with chronic hypertension have primary or essential hypertension. In the remaining 10% the hypertension is secondary to a medical condition such as renal or collagen disease (Harvey and Sibai, 2013). Chronic hypertension in pregnancy is associated with an increased incidence of placental abruption, superimposed preeclampsia, and increased perinatal mortality (threefold or fourfold). Fetal effects include intrauterine growth restriction (IUGR) and preterm birth (Cunningham, Leveno, Bloom, et al., 2010; Sibai, 2012).

Ideally the management of chronic hypertension in pregnancy begins before conception. An evaluation is performed to assess the cause and severity of the hypertension and the presence of any target organ damage (e.g., heart, eye, and kidney). Moreover, the woman should be encouraged to make lifestyle changes before conception such as smoking and alcohol cessation, participating in aerobic exercise, and losing weight if indicated. A diet that includes a maximum of 2.4 g sodium per day is recommended (Gilbert, 2011). These lifestyle modifications should continue throughout the pregnancy.

Based on the BP and presence of target organ damage, women with chronic hypertension are classified as either high or low risk for pregnancy complications. Antihypertensive medications are frequently discontinued before pregnancy in women with low risk chronic hypertension. This decreases the risk of fetal exposure to some medications (e.g., angiotensin-converting enzyme [ACE] inhibitors) that can be teratogenic (Harvey and Sibai, 2013). Women who are high risk are managed with antihypertensive medication and frequent assessments of maternal and fetal well-being. Methyldopa (Aldomet) is most often recommended for treating chronic hypertension in pregnancy. However, because it is rarely used for treating chronic hypertension in nonpregnant women, it may not be practical to switch medications because of pregnancy. Labetalol and nifedipine are other antihypertensive medications used during pregnancy (see Table 12-5). Women who are high risk are monitored closely, and the route and timing of the birth depend on the maternal and fetal status. After giving birth the woman should be monitored closely for complications such as pulmonary edema, hypertensive encephalopathy, and renal failure. Women with chronic hypertension can breastfeed if they desire. All antihypertensive medications are present to some degree in breast milk. Levels of methyldopa in breast milk appear to be low and are considered safe. Labetalol also has a low concentration in breast milk. Little is known about the transfer of calcium channel blockers such as nifedipine in breast milk, but no apparent side effects have been noted in infants (Sibai, 2012).

HYPEREMESIS GRAVIDARUM

Nausea and vomiting complicate as many as 80% of all pregnancies, typically beginning at 4 weeks of gestation. These symptoms are usually confined to the first 20 weeks of gestation (Kelly and Savides, 2009). Although nausea and vomiting are distressing, they are typically benign, with no significant metabolic alterations or risks to the mother or fetus. The cause of nausea and vomiting in pregnancy is not well understood, although it may involve relaxation of the smooth muscle of the stomach and increasing levels of estrogen, progesterone, and human chorionic gonadotropin (hCG). Pregnancies complicated by nausea and vomiting generally have a more favorable outcome than those without these symptoms (Gordon, 2012; King and Murphy, 2009).

When vomiting during pregnancy becomes excessive enough to cause weight loss, electrolyte imbalance, nutritional deficiencies, and ketonuria, the disorder is termed **hyperemesis gravidarum.** This disorder occurs in approximately 0.5% of all live births. Hyperemesis gravidarum usually begins during the first trimester, but approximately 10% of women with the disorder continue to have symptoms throughout the pregnancy (Kelly and Savides, 2009). Hyperemesis gravidarum is the second most common reason for hospitalization during pregnancy in the United States (King and Murphy, 2009).

Risk factors for the condition include clinical hyperthyroid disorders, prepregnancy psychiatric diagnosis, previous pregnancy complicated by hyperemesis gravidarum, molar pregnancy, multiple gestation with a male and female fetus, diabetes, and gastrointestinal disorders (King and Murphy, 2009). For unknown reasons women carrying a female fetus are more likely than those carrying a male fetus to develop hyperemesis (Cunningham, Leveno, Bloom, et al., 2010; Kelly and Savides, 2009). A family history of hyperemesis may also be present (Gilbert, 2011; King and Murphy, 2009). Women 30 years of age and older and women who smoke have a lower risk of hyperemesis (King and Murphy, 2009).

Complications accompanying severe hyperemesis gravidarum include esophageal rupture and deficiencies of vitamin K and thiamine with resulting Wernicke encephalopathy (CNS involvement) (Cunningham, Leveno, Bloom, et al., 2010; Kelly and Savides, 2009). Fetal and neonatal complications include small-for-gestational-age fetuses, low birth weight, prematurity, and 5-minute Apgar scores less than 7 (Kelly and Savides, 2009).

Etiology

The cause of hyperemesis gravidarum remains obscure. Several theories have been proposed as to the cause, although none of them adequately explains the disorder. It may be related to high levels of estrogen or hCG or associated with transient hyperthyroidism during pregnancy. Gastric dysrhythmias, esophageal reflux, and reduced gastric motility may also contribute to the development of hyperemesis gravidarum (Kelly and Savides, 2009).

Psychosocial, cultural, and psychogenic factors may play a part in the development of hyperemesis gravidarum for some women (King and Murphy, 2009). Conflicting feelings regarding prospective motherhood, body changes, and lifestyle alterations may contribute to episodes of vomiting, particularly if these feelings are excessive or unresolved. Women with associated psychosocial factors usually improve dramatically while in the hospital but may resume vomiting after discharge (Cunningham, Leveno, Bloom, et al., 2010).

Clinical Manifestations

The woman with hyperemesis gravidarum usually has significant weight loss and dehydration. She may have dry mucous membranes, decreased BP, increased pulse rate, and poor skin turgor. Frequently she is unable to keep down even clear liquids taken by mouth. Laboratory tests may reveal electrolyte imbalances.

Management

Assessment

Whenever a pregnant woman has nausea and vomiting, the first priority is a thorough assessment to determine the severity of the problem. In most cases the woman should be told to come immediately to the health care provider's office or the emergency department because the severity of the illness is often difficult to determine by telephone conversation.

The assessment should include frequency, severity, and duration of episodes of nausea and vomiting. If the woman reports vomiting,

the assessment should also include the approximate amount and color of the vomitus. Other symptoms such as diarrhea, indigestion, and abdominal pain or distention also are identified. The woman is asked to report any precipitating factors relating to the onset of her symptoms. Any pharmacologic or nonpharmacologic treatment measures used should be recorded. Prepregnancy weight and documented weight gain or loss during pregnancy are important to note.

The woman's weight and vital signs are measured; and a complete physical examination is performed, with attention to signs of fluid and electrolyte imbalance and nutritional status. The most important initial laboratory test to be obtained is a determination of ketonuria. Other laboratory tests that may be ordered are a urinalysis, a complete blood cell count, electrolytes, liver enzymes, and bilirubin levels. These tests help rule out the presence of underlying diseases such as gastroenteritis, pyelonephritis, pancreatitis, cholecystitis, peptic ulcer, and hepatitis (Cunningham, Leveno, Bloom, et al., 2010). Because of the recognized association between hyperemesis gravidarum and hyperthyroidism, thyroid levels may also be measured (Nader, 2009).

Psychosocial assessment includes asking the woman about anxiety, fears, and concerns related to her own health and the effects on pregnancy outcome. Family members should be assessed both for anxiety and their role in providing support for the woman.

Initial Care

Initially the woman who is unable to keep down clear liquids by mouth requires IV therapy for correction of fluid and electrolyte imbalances. In the past women requiring IV therapy were admitted to the hospital. However, today they may be and often are successfully managed at home, even if on enteral therapy. Medications may be used if nausea and vomiting are uncontrolled. The ACOG recommends the use of pyridoxine (vitamin B_6), either alone or in combination with doxylamine (Unisom) as initial medical management because these medications are considered to be safe and effective (Gordon, 2012). Other frequently prescribed drugs include promethazine (Phenergan), chlorpromazine (Thorazine), prochlorperazine (Compazine), metoclopramide (Reglan), and ondansetron (Zofran) (Gordon, 2012; Kelly and Savides, 2009). Corticosteroids (methylprednisolone [Medrol] or hydrocortisone) may be prescribed, although there is little evidence that their use is effective (Cunningham, Leveno, Bloom, et al., 2010). Finally, enteral or parenteral nutrition may be used for women who are nonresponsive to other medical therapies (Kelly and Savides, 2009). Because of potential risks, parenteral therapy should only be used after multiple medical management and enteral tube feeding attempts have been unsuccessful (Gordon, 2012).

Nursing care of the woman with hyperemesis gravidarum involves implementing the medical plan of care, whether it is given in the hospital or home setting. Interventions may include initiating and monitoring IV therapy, administering drugs and nutritional supplements, and monitoring the woman's response to interventions. The nurse observes the woman for any signs of complications such as metabolic acidosis (secondary to starvation), jaundice, or hemorrhage and alerts the health care provider should these occur. Monitoring includes assessment of the woman's nausea, retching without vomiting, and vomiting, given that these symptoms, although related, are separate. Intake and output, including the amount of emesis, should be measured accurately and recorded. Oral hygiene while the woman is receiving nothing by mouth and after episodes of vomiting helps allay associated discomforts. Assistance with positioning and providing a quiet, restful environment that is free from odors may increase the woman's comfort.

PATIENT TEACHING

Diet for Hyperemesis

- Avoid an empty stomach. Eat frequently, at least every 2 to 3 hours. Separate liquids from solids and alternate every 2 to 3 hours.
- Eat a high-protein snack at bedtime.
- Eat dry, bland, low-fat, and high-protein foods. Cold foods may be better tolerated than those served at a warm temperature.
- In general eat what sounds good to you rather than trying to balance your meals.
- Follow the salty and sweet approach; even so-called junk foods are okay.
- Eat protein after sweets.
- Dairy products may stay down more easily than other foods.
- If you vomit even when your stomach is empty, try sucking on a Popsicle.
- Try ginger tea. Peel and finely dice a knuckle-sized piece of ginger and place it in a mug of boiling water. Steep for 5 to 8 minutes and add brown sugar to taste.
- Try warm ginger ale (with sugar, not artificial sweetener) or water with a slice of lemon.
- Drink liquids from a cup with a lid.

Once the vomiting has stopped, feedings are started in small amounts at frequent intervals. In the beginning limited amounts of oral fluids and bland foods such as crackers, toast, or baked chicken are offered. The diet progresses slowly as tolerated by the woman until she is able to consume a nutritionally sound diet. Because sleep disturbances may accompany hyperemesis gravidarum, promoting adequate rest is important. The nurse can help coordinate treatment measures and periods of visitation to provide opportunity for rest periods.

Follow-up Care

Most women are able to take nourishment by mouth after several days of treatment. They should be encouraged to eat small, frequent meals and foods that sound appealing (e.g., nongreasy, dry, sweet, and salty foods). In many instances women discover that foods they normally like have no appeal at all during this time. See the Patient Teaching box for more suggestions. Many pregnant women find exposure to cooking odors nauseating. Having other family members cook may lessen the woman's nausea and vomiting, even if only temporarily. The woman is counseled to contact her health care provider immediately if the nausea and vomiting recur.

The woman with hyperemesis gravidarum needs calm, compassionate, and sympathetic care, with recognition that the manifestations of hyperemesis can be physically and emotionally debilitating to her and stressful for her family. Irritability, tearfulness, and mood changes are often consistent with this disorder. Fetal well-being is a primary concern of the woman. The nurse can provide an environment conducive to discussion of concerns and help the woman identify and mobilize sources of support. The family should be included in the plan of care whenever possible. Their participation may help alleviate some of the emotional stress associated with this disorder.

HEMORRHAGIC DISORDERS

Bleeding in pregnancy may jeopardize maternal and fetal well-being. Maternal blood loss decreases oxygen-carrying capacity, which

places the woman at increased risk for hypovolemia, anemia, infection, and preterm labor and adversely affects oxygen delivery to the fetus. Fetal risks from maternal hemorrhage include blood loss or anemia, hypoxemia, hypoxia, anoxia, and preterm birth. Hemorrhagic disorders in pregnancy are medical emergencies. The incidence and type of bleeding vary by trimester. Ruptured ectopic pregnancy and abruptio placentae (placental abruption) have the highest incidence of maternal mortality. Prompt assessment and intervention by the health care team are essential to save the lives of both the woman and her fetus.

Early Pregnancy Bleeding

Bleeding during early pregnancy is alarming to the woman and of concern to health care providers. The common bleeding disorders of early pregnancy include miscarriage (spontaneous abortion), reduced cervical competence (premature dilation of the cervix), ectopic pregnancy, and hydatidiform mole (molar pregnancy).

Miscarriage (Spontaneous Abortion)

A pregnancy that ends as a result of natural causes before 20 weeks of gestation is defined as a miscarriage (spontaneous abortion). This 20-week marker is considered to be the point of viability when a fetus may survive in an extrauterine environment. A fetal weight less than 500 g also may be used to define an abortion (Cunningham, Leveno, Bloom, et al., 2010). The term *miscarriage* is used throughout this discussion because it is more appropriate than abortion to use with patients. Abortion may be perceived as an insensitive term to use with families who are grieving a pregnancy loss. Therapeutic or elective induced abortion is discussed in Chapter 5.

Incidence and Etiology. Of all clinically recognized pregnancies, 10% to 15% end in miscarriage (Simpson and Jauniaux, 2012). The majority—more than 80% of miscarriages—are early pregnancy losses, occurring before 12 weeks of gestation (Cunningham, Leveno, Bloom, et al., 2010). Of all clinically recognized pregnancy losses, at least 50% result from chromosomal abnormalities (Cunningham, Leveno, Bloom, et al., 2010; Simpson and Jauniaux, 2012). Other possible causes of early miscarriage include endocrine imbalance (as in women who have luteal phase defects, hypothyroidism, or insulin-dependent diabetes mellitus with high blood glucose levels in the first trimester), immunologic factors (e.g., antiphospholipid antibodies), systemic disorders (e.g., lupus erythematosus), and genetic factors. Infections are not a common cause of early miscarriage (Cunningham, Leveno, Bloom, et al., 2010), but there is an increased risk for a spontaneous abortion with varicella infection in the first trimester (Gilbert, 2011).

A late miscarriage, sometimes called a *second-trimester loss*, occurs between 12 and 20 weeks of gestation. It usually results from maternal causes such as advancing maternal age and parity; premature dilation of the cervix and other anomalies of the reproductive tract; inadequate nutrition; tobacco, alcohol, and caffeine use (Cunningham, Leveno, Bloom, et al., 2010); obesity; and stressful life events (Gilbert, 2011). Little can be done to prevent genetically caused pregnancy loss, but correction of maternal disorders, a healthy lifestyle, adequate early prenatal care, and treatment of pregnancy complications can do much to prevent other causes of miscarriage.

Types. The types of miscarriage include threatened, inevitable, incomplete, complete, and missed. All types of miscarriage can recur in subsequent pregnancies. All types except the threatened miscarriage can lead to infection (Fig. 12-6).

Clinical Manifestations. Signs and symptoms of miscarriage depend on the duration of pregnancy. The presence of uterine bleeding, uterine contractions, or abdominal pain is an ominous

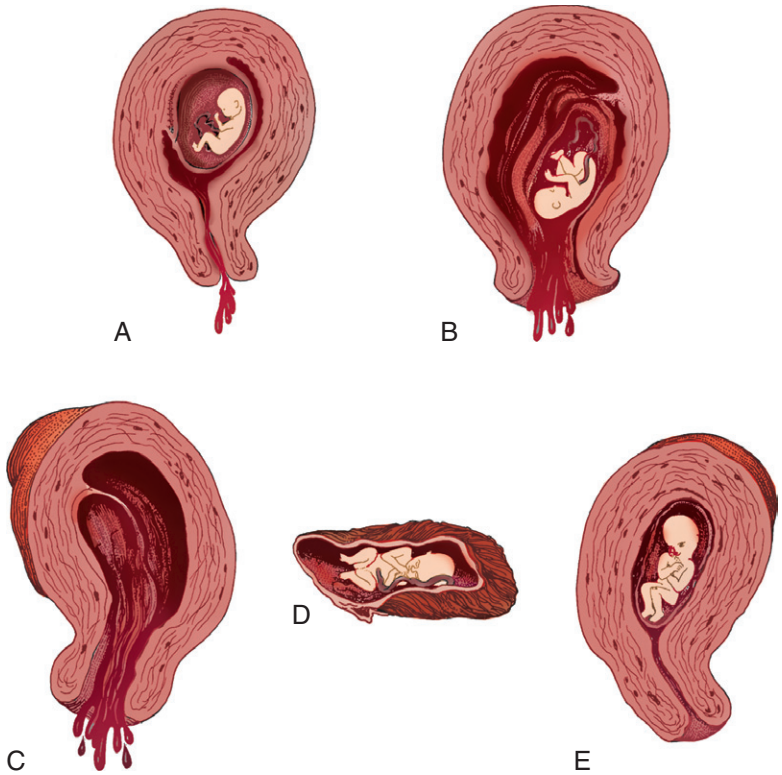

FIG 12-6 Miscarriage. **A,** Threatened. **B,** Inevitable. **C,** Incomplete. **D,** Complete. **E,** Missed.

sign during early pregnancy and must be considered a threatened miscarriage until proven otherwise.

If miscarriage occurs before the sixth week of pregnancy, the woman may report what she believes to be a heavy menstrual flow. Miscarriage that occurs between weeks 6 and 12 of pregnancy causes moderate discomfort and blood loss. After week 12 miscarriage is typified by severe pain similar to that of labor because the fetus must be expelled. Diagnosis of the type of miscarriage is based on the signs and symptoms present (Table 12-6).

Symptoms of a *threatened* miscarriage (see Fig. 12-6, *A*) include spotting of blood but with the cervical os closed. Mild uterine cramping may be present.

TABLE 12-6 ASSESSING MISCARRIAGE AND THE USUAL MANAGEMENT

TYPE OF MISCARRIAGE	AMOUNT OF BLEEDING	UTERINE CRAMPING	PASSAGE OF TISSUE	CERVICAL DILATION	MANAGEMENT
Threatened	Slight, spotting	Mild	No	No	Bed rest is often ordered but has not proven to be effective in preventing progression to actual miscarriage. Repetitive transvaginal ultrasounds and assessment of human chorionic gonadotropin and progesterone levels may be done to determine if the fetus is still alive and in the uterus. Further treatment depends on whether progression to actual miscarriage occurs.
Inevitable	Moderate	Mild to severe	No	Yes	Bed rest if no pain, fever, or bleeding. If rupture of membranes, bleeding, pain, or fever is present, the uterus is emptied promptly, usually by dilation and curettage.
Incomplete	Heavy, profuse	Severe	Yes	Yes, with tissue in cervix	May or may not require additional cervical dilation before curettage. Suction curettage may be performed.
Complete	Slight	Mild	Yes	No (cervix has already closed after tissue passed)	No further intervention may be needed if uterine contractions are adequate to prevent hemorrhage and no infection is present. Suction curettage may be performed to ensure no retained fetal or maternal tissue.
Missed	None, spotting	None	No	No	If spontaneous evacuation of the uterus does not occur within 1 month, the uterus is emptied by a method appropriate for the gestational age. Blood clotting factors are monitored until uterus is empty. Disseminated intravascular coagulation and incoagulability of blood with uncontrolled hemorrhage may develop in cases of fetal death after the twelfth week if products of conception are retained for longer than 5 weeks. May be treated with dilation and curettage, or misoprostol (Cytotec) given orally or vaginally.
Septic	Varies, usually malodorous	Varies	Varies	Yes, usually	The uterus is immediately emptied by a method appropriate for the gestational age. Cervical culture and sensitivity studies are performed, and broad-spectrum antibiotic therapy (e.g., ampicillin) is started. Treatment for septic shock is initiated if necessary.
Recurrent (generally defined as three or more consecutive miscarriages)	Varies	Varies	Yes	Yes, usually	Varies; depends on type. Prophylactic cerclage may be performed if premature cervical dilation is the cause. Tests of value include parental cytogenetic analysis and lupus anticoagulant and anticardiolipin antibody assays on the woman.

Data from Cunningham F, Leveno K, Bloom S, et al, editors: *Williams obstetrics*, ed 23, New York, 2010, McGraw-Hill; Gilbert ES: *Manual of high risk pregnancy and delivery*, ed 5, St Louis, 2011, Mosby.

Inevitable (see Fig. 12-6, *B*) and *incomplete* (see Fig. 12-6, *C*) miscarriages involve a moderate-to-heavy amount of bleeding with an open cervical os. Tissue may be present with the bleeding. Mild-to-severe uterine cramping may be present. An inevitable miscarriage is often accompanied by rupture of membranes (ROM) and cervical dilation. Passage of the products of conception occurs. An incomplete miscarriage involves the expulsion of the fetus with retention of the placenta.

In a *complete* miscarriage (see Fig. 12-6, *D*) the cervix has already closed after all fetal tissue was expelled. Slight bleeding may occur, and mild uterine cramping may also be present.

The term *missed* miscarriage (see Fig. 12-6, *E*) refers to a pregnancy in which the fetus has died but the products of conception are retained in utero for up to several weeks. It may be diagnosed by ultrasound examination after the uterus stops increasing or even decreases in size. There may be no bleeding or cramping, and the cervical os remains closed.

Recurrent early (habitual) miscarriage is three or more spontaneous pregnancy losses before 20 weeks of gestation. The causes of recurrent miscarriage are the same as those discussed earlier in this section. Another possible cause of recurrent pregnancy loss is parental chromosomal abnormalities. The evaluation of couples experiencing recurrent pregnancy loss usually includes karyotyping of both partners, evaluating the woman's uterine cavity, and testing for antiphospholipid antibody syndrome. No cause can be identified in approximately half of all couples who experience recurrent pregnancy loss. However, 60% to 70% of these couples will go on to have a successful pregnancy with no treatment (Cunningham, Leveno, Bloom, et al., 2010).

Miscarriages can become septic, although this is uncommon. Symptoms of a septic miscarriage include fever and abdominal tenderness. Vaginal bleeding, which may be slight to heavy, is usually malodorous.

Management

Initial Care. Management depends on the classification of the miscarriage and signs and symptoms (see Table 12-6). Traditionally threatened miscarriages have been managed expectantly with supportive care. However, there are no proven effective therapies for this condition. Although bed rest is often prescribed, it does not prevent progression to actual miscarriage. Repetitive transvaginal ultrasounds and measurement of hCG and progesterone levels may be performed to determine if the fetus is alive and within the uterus (Cunningham, Leveno, Bloom, et al., 2010).

Follow-up treatment depends on whether the threatened miscarriage progresses to actual miscarriage or symptoms subside and the pregnancy remains intact. If bleeding and infection do not occur, expectant management is a reasonable option. In approximately half of all threatened miscarriages managed in this way, the pregnancy continues (Cunningham, Leveno, Bloom, et al., 2010).

Once the cervix begins to dilate, the pregnancy cannot continue, and miscarriage becomes inevitable. If all the products of conception are passed, no surgical intervention is necessary. However, if heavy bleeding, excessive cramping, or infection is present, the remaining embryonic, fetal, or placental tissue must be removed from the uterus, usually by suction curettage. In women who are clinically stable, expectant management to allow spontaneous resolution of an incomplete miscarriage is another treatment option (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011).

Most missed miscarriages eventually end spontaneously. Women may be offered expectant management at the time the pregnancy loss is diagnosed. Expectant management results in eventual spontaneous miscarriage in 16% to 76% of cases (Gilbert, 2011).

Medical management is another treatment option if bleeding and infection are not present. Prostaglandin medications (e.g., misoprostol [Cytotec]) may be given orally or vaginally and are usually effective in completing the miscarriage within 7 days (Cunningham, Leveno, Bloom, et al., 2010). If medical management is chosen, nursing care is similar to the care for any woman whose labor is being induced (see Chapter 17). Special care may be needed for management of side effects of prostaglandin such as nausea, vomiting, and diarrhea. If the products of conception are not passed completely, the woman may be prepared for manual or surgical evacuation of the uterus.

A third management option, and one that is often chosen, is **dilation and curettage (D&C),** a surgical procedure in which the cervix is dilated and a suction curette is inserted to scrape the uterine walls and remove uterine contents (Cunningham, Leveno, Bloom, et al., 2010). Before a surgical procedure is performed, a full history should be obtained, and general and pelvic examinations conducted. General preoperative and postoperative care is appropriate for the woman requiring surgical intervention for miscarriage. Analgesics and anesthesia that are appropriate to the procedure are used. The nurse reinforces explanations, answers any questions or concerns, and prepares the woman for surgery.

After evacuation of the uterus, oxytocin is often given to prevent hemorrhage. For excessive bleeding after the miscarriage, ergot products such as ergonovine (Methergine) or a prostaglandin derivative such as carboprost tromethamine (Hemabate) may be given to contract the uterus. (See the Medication Guide: Drugs Used To Manage Postpartum Hemorrhage, in Chapter 21.) Antibiotics are given as necessary. Analgesics such as antiprostaglandin agents (e.g., nonsteroidal antiinflammatory drugs [NSAIDs]) may decrease discomfort from cramping. Transfusion therapy may be required for shock or anemia. The woman who is Rh negative and is not isoimmunized is given $Rh_O(D)$ immunoglobulin (Cunningham, Leveno, Bloom, et al., 2010).

Psychosocial aspects of care focus on what the pregnancy loss means to the woman and her family. Grief from perinatal loss is complex and unique to each individual. Explanations are provided regarding the nature of the miscarriage, expected procedures, and possible future implications for childbearing.

As with other fetal or neonatal losses, the woman should be offered the option of seeing the products of conception. She may also want to know what the hospital does with the products of conception or whether she needs to make a decision about final disposition of fetal remains.

! NURSING ALERT

Procedures for disposition of the fetal remains vary from hospital to hospital and state to state. The nurse should know what the usual procedures are in his or her setting.

Follow-up Care. The woman will likely be discharged home within a few hours after a D&C or as soon as her vital signs are stable, vaginal bleeding remains minimal, and she has recovered from anesthesia. Discharge teaching emphasizes the need for rest. If significant blood loss has occurred, iron supplementation may be ordered. Teaching includes information about normal physical findings such as cramping, type and amount of bleeding, resumption of sexual activity, and family planning (see Patient Teaching box). Frequently the woman and her partner want to know when she should attempt to become pregnant again. Discuss with them the importance of completely resolving the loss before attempting

another pregnancy (Gilbert, 2011). Follow-up care should assess the woman's physical and emotional recovery. Referrals to local support groups should be provided as needed. Share Pregnancy and Infant Loss Support, Inc. (www.nationalshare.org) is an excellent online resource for families who have experienced an early pregnancy loss.

Follow-up telephone calls after a loss are important. The woman may appreciate a telephone call on what would have been her due date. These calls provide opportunities for the woman to ask questions, seek advice, and receive information to help process her grief (see Community Focus box).

Reduced Cervical Competence (Recurrent Premature Dilation of the Cervix)

One cause of late miscarriage is **reduced cervical competence (premature dilation of the cervix),** which has traditionally been defined as passive and painless dilation of the cervix during the second trimester. In the past this condition was called *cervical incompetence*. This definition assumed an all-or-nothing role for the cervix: it was either competent or incompetent. However, current thinking is that cervical competence varies and exists as a continuum that is determined in part by cervical length. Other related causative factors include composition of the cervical tissue and the individual circumstances associated with the pregnancy in terms of maternal stress and lifestyle. Iams (2009) and other high risk perinatal experts refer to this condition as *cervical insufficiency*.

Etiology. Etiologic factors include a history of previous cervical trauma such as lacerations during childbirth, excessive cervical dilation for curettage or biopsy, or ingestion of diethylstilbestrol (DES) by the woman's mother while pregnant with the woman. However, because DES has not been used since the early 1970s, this risk factor should soon be of only historic interest. Women who have had prior cervical surgery such as a biopsy in which a large cone specimen was removed or destroyed or who have had multiple prior cervical procedures are probably at risk for cervical insufficiency (Ludmir and Owen, 2012).

Diagnosis. Reduced cervical competence is a clinical diagnosis based on history. Short labors, recurring loss of the pregnancy at progressively earlier gestational ages, advanced cervical dilation at the time of first presentation for care, and a history of prior cervical surgery or trauma suggest reduced cervical competence (Iams, 2009). Ultrasound examination during pregnancy is used to diagnose this condition objectively. A short cervix (less than 25 mm) indicates reduced cervical competence. Often the short cervix is accompanied by cervical funneling (beaking) or effacement of the internal cervical os (Cunningham, Leveno, Bloom, et al., 2010; Iams, 2009; Ludmir and Owen, 2012).

Management. Medical management consists of bed rest, pessaries, antibiotics, antiinflammatory drugs, and progesterone supplementation (Iams, 2009). Surgical management with placement of a cervical **cerclage** may be chosen instead. During pregnancy the McDonald technique is often the procedure of choice. In this procedure suture is placed around the cervix beneath the mucosa to constrict the internal os of the cervix (Fig. 12-7) (Cunningham, Leveno, Bloom, et al., 2010). A cerclage may be placed prophylactically or as a rescue procedure once the cervix has been found to be effaced or dilated (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011).

A prophylactic cerclage is usually placed at 11 to 15 weeks of gestation. The cerclage is removed electively (usually in an office or as a clinic procedure) when the woman reaches 37 weeks of gestation, or it may be left in place until spontaneous labor begins. Occasionally the cerclage is left in place, and a cesarean birth performed. The best treatment for reduced cervical competence is uncertain at this time. Research results indicate that selective cerclage placement during pregnancy based on repeated ultrasound examination of the

PATIENT TEACHING

Discharge Teaching for the Woman After Early Miscarriage

- Clean the perineum after each voiding or bowel movement and change perineal pads often.
- Shower (avoid tub baths) for 2 weeks.
- Avoid tampon use, douching, and vaginal intercourse for 2 weeks.
- Notify health care provider if an elevated temperature or a foul-smelling vaginal discharge develops.
- Eat foods high in iron and protein to promote tissue repair and red blood cell replacement.
- Seek assistance from support groups, clergy, or professional counseling as needed.
- Allow yourself (and your partner) to grieve the loss before becoming pregnant again.

COMMUNITY FOCUS

Online Resources for Pregnancy-Related Bleeding Problems

- Visit the Miscarriage Support website (www.silentgrief.com), which provides assistance for families who have experienced the loss of a child by miscarriage. Review the information about the stages of grief and resources. What resources are available in your community for women who experience a perinatal loss?
- Visit the American Pregnancy Association website (www.americanpregnancy.org) and go to the pregnancy complications link. Select an antepartum hemorrhagic disorder such as miscarriage, ectopic pregnancy, molar pregnancy, placental abruption, or placenta previa and evaluate the accuracy and comprehensiveness of the information regarding causes, risk factors, symptoms, diagnosis, and treatment.

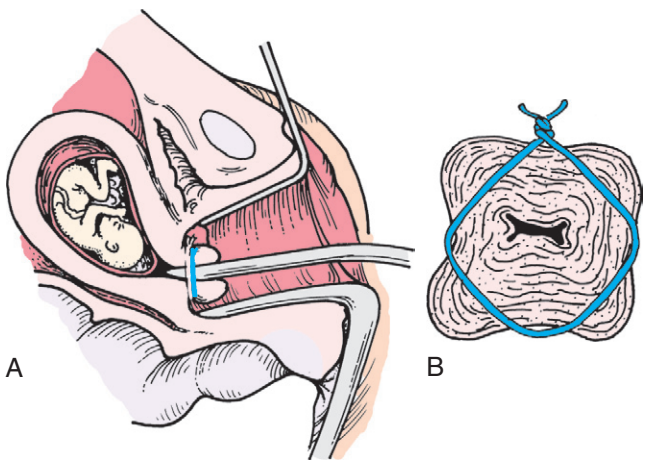

FIG 12-7 A, Cerclage correction of premature dilation of the cervical os. **B,** Cross-sectional view of closed internal os.

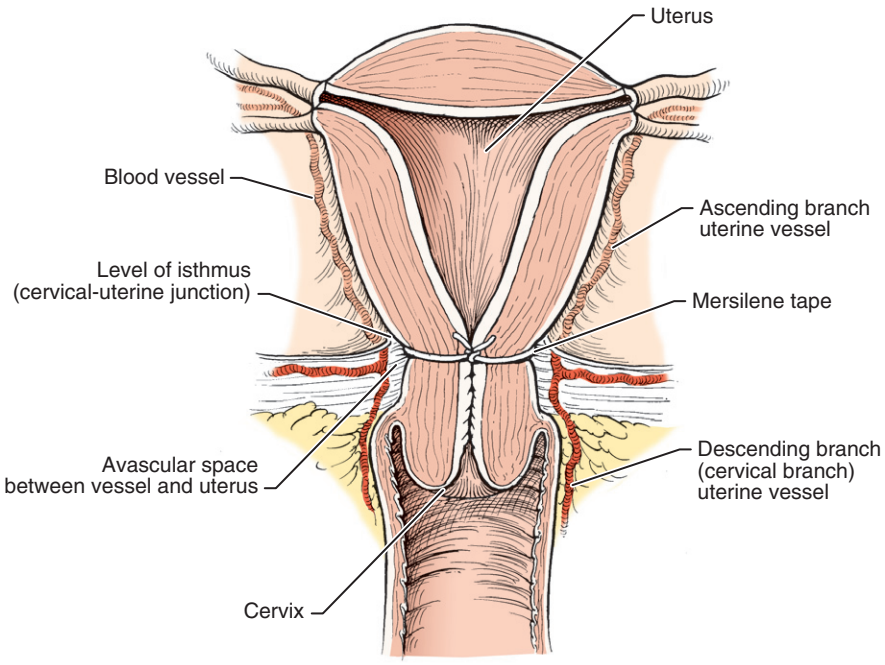

FIG 12-8 Abdominal cerclage. Surgical placement of circumferential Mersilene tape around uterine isthmus and median to uterine vessel. Knot is tied anteriorly. (From Gabbe S, Niebyl J, Simpson J, et al, editors: *Obstetrics: normal and problem pregnancies,* ed 6, Philadelphia, 2012, Saunders.)

cervix may produce pregnancy outcomes that are just as good as those obtained after prophylactic cerclage placement. Ultrasound surveillance begins at 15 to 16 weeks of gestation. Selective cerclage placement is offered if the cervical length decreases to less than 20 to 25 mm before 23 to 24 weeks (Iams, 2009). Risks of the procedure include premature ROM (PROM), preterm labor, and chorioamnionitis. Although no consensus has been reached, 24 weeks is often used as the upper gestational age limit for cerclage placement (Iams, 2009).

In women with an extremely short cervix such as those who were exposed prenatally to DES, who have a history of a large cone biopsy, or who have had a failed vaginal cerclage, an abdominal cerclage may be performed instead. This procedure is usually done at 11 to 13 weeks of gestation by means of a laparotomy. Suture (Mersilene tape) is placed at the junction of the lower uterine segment and the cervix (Fig. 12-8). Cesarean birth is necessary following an abdominal cerclage, and the suture is left in place if future pregnancies are desired. Although the procedure is usually done during pregnancy, it has been performed between pregnancies with subsequent positive pregnancy outcomes (Ludmir and Owen, 2012).

The nurse assesses the woman's feelings about her pregnancy and her understanding of reduced cervical competence. Evaluating her support systems is also important. Because the diagnosis of reduced cervical competence is usually not made until the woman has lost one or more pregnancies, she may feel guilty or to blame for this possible loss. Therefore assessing for previous reactions to stresses and appropriateness of coping responses is important. The woman needs the support of both her health care providers and her family.

Follow-up Care. The woman will likely be on bed rest for a least a few days immediately following cerclage placement. She will probably be advised to avoid sexual intercourse until after a postoperative check. Thereafter decisions about physical activity and intercourse are individualized based on the status of the woman's cervix as determined by digital and ultrasound examination (Ludmir and Owen, 2012). The woman must understand the importance of initial activity restriction at home and the need for close observation and supervision. Additional instruction includes the need to watch for and report signs of preterm labor, ROM, and infection. Finally the woman should know the signs that would warrant an immediate return to the hospital, including strong contractions less than 5 minutes apart, ROM, severe perineal pressure, and an urge to push. If management is unsuccessful and the fetus is born before viability, appropriate grief support should be provided. If the fetus is born prematurely, appropriate anticipatory guidance and support are necessary.

Ectopic Pregnancy

Incidence and Etiology. An **ectopic pregnancy** is one in which the fertilized ovum is implanted outside the uterine cavity (Fig. 12-9). Two percent of all first-trimester pregnancies in the United States are ectopic, and these account for 9% of all pregnancy-related maternal deaths. Women are less likely to have a successful subsequent pregnancy after an ectopic pregnancy (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011). Ectopic pregnancy is a leading cause of infertility.

Ectopic pregnancies are often called *tubal pregnancies* because approximately 95% are located in the uterine tube (Cunningham, Leveno, Bloom, et al., 2010). Although they are much less common, ectopic pregnancies can also occur in the abdominal cavity, on an ovary, or on the cervix. Of all tubal ectopic pregnancies, more than half (approximately 55%) are located in the ampulla, or largest portion of the tube (Gilbert, 2011).

The reported incidence of ectopic pregnancy rose through 1990 in the United States. Since then, because more cases are managed medically, reliable data on the actual number of ectopic pregnancies have not been available (Cunningham, Leveno, Bloom, et al., 2010). Some of the increased incidence is likely because of improved

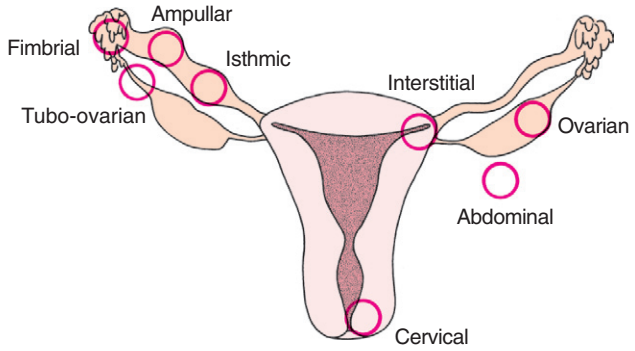

FIG 12-9 Sites of implantation of ectopic pregnancies. Order of frequency of occurrence is ampulla, isthmus, interstitium, fimbria, tubo-ovarian ligament, ovary, abdominal cavity, and cervix (external os).

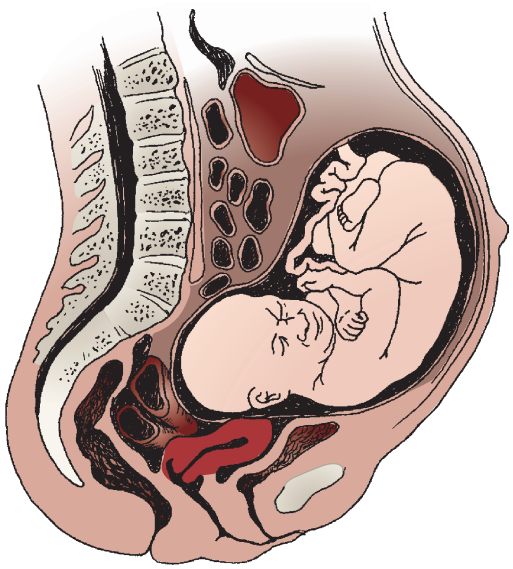

FIG 12-10 Ectopic pregnancy, abdominal.

diagnostic techniques such as more sensitive β-hCG measurement and transvaginal ultrasound, resulting in the identification of more cases. Other causes for the rise include an increased incidence of sexually transmitted infections, tubal infection and damage, popularity of contraceptive methods that predispose failures to be ectopic (e.g., the intrauterine device [IUD]), use of tubal sterilization methods that increase the chance of ectopic pregnancy, increased use of assisted reproductive techniques, and increased use of tubal surgery (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011).

Ectopic pregnancy is classified according to site of implantation (e.g., tubal, ovarian, or abdominal). The uterus is the only organ capable of containing and sustaining a term pregnancy. Only approximately 5% of abdominal pregnancies reach viability. However, surgery to remove the embryo or fetus is usually performed as soon as an abdominal pregnancy is identified because of the high risk for hemorrhage at any time during the pregnancy (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011). The chance of fetal survival in an abdominal pregnancy depends on gestational age at birth. The risk for fetal deformity in an abdominal pregnancy is high as a result of pressure deformities caused by oligohydramnios. The most common problems include facial or cranial asymmetry, various joint deformities, limb deficiency, and CNS anomalies (Fig. 12-10) (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011).

Clinical Manifestations. Most cases of ectopic (tubal) pregnancy are diagnosed before rupture based on the three most classic symptoms: (1) abdominal pain, (2) delayed menses, and (3) abnormal vaginal bleeding (spotting) that occurs approximately 6 to 8 weeks after the last normal menstrual period (Gilbert, 2011). Abdominal pain occurs in almost every case. It usually begins as a dull, lower-quadrant pain on one side. The discomfort can progress from a dull to a colicky pain when the tube stretches, to sharp, stabbing pain (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011). It progresses to a diffuse, constant, severe pain that is generalized throughout the lower abdomen (Gilbert, 2011). As many as 90% of women with an ectopic pregnancy report a period that is delayed 1 to 2 weeks or lighter than usual or an irregular period. Mild-to-moderate dark red or brown intermittent vaginal bleeding occurs in up to 80% of women (Gilbert, 2011).

If the ectopic pregnancy is not diagnosed until after rupture has occurred, referred shoulder pain may be present in addition to generalized, one-sided, or deep lower-quadrant acute abdominal pain. Referred shoulder pain results from diaphragmatic irritation caused by blood in the peritoneal cavity. The woman may exhibit signs of shock such as faintness and dizziness related to the amount of bleeding in the abdominal cavity and not necessarily related to obvious vaginal bleeding. An ecchymotic blueness around the umbilicus (Cullen sign) indicating hematoperitoneum may also develop in an undiagnosed, ruptured intraabdominal ectopic pregnancy.

Diagnosis. The differential diagnosis of ectopic pregnancy involves consideration of numerous disorders that share many signs and symptoms. Many of these women come to the emergency department experiencing first-trimester bleeding or pain. Miscarriage, ruptured corpus luteum cyst, appendicitis, salpingitis, ovarian cysts, torsion of the ovary, and UTI are possible diagnoses. The key to early detection of ectopic pregnancy is having a high index of suspicion for this condition. *Every* woman with abdominal pain, vaginal spotting or bleeding, and a positive pregnancy test should undergo screening for ectopic pregnancy.

The most important screening tools for ectopic pregnancy are quantitative β-hCG levels and transvaginal ultrasound examination. When β-hCG levels are greater than 1500 to 2000 milli-international units/mL, a normal intrauterine pregnancy should be visible on transvaginal ultrasound. Therefore, if β-hCG levels are greater than 1500 milli-international units/mL but no intrauterine pregnancy is seen on transvaginal ultrasound, an ectopic pregnancy is very likely. β-hCG levels will probably be redrawn every 48 hours to determine if the pregnancy is viable. A transvaginal ultrasound may also be repeated to determine if the pregnancy is inside the uterus. Sometimes the location of an ectopic pregnancy is visible on transvaginal ultrasound (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011).

Another laboratory test that can be ordered to decide if the pregnancy is developing normally is a progesterone level. A progesterone level >25 ng/mL almost always rules out the presence of an ectopic pregnancy. However, a level <5 ng/mL suggests either an ectopic or an abnormal intrauterine pregnancy (Cunningham, Leveno, Bloom, et al., 2010).

The woman should also be assessed for the presence of active bleeding, which is associated with tubal rupture. If internal bleeding is present, assessment may reveal vertigo, shoulder pain, hypotension, and tachycardia. A vaginal examination should be performed only once and then with great caution. Approximately 20% of

women with a tubal pregnancy have a palpable mass on examination. Rupturing the mass is possible during a bimanual examination; thus a gentle touch is critical.

Medical Management. Medical management involves giving methotrexate to dissolve the tubal pregnancy. Methotrexate is an antimetabolite and folic acid antagonist that destroys rapidly dividing cells. The woman must be hemodynamically stable to be eligible for medical management. The best results following methotrexate therapy are usually obtained if the mass is unruptured and measures less than 3.5 cm in diameter by ultrasound, if no fetal cardiac activity is noted on ultrasound, and if the serum β-hCG level is less than 5000 milli-international units/mL (Cunningham, Leveno, Bloom, et al., 2010). To be a candidate for medical management the woman must also be willing to comply with posttreatment lifestyle restrictions and monitoring.

MEDICATION ALERT

The woman on methotrexate therapy who drinks alcohol and takes vitamins containing folic acid (such as prenatal vitamins) increases her risk of having side effects of the drug or exacerbating the ectopic rupture.

Methotrexate therapy avoids surgery and is a safe, effective, and cost-effective way of managing many cases of tubal pregnancy. The woman is informed of how the medication works, possible side effects, who to call if she has concerns or if problems develop, and the importance of follow-up care (Box 12-5).

! NURSING ALERT

Women receiving methotrexate to treat an ectopic pregnancy should refrain from taking any analgesic stronger than acetaminophen. Stronger analgesics can mask symptoms of tubal rupture.

Surgical Management. Surgical management depends on the location and cause of the ectopic pregnancy, the extent of tissue involvement, and the woman's desires regarding future fertility. One option is removal of the entire tube (salpingectomy). If the tube has not ruptured and the woman desires future fertility, salpingostomy may be performed instead. In this procedure an incision is made over the pregnancy site in the tube, and the products of conception are gently and very carefully removed. The incision is not sutured but left to close by secondary intention, given that this method results in less scarring.

If surgery is planned, general preoperative and postoperative care is appropriate for the woman with an ectopic pregnancy. Before surgery vital signs (pulse, respirations, and BP) are assessed every 15 minutes or as needed, according to the severity of the bleeding and the woman's condition. Preoperative laboratory tests include determination of blood type and Rh status, complete blood cell count, and serum quantitative β-hCG level. Ultrasonography is used to confirm an extrauterine pregnancy. Blood replacement may be necessary. The nurse verifies the woman's Rh and antibody status and administers $Rh_o(D)$ immunoglobulin after surgery if appropriate.

Follow-up Care. The woman and her family should be encouraged to share their feelings and concerns related to the loss. Vaginal intercourse should be avoided until β-hCG levels indicate that the ectopic pregnancy has dissolved completely. This could require abstaining from sexual activity for several months. Abstinence is necessary because there is a small risk that the pelvic pressure associated with vaginal intercourse could rupture the mass. More important, intercourse causes pain similar to that experienced with impending or actual tubal rupture, making it difficult to easily identify the source of the pain. For future reference, every woman who has been diagnosed with an ectopic pregnancy should be instructed to contact her health care provider as soon as she suspects that she might be pregnant because of the increased risk for recurrent ectopic pregnancy. These women may need referral to grief or infertility support groups. In addition to the loss of the current pregnancy, they are faced with the possibility of future pregnancy losses or infertility.

BOX 12-5 NURSING CONSIDERATIONS FOR WOMEN UNDERGOING METHOTREXATE TREATMENT FOR ECTOPIC PREGNANCY

Administration

- Obtain woman's height and weight. These measurements are used to calculate the correct dose.
- Check to make sure that laboratory and diagnostic tests have been completed, including:
  - Complete blood cell count and blood type and Rh-antibody status.
  - Liver and renal function tests.
  - Serum beta–human chorionic gonadotropin (β-hCG) level (should be <5000 milli-international units/mL).
  - Transvaginal ultrasound confirming size of mass and absence of fetal cardiac activity.
- Administer methotrexate intramuscularly (IM). The usual dose is 50 mg/m^2, but it may also be ordered as 1 mg/kg.
- Administer Rho(D) immunoglobulin (150 mcg to 300 mcg IM as ordered if woman has Rh-negative blood).

Patient and Family Teaching

- Review how methotrexate works.
- Inform woman of possible side effects—gas pain, stomatitis and conjunctivitis are common; rare effects include pleuritis, gastritis, diarrhea, oral ulcers, dermatitis, alopecia, enteritis, increased liver enzymes, and bone marrow suppression.
- Advise woman to:
  - Discontinue folic acid supplements.
  - Avoid "gas-forming" foods.
  - Avoid sun exposure because the drug makes her more photosensitive.
  - Refrain from strenuous activities.
  - Avoid putting anything in her vagina—no tampons, douches, or vaginal intercourse.
  - Report to her health care provider immediately if she has severe abdominal pain, which may be a sign of impending or actual tubal rupture.

Follow-Up

- Have woman return to the clinic or office as instructed by her health care provider for measurement of β-hCG level.
- If β-hCG level does not drop appropriately, a second dose of methotrexate may be necessary.
- Advise woman that she will need to return to the clinic or office for weekly measurements of β-hCG until the level is less than 15 milli-international units/mL. Weekly follow-up visits may be required for several months until the desired β-hCG level is reached.

Hydatidiform Mole (Molar Pregnancy)

Hydatidiform mole (molar pregnancy) is a benign proliferative growth of the placental trophoblast in which the chorionic villi develop into edematous, cystic, avascular transparent vesicles that hang in a grapelike cluster. Hydatidiform mole is a **gestational trophoblastic disease (GTD).** GTD is a group of pregnancy-related trophoblastic proliferative disorders without a viable fetus that are caused by abnormal fertilization. In addition to hydatidiform mole, GTD includes invasive mole and choriocarcinoma (DiGiulio, Wiedaseck, and Monchek, 2012).

Incidence and Etiology. Hydatidiform mole occurs in 1 in 1000 pregnancies in the United States (Cohn, Ramaswamy, and Blum, 2009). The cause is unknown, although it may be related to an ovular defect or a nutritional deficiency. Women at increased risk for hydatidiform mole formation are those who have had a prior molar pregnancy and those who are in their early teens or older than 40 years of age (DiGiulio, Wiedaseck, and Monchek, 2012).

Types. A hydatidiform mole may be further categorized as a complete or partial mole. The complete mole results from fertilization of an egg in which the nucleus has been lost or inactivated (Fig. 12-11, *A*). The nucleus of a sperm (23,X) duplicates itself (resulting in the diploid number 46,XX) because the ovum has no genetic material or the material is inactive. It is also possible for an "empty" egg to be fertilized by two normal sperm, thereby producing either a 46,XX or 46,XY karyotype. The mole resembles a bunch of white grapes (see Fig. 12-11, *B*). The hydropic (fluid-filled) vesicles grow rapidly, causing the uterus to be larger than expected for the duration of the pregnancy. Usually the complete mole contains no fetus, placenta, amniotic membranes, or fluid (Fig. 12-12). Maternal blood has no placenta to receive it; therefore hemorrhage into the uterine cavity and vaginal bleeding occur. Approximately 15% to 20% of women with a complete mole have evidence of persistent GTD (Cunningham, Leveno, Bloom, et al., 2010).

For a partial mole chromosomal studies often show a karyotype of 69,XXY; 69,XXX; or rarely 69,XYY. This arrangement occurs as a result of two sperm fertilizing an apparently normal ovum (Fig. 12-13). Partial moles often have embryonic or fetal parts and an amniotic sac. Congenital anomalies are usually present. The risk of persistent GTD is much less than with a complete mole. If persistent

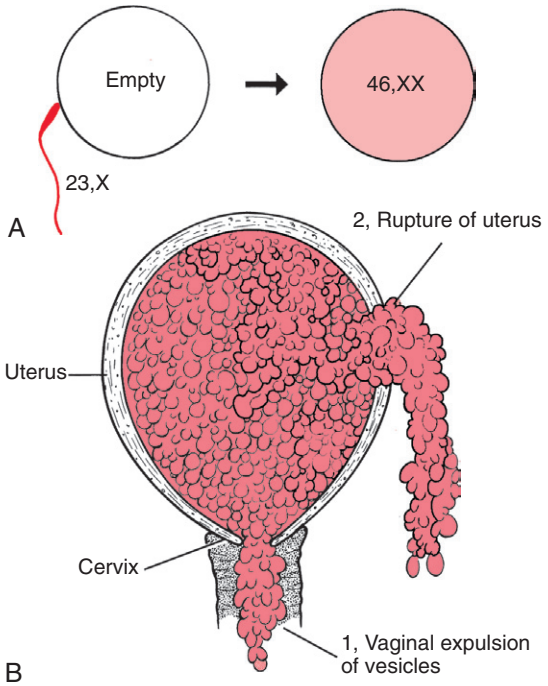

FIG 12-11 A, Chromosomal origin of complete mole. Single sperm *(color)* fertilizes an "empty" ovum. Reduplication of 23,X of sperm set gives completely homozygous diploid 46,XX. Similar process follows fertilization of empty ovum by two sperm with two independently drawn sets of 23,X or 23,Y; therefore both karyotypes of 46,XX and 46,XY can result. **B,** Uterine rupture with hydatidiform mole. *1,* Evacuation of mole through cervix. *2,* Rupture of uterus and spillage of mole into peritoneal cavity (rare).

FIG 12-12 Gross specimen in a woman treated for complete hydatidiform mole with primary hysterectomy. (Courtesy John Soper, MD. From DiSaia PJ, Creasman WT: *Clinical gynecologic oncology*, ed 8, Philadelphia, 2012, Mosby.)

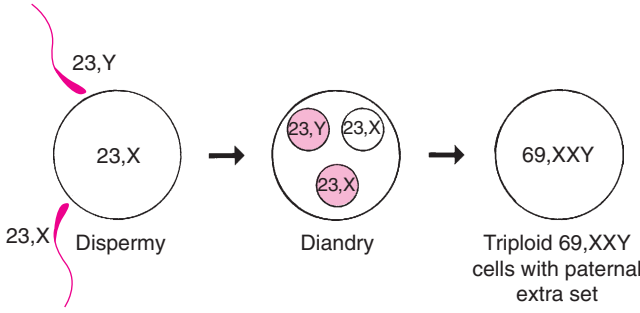

FIG 12-13 Chromosomal origin of triploid partial mole. Normal ovum with 23,X haploid set is fertilized by two sperm to give total of 69 chromosomes. Sex configuration of XXY, XXX, or XYY is possible.

GTD does occur, it is usually not a choriocarcinoma (Cunningham, Leveno, Bloom, et al., 2010).

Clinical Manifestations. In the early stages the clinical manifestations of a complete hydatidiform mole cannot be distinguished from those of normal pregnancy. Later vaginal bleeding occurs in almost 95% of cases. The vaginal discharge may be dark brown (resembling prune juice) or bright red and either scant or profuse. It may continue for only a few days or intermittently for weeks. Early in pregnancy the uterus in approximately one half of affected women is significantly larger than expected from menstrual dates. The percentage of women with an excessively enlarged uterus increases as length of time since the last menstrual period increases. Approximately 25% of affected women have a uterus smaller than would be expected from menstrual dates.

Anemia from blood loss, excessive nausea and vomiting (hyperemesis gravidarum), and abdominal cramps caused by uterine distention are relatively common findings. Women may also pass vesicles, which frequently are avascular edematous villi, from the uterus. Preeclampsia occurs in approximately 70% of women with large, rapidly growing hydatidiform moles and occurs earlier than usual in the pregnancy. If preeclampsia is diagnosed before 24 weeks of gestation, hydatidiform mole should be suspected and ruled out. Hyperthyroidism is another serious complication of hydatidiform mole. Usually treatment of the hydatidiform mole restores thyroid function to normal. Partial moles cause few of these symptoms and may be mistaken for an incomplete or missed miscarriage (Cohn, Ramaswamy, Blum, et al., 2009; DiGiulio, Wiedaseck, and Monchek, 2012; Nader, 2009; Roberts and Funai, 2009).

Diagnosis. Transvaginal ultrasound and serum hCG levels are used for diagnosis. Transvaginal ultrasound is the most accurate tool for diagnosing a hydatidiform mole. A characteristic pattern of multiple diffuse intrauterine masses, often called a *snowstorm pattern,* is seen in place of or along with an embryo or a fetus. The trophoblastic tissue secretes the hCG hormone. In a molar pregnancy hCG levels are persistently high or rising beyond 10 to 12 weeks of gestation, the time they would begin to decline in a normal pregnancy (Gilbert, 2011).

Management. Although most moles abort spontaneously, suction curettage offers a safe, rapid, and effective method of evacuating a hydatidiform mole if necessary (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011). Induction of labor with oxytocic agents or prostaglandin is not recommended because of the increased risk of embolization of trophoblastic tissue. Postevacuation administration of $Rh_O(D)$ immunoglobulin to women who are Rh negative is necessary to prevent isoimmunization (Gilbert, 2011).

The nurse provides the woman and her family with information about the disease process, the necessity for a long course of follow-up, and the possible consequences of the disease. The nurse also helps the woman and her family cope with the pregnancy loss and recognize that the pregnancy was not normal. In addition, the woman and her family are encouraged to express their feelings, and information is provided about local support groups or counseling resources as needed. Internet resources such as Share: Pregnancy and Infant Loss Support, Inc. (www.nationalshare.org) and the International Society for the Study of Trophoblastic Disease (www.isstd.org) may also be useful. Explanations about the importance of postponing a subsequent pregnancy and contraceptive counseling are provided to emphasize the need for consistent and reliable use of the method chosen.

! NURSING ALERT

To avoid confusion regarding rising levels of hCG that are normal in pregnancy but could indicate GTD, pregnancy should be avoided during the follow-up assessment period. Any contraceptive method except an IUD is acceptable. Oral contraceptives are preferred because they are highly effective.

Follow-up Care. Follow-up care includes frequent physical and pelvic examinations along with weekly measurements of the β-hCG level until the level decreases to normal and remains normal for 3 consecutive weeks. Monthly measurements are then taken for 6 months. The follow-up assessment period usually continues for a year. During that time a rising β-hCG level and an enlarging uterus may indicate GTD (DiGiulio, Wiedaseck, and Monchek, 2012; Gilbert, 2011).

Late Pregnancy Bleeding

The major causes of bleeding in late pregnancy are placenta previa and premature separation of the placenta (abruptio placentae or placental abruption). Rapid assessment for and diagnosis of the cause of bleeding are essential to reduce maternal and perinatal morbidity and mortality (Table 12-7).

Placenta Previa

Because of advances in ultrasonography, especially transvaginal ultrasound, and an increased understanding of the changing relationship between the placenta and the internal cervical os as pregnancy progresses, definitions and classifications of placenta previa have changed. In **placenta previa** the placenta is implanted in the lower uterine segment such that it completely or partially covers the cervix or is close enough to the cervix to cause bleeding when the cervix dilates or the lower uterine segment effaces (Fig. 12-14) (Hull and Resnik, 2009). When transvaginal ultrasound is used, the placenta is classified as a *complete placenta previa* if it covers the internal cervical os totally. In a *marginal placenta previa* the edge of the placenta is seen on transvaginal ultrasound to be 2.5 cm or closer to the internal cervical os. When the exact relationship of the placenta to the internal cervical os has not been determined or in the case of apparent placenta previa in the second trimester, the term *low-lying placenta* is used (Hull and Resnik, 2009).

Incidence and Etiology. Placenta previa affects approximately 1 in 200 women with pregnancies at term. Some evidence suggests that the incidence of placenta previa is increasing, perhaps as a result of the increasing cesarean birth rate. In addition to a history of previous cesarean birth, other risk factors for placenta previa include advanced maternal age (more than 35 to 40 years of age), multiparity, history of prior suction curettage, and smoking (Hull and Resnik, 2009). Living at a higher altitude is also a risk factor for placenta previa. Like cigarette smoking, a higher altitude causes a decrease in uteroplacental oxygenation and thus a need for increased placental surface area (Francois and Foley, 2012). Placenta previa also occurs more frequently in women carrying male fetuses. A possible explanation for this is that placental sizes are larger in pregnancies involving male fetuses. Disagreement exists regarding an increased risk for placenta previa with multiple gestations. Some studies have found a higher incidence with twins, but others have not (Francois and Foley, 2012). Women who had placenta previa in a previous pregnancy are more likely to develop the problem in a subsequent pregnancy, perhaps as a result of a genetic predisposition. Previous cesarean birth and curettage in the past for miscarriage or induced

TABLE 12-7 SUMMARY OF FINDINGS: PLACENTAL ABRUPTION AND PLACENTA PREVIA

	PLACENTAL ABRUPTION			
	GRADE 1 MILD SEPARATION (10%-20%)	GRADE 2 MODERATE SEPARATION (20%-50%)	GRADE 3 SEVERE SEPARATION (>50%)	PLACENTA PREVIA
Bleeding, external, vaginal	Minimal	Absent to moderate	Absent to moderate	Minimal to severe and life threatening
Total amount of blood loss	<500 mL	1000-1500 mL	>1500 mL	Varies
Color of blood	Dark red	Dark red	Dark red	Bright red
Shock	Rare; none	Mild shock	Common, often sudden, profound	Uncommon
Coagulopathy	Rare, none	Occasional DIC	Frequent DIC	None
Uterine tonicity	Normal	Increased, may be localized to one region or diffuse over uterus; uterus fails to relax between contractions	Tetanic, persistent uterine contractions; boardlike uterus	Normal
Tenderness (pain)	Usually absent	Present	Agonizing, unremitting uterine pain	Absent
Ultrasonographic Findings				
Location of placenta	Normal, upper uterine segment	Normal, upper uterine segment	Normal, upper uterine segment	Abnormal, lower uterine segment
Station of presenting part	Variable to engaged	Variable to engaged	Variable to engaged	High, not engaged
Fetal position	Usual distribution*	Usual distribution*	Usual distribution*	Commonly transverse, breech, or oblique
Gestational or chronic hypertension	Usual distribution*	Commonly present	Commonly present	Usual distribution*
Fetal effects	Normal fetal heart rate pattern	Abnormal fetal heart rate pattern	Abnormal fetal heart rate pattern; fetal death can occur	Normal fetal heart rate pattern

DIC, Disseminated intravascular coagulation.
*Usually refers to the expected variations of incidence seen when there is no concurrent problem.

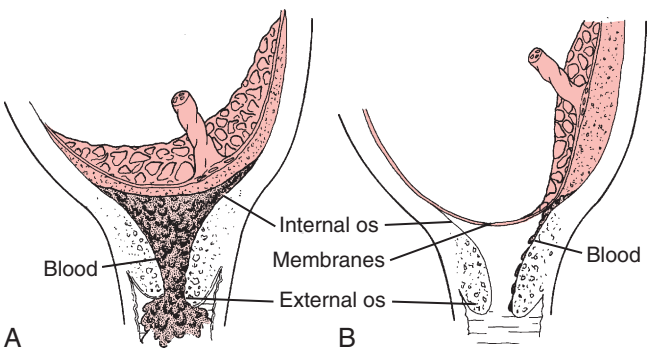

FIG 12-14 Types of placenta previa. **A,** Complete. **B,** Marginal.

abortion are also risk factors for placenta previa because both result in endometrial damage and uterine scarring (Francois and Foley, 2012; Hull and Resnik, 2009).

Clinical Manifestations. Placenta previa is typically characterized by painless bright red vaginal bleeding during the second or third trimester. In the past placenta previa was usually diagnosed after an episode of bleeding. However, currently most cases are diagnosed by ultrasound before significant vaginal bleeding occurs. This bleeding is associated with the disruption of placental blood vessels that occurs with stretching and thinning of the lower uterine segment (Francois and Foley, 2012). The initial bleeding is usually a small amount and stops as clots form. However, it can recur at any time (Gilbert, 2011).

Vital signs may be normal, even with heavy blood loss, because a pregnant woman can lose up to 40% of her blood volume without showing signs of shock. Clinical presentation and decreasing urinary output may be better indicators of acute blood loss than vital signs alone. The FHR is normal unless a major detachment of the placenta occurs.

Abdominal examination usually reveals a soft, relaxed, nontender uterus with normal tone. The presenting part of the fetus usually remains high because the placenta occupies the lower uterine segment. Thus the fundal height is often greater than expected for gestational age. Because of the abnormally located placenta, fetal malpresentation (breech and transverse or oblique lie) is common.

Maternal and Fetal Outcomes. The major maternal complication associated with placenta previa is hemorrhage. Another serious complication is development of an abnormal placental attachment (e.g., *placenta accreta, increta,* or *percreta*) (see Chapter 21).

If excessive bleeding cannot be controlled, hysterectomy may be necessary (Cunningham, Leveno, Bloom, et al., 2010; Hull and Resnik, 2009). Because most women with placenta previa have a cesarean birth, surgery-related trauma to structures adjacent to the uterus and anesthesia complications are also possible. In addition, blood transfusion reactions, anemia, thrombophlebitis, and infection may occur.

The greatest risk of fetal death is caused by preterm birth. Other fetal risks include stillbirth, malpresentation, and fetal anemia. IUGR has also been associated with placenta previa. This association can be related to poor placental exchange (Gilbert, 2011). One study found an increased incidence of fetal anomalies in pregnancies complicated by placenta previa (Cunningham, Leveno, Bloom, et al., 2010).

Diagnosis. All women with painless vaginal bleeding after 20 weeks of gestation should be assumed to have a placenta previa until proven otherwise. A transabdominal ultrasound examination should be performed initially, followed by a transvaginal scan unless the transabdominal ultrasound clearly shows that the placenta is not located in the lower uterine segment. A transvaginal ultrasound is better than a transabdominal scan for accurately determining placental location (Hull and Resnik, 2009). If ultrasonographic scanning reveals a normally implanted placenta, a speculum examination may be performed to rule out local causes of bleeding (e.g., cervicitis, polyps, carcinoma of the cervix), and a coagulation profile is obtained to rule out other causes of bleeding.

Management. Once placenta previa has been diagnosed, a management plan is developed. The woman is managed either expectantly or actively, depending on the gestational age, amount of bleeding, and fetal condition.

Expectant Management. Expectant management (observation and bed rest) is implemented if the fetus is at less than 36 weeks of gestation and has a normal FHR tracing, the bleeding is mild (<250 mL) and stops, and the woman is not in labor. The purpose of expectant management is to allow the fetus time to mature (Gilbert, 2011). The woman initially is hospitalized in a labor and birth unit for continuous FHR and contraction monitoring. Large-bore IV access should be initiated immediately. Initial laboratory tests include hemoglobin, hematocrit, platelet count, and coagulation studies. A "type and screen" blood sample should be maintained at all times in the transfusion services department of the hospital to allow for immediate crossmatch of blood component therapy if necessary. If the woman is at less than 34 weeks of gestation, antenatal corticosteroids should be administered (Francois and Foley, 2012; Gilbert, 2011).

If the bleeding stops, the woman most likely is placed on bed rest with bathroom privileges and limited activity (able to use the bathroom, shower, and move around her hospital room for 15 to 30 minutes at a time 4 times a day). No vaginal or rectal examinations are performed, and the woman is placed on "pelvic rest" (nothing in the vagina). Ultrasound examinations may be performed every 2 to 3 weeks. Fetal surveillance may include a nonstress test (NST) or BPP once or twice weekly. Bleeding is assessed by checking the amount of bleeding on perineal pads, bed pads, and linens. Serial laboratory values are evaluated for decreasing hemoglobin and hematocrit levels and changes in coagulation values. The woman should also be monitored for signs of preterm labor. Magnesium sulfate can be given for tocolysis if uterine contractions are identified (Francois and Foley, 2012; Gilbert, 2011).

The woman with placenta previa should always be considered a potential emergency because massive blood loss with resulting hypovolemic shock can occur quickly if bleeding resumes. The possibility always exists that she will require an emergency cesarean birth. Placenta previa in a preterm gestation may be an indication for transfer to a tertiary-care perinatal center, given that a neonatal intensive care unit may be necessary for care of the preterm infant. In addition, because many community hospitals are not prepared to perform emergency surgery 24 hours per day, 7 days per week, transfer of the woman to a tertiary-care center may be necessary to ensure constant access to cesarean birth.

Home Care. Sometimes women with placenta previa are discharged from the hospital before giving birth to be managed at home. The woman's condition should be stable, and she should have experienced no vaginal bleeding for at least 48 hours before discharge (Hull and Resnik, 2009). A candidate for home care must meet other strict criteria as well. She should be willing and able to comply with activity restrictions (bed rest with bathroom privileges and pelvic rest); live within 20 minutes of the hospital; and have access to a telephone, close supervision by family or friends in the home, and constant access to transportation (Francois and Foley, 2012). If bleeding resumes, she needs to return to the hospital immediately. She must also be able to keep all appointments for fetal testing, laboratory assessments, and prenatal care. Visits by a perinatal home care nurse may be arranged.

If hospitalization or home care with activity restriction is prolonged, the woman can have concerns about her work- or family-related responsibilities or become bored with inactivity. She should be encouraged to participate in her own care and decisions about care as much as possible. Providing diversionary activities or encouraging her to participate in activities she enjoys and can perform during bed rest are necessary. Participating in a support group made up of other women on bed rest while hospitalized or online if at home may be a helpful coping mechanism (see Patient Teaching box, p. 309).

Active Management. If the woman is at or beyond 36 weeks of gestation or bleeding is excessive or persistent, immediate cesarean birth is indicated (Hull and Resnik, 2009). Expectant management is terminated as soon as the fetus is mature, if excessive bleeding develops, active labor begins, or any other obstetric reason to end the pregnancy (e.g., chorioamnionitis) develops (Gilbert, 2011). Cesarean birth is indicated in all women with ultrasound evidence of placenta previa. However, vaginal birth may be considered in an asymptomatic woman whose placenta clearly lies more than 2 to 3 cm from the cervical os (Francois and Foley, 2012; Hull and Resnik, 2009).

If cesarean birth is planned, the nurse continuously monitors maternal and fetal status while preparing the woman for surgery. Maternal vital signs are assessed frequently for decreasing BP, increasing pulse rate, changes in level of consciousness, and oliguria. Fetal assessment is maintained by continuous electronic fetal monitoring (EFM) to assess for signs of hypoxia.

Blood loss may not stop with the birth of the infant. The large vascular channels in the lower uterine segment may continue to bleed because of the diminished muscle content of that segment. The natural mechanism to control bleeding so characteristic of the upper part of the uterus (i.e., the interlacing muscle bundles, the "living ligature" contracting around open vessels) is absent in the lower part of the uterus. Therefore postpartum hemorrhage may occur even if the fundus is contracted firmly (see Chapter 21).

Emotional support for the woman and her family is extremely important. The actively bleeding woman is concerned not only for her own well-being but also for that of her fetus. All procedures should be explained, and a support person should be present. The

FIG 12-15 Placental abruption. Premature separation of normally implanted placenta. A large retroplacental clot is present. (From Creasy RK, Resnik R, Iams JD, et al: *Creasy and Resnik's maternal-fetal medicine: principles and practice*, ed 6, Philadelphia, 2009, Saunders.)

woman should be encouraged to express her concerns and feelings. If the woman and her support person or family desire pastoral support, the nurse can notify the hospital chaplain service or provide information about other supportive resources.

Premature Separation of Placenta (Abruptio Placentae [Placental Abruption])

Premature separation of the placenta, or **abruptio placentae (placental abruption),** is the detachment of part or all of a normally implanted placenta from the uterus (Fig. 12-15). Separation occurs in the area of the decidua basalis after 20 weeks of gestation and before the birth of the infant.

Incidence and Etiology. Premature separation of the placenta is a serious complication that accounts for significant maternal and fetal morbidity and mortality. Approximately 1 in 75 to 1 in 226 pregnancies is complicated by placental abruption. The range in incidence likely reflects both variable criteria for diagnosis and an increased recognition of milder forms of abruption. Approximately one third of all antepartum bleeding is caused by placental abruption (Francois and Foley, 2012) (see Critical Thinking Case Study).

Maternal hypertension, whether chronic or pregnancy related, is the most consistently identified risk factor for abruption. Cocaine use is also a risk factor because it causes vascular disruption in the placental bed. Blunt external abdominal trauma, most often the result of motor vehicle accidents (MVAs) or maternal battering, is another frequent cause of placental abruption (Cunningham, Leveno, Bloom, et al., 2010; Francois and Foley, 2012). Other risk factors include cigarette smoking, a history of abruption in a previous pregnancy, preterm PROM, and the presence of inherited or acquired thrombophilias (e.g., factor V Leiden mutation or protein C or S deficiency) (Cunningham, Leveno, Bloom, et al., 2010; Francois and Foley, 2012; Hull and Resnik, 2009; Paidas and Hossain, 2009). Abruption is more likely to occur in twin gestations than in singletons (Francois and Foley, 2012). Women who have had two previous abruptions have a recurrence risk of 25% in the next pregnancy (Hull and Resnik, 2009).

Classification. The most common classification of placental abruption is according to type and severity. This classification system is summarized in Table 12-7.

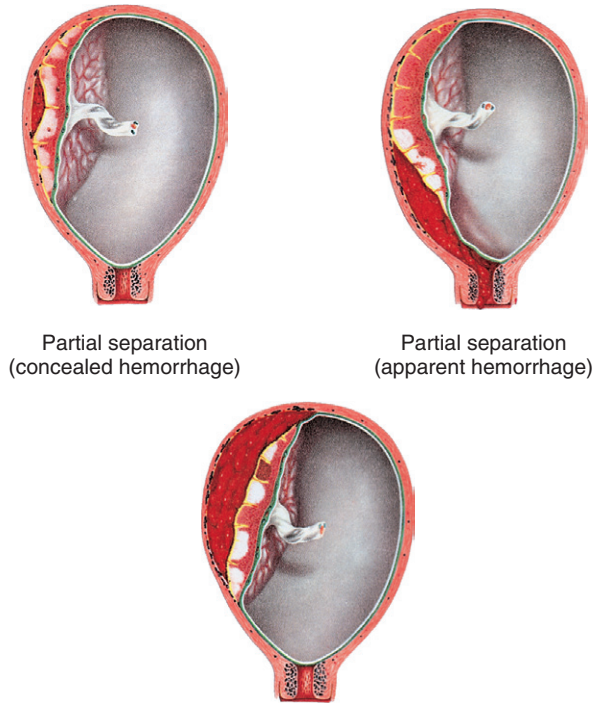

FIG 12-16 Placental abruption showing partial and complete placental separation.

CRITICAL THINKING CASE STUDY

Third-Trimester Vaginal Bleeding

Ashley is a 29-year-old G6 P5 who presents to the emergency department with heavy vaginal bleeding and contractions. She has had no prenatal care but is approximately 33 weeks of gestation by her LMP. During her medical screening examination Ashley admitted to past cocaine use and reported that her boyfriend punched her in the abdomen earlier in the day.

1. Evidence—Is there sufficient evidence to determine the cause of Ashley's bleeding?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Possible diagnoses for Ashley
   b. Laboratory and diagnostic tests necessary to diagnose the cause of Ashley's bleeding
   c. Management options for Ashley
   d. Need for a social work consultation regarding intimate partner violence
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

LMP, Last menstrual period.

Clinical Manifestations. The separation may be partial or complete, or only the margin of the placenta may be involved. Bleeding from the placental site may dissect (separate) the membranes from the decidua basalis and flow out through the vagina (70% to 80%), it may remain concealed (retroplacental hemorrhage) (10% to 20%), or both (Fig. 12-16) (Francois and Foley, 2012; Gilbert, 2011). Clinical symptoms vary with degree of separation (see Table 12-7).

If cesarean birth is performed, blood clots may be noted on entry into the uterus. A blood clot is often attached to the posterior surface of the placenta (referred to as a *retroplacental clot*) (see Fig. 12-15).

Classic symptoms of placental abruption include vaginal bleeding, abdominal pain, and uterine tenderness and contractions (Cunningham, Leveno, Bloom, et al., 2010; Hull and Resnik, 2009). Bleeding may result in maternal hypovolemia (i.e., shock, oliguria, anuria) and coagulopathy. Mild-to-severe uterine hypertonicity is present. Pain is mild to severe and localized over one region of the uterus or diffuses over the uterus with a boardlike abdomen.

Extensive myometrial bleeding damages the uterine muscle. If blood accumulates between the separated placenta and the uterine wall, it may produce a Couvelaire uterus. The uterus appears purple or blue rather than its usual "bubble-gum pink" color, and contractility is lost. Shock may occur and is out of proportion to apparent blood loss. Laboratory findings include a positive Apt test result (blood in the amniotic fluid); a decrease in hemoglobin and hematocrit levels, which may appear later; and a decrease in coagulation factor levels. Clotting defects (e.g., disseminated intravascular coagulation [DIC]) may be present when more than 50% of the placental surface area abrupts (Francois and Foley, 2012). A Kleihauer-Betke (KB) test may be ordered to determine the presence of fetal-to-maternal bleeding (transplacental hemorrhage), although this test appears to have no value in the general workup of women with abruption. The KB test may be useful to guide Rh_o(D) immunoglobulin therapy in Rh-negative women who have had an abruption (Hull and Resnik, 2009).

Maternal and Fetal Outcomes. The mother's prognosis depends on the extent of placental detachment, overall blood loss, degree of coagulopathy present, and time between placental detachment and birth. Maternal complications are associated with the abruption or its treatment. Hemorrhage, hypovolemic shock, hypofibrinogenemia, and thrombocytopenia are associated with severe abruption. Renal failure and pituitary necrosis may result from ischemia. In rare cases women who are Rh negative can become sensitized if fetal-to-maternal hemorrhage occurs and the fetal blood type is Rh positive.

Fetal complications, which include IUGR and preterm birth, are related to the severity and timing of the hemorrhage. The size of the hemorrhage is related to fetal survival. Large (>60 mL) hemorrhages are associated with 50% or higher fetal mortality (Francois and Foley, 2012). Risks for neurologic defects, cerebral palsy, and death from sudden infant death syndrome are greater in newborns following placental abruption (Cunningham, Leveno, Bloom, et al., 2010; Francois and Foley, 2012).

Diagnosis. Placental abruption is primarily a clinical diagnosis. Although ultrasound can be used to rule out placenta previa, it cannot detect all cases of abruption. A retroplacental mass may be detected with ultrasonographic examination, but negative findings do not rule out a life-threatening abruption. In fact, at least 50% of abruptions cannot be identified on ultrasound (Hull and Resnik, 2009). Hypofibrinogenemia and evidence of DIC support the diagnosis, but many women with placental abruption do not develop coagulopathy. The diagnosis of abruption is confirmed after birth by visual inspection of the placenta. Adherent clots on the maternal surface of the placenta and depression of the underlying placental surface are usually present (see Fig. 12-15) (Francois and Foley, 2012; Gilbert, 2011).

Placental abruption should be highly suspected in the woman who experiences a sudden onset of intense, usually localized, uterine pain, with or without vaginal bleeding. Initial assessment is much the same as for placenta previa. Physical examination usually reveals abdominal pain, uterine tenderness, and contractions. The fundal height may be measured over time because an increasing fundal height indicates concealed bleeding. Approximately 60% of live fetuses exhibit abnormal FHR patterns, and elevated uterine resting tone may also be noted on the monitor tracing (Francois and Foley, 2012). Coagulopathy, as evidenced by abnormal clotting studies (fibrinogen, platelet count, partial thromboplastin time [PTT], fibrin split products), may be present if a large or complete abruption has occurred.

Management

Expectant Management. Management depends on the severity of blood loss and fetal maturity and status. If the fetus is less than 34 weeks of gestation and both the woman and fetus are stable, expectant management can be implemented. The woman is monitored closely because the abruption may extend at any time. The fetus is assessed regularly for evidence of appropriate growth because there is risk for IUGR. In addition, assessments of fetal well-being (e.g., NST and BPP) are performed regularly. See Chapter 10 for further discussion of these tests. Corticosteroids are given to accelerate fetal lung maturity (Hull and Resnik, 2009).

Active Management. Immediate birth is the management of choice if the fetus is at term gestation or the bleeding is moderate to severe and the mother or fetus is in jeopardy. At least one large-bore (16- to 18-gauge) IV line should be started. Maternal vital signs are monitored frequently to observe for signs of declining hemodynamic status such as increasing pulse rate and decreasing BP. Serial laboratory studies include hematocrit or hemoglobin determinations and clotting studies. Continuous EFM is mandatory. An indwelling catheter is inserted for continuous assessment of urine output, an excellent indirect measure of maternal organ perfusion. Blood and fluid volume replacement may be necessary, along with administration of blood products to correct any coagulation defects.

Vaginal birth is usually feasible and is desirable, especially in cases of fetal death. Labor induction or augmentation may be initiated as long as the mother and fetus are monitored closely for any evidence of compromise. Although vaginal birth is usually preferable, cesarean birth may become necessary. Cesarean birth should not be attempted when the women has severe and uncorrected coagulopathy because it can result in uncontrollable bleeding (Francois and Foley, 2012).

Nursing care of women experiencing moderate-to-severe abruption is demanding because it requires constant close monitoring of the maternal and fetal condition. Information about placental abruption, including the cause, treatment, and expected outcome, is given to the woman and her family. Emotional support is also extremely important because the woman and her family may be experiencing fetal loss in addition to the woman's critical illness.

Cord Insertion and Placental Variations

When fetal vessels lie over the cervical os, the condition is termed *vasa previa*. Usually these vessels are protected only by the fetal membranes (not by Wharton's jelly); thus they are at risk for rupture or compression. There are two variations of vasa previa. In both situations ROM or traction on the cord may rupture one or more of the fetal vessels. As a result the fetus may rapidly bleed to death. Risk factors for vasa previa include low-lying placentas, pregnancies resulting from assisted reproductive technology, and multiple gestations (Francois and Foley, 2012).

One variation of vasa previa, velamentous insertion of the cord, occurs when the cord vessels begin to branch at the membranes and then course onto the placenta (Fig. 12-17). The other variant of vasa previa occurs when the placenta has divided into two or more lobes

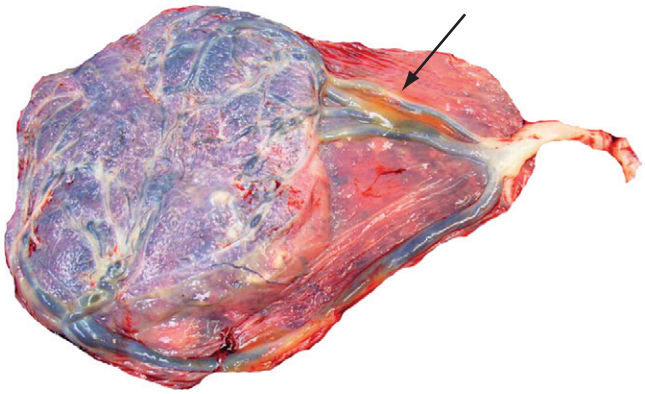

FIG 12-17 Vasa previa (velamentous insertion of cord). *Arrow* shows velamentous cord insertion in placenta. (From Creasy RK, Resnik R, Iams JD, et al: *Creasy and Resnik's maternal-fetal medicine: principles and practice*, ed 6, Philadelphia, 2009, Saunders.)

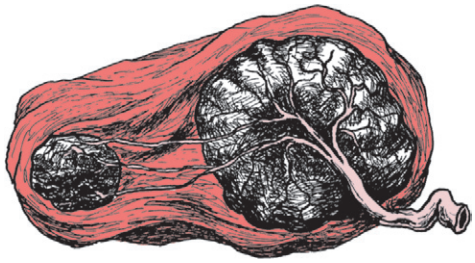

FIG 12-18 Vasa previa (succenturiate placenta).

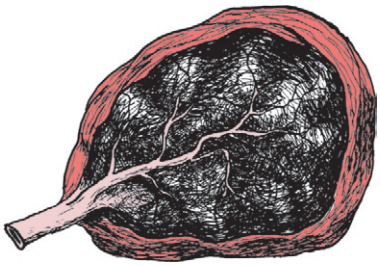

FIG 12-19 Battledore (marginal) cord insertion.

rather than remaining as a single mass. This is known as a *succenturiate* placenta (Fig. 12-18). Fetal vessels then run between the lobes of the placenta. The vessels collect at the periphery, and the main trunks eventually unite to form the vessels of the cord. During the third stage of labor one or more of the separate lobes may remain attached to the decidua basalis, preventing uterine contraction and increasing the risk of postpartum hemorrhage.

Another placental variation is *Battledore* (marginal) insertion of the cord (Fig. 12-19). This variation also increases the risk of fetal hemorrhage, especially after marginal separation of the placenta.

Clotting Disorders in Pregnancy

Normal Clotting

Normally a delicate balance (homeostasis) exists between the opposing hemostatic and fibrinolytic systems. The hemostatic system stops the flow of blood from injured vessels, first by a platelet plug, then by the formation of a fibrin clot. The coagulation process involves an interaction of the coagulation factors that constantly circulate in the bloodstream, in which each factor sequentially activates the factor next in line, the "cascade effect" sequence. The fibrinolytic system is the process through which the fibrin clot is split into fibrinolytic degradation products and circulation is restored.

BOX 12-6 CLINICAL MANIFESTATIONS AND LABORATORY SCREENING RESULTS FOR WOMEN WITH DISSEMINATED INTRAVASCULAR COAGULATION

Possible Physical Examination Findings	Laboratory Coagulation Screening Test Results
• Spontaneous bleeding from gums, nose	• Platelets: Decreased
• Oozing, excessive bleeding from venipuncture site, intravenous access site, or site of insertion of urinary catheter	• Fibrinogen: Decreased
• Petechiae (e.g., on arm where blood pressure cuff was placed)	• Factor V (proaccelerin): Decreased
• Other signs of bruising	• Factor VIII (antihemolytic factor): Decreased
• Hematuria	• Prothrombin time: Prolonged
• Gastrointestinal bleeding	• Partial prothrombin time: Prolonged
• Tachycardia	• Fibrin degradation products: Increased
• Diaphoresis	• D-dimer test (specific fibrin degradation fragment): Increased
	• Red blood smear: Fragmented red blood cells

Clotting Problems

Disseminated Intravascular Coagulation. **Disseminated intravascular coagulation (DIC),** or consumptive coagulopathy, is a pathologic form of clotting that is diffuse and consumes large amounts of clotting factors, causing widespread external bleeding, internal bleeding, or both, and clotting (Cunningham, Leveno, Bloom, et al., 2010). DIC is never a primary diagnosis. Instead it results from some problem that triggered the clotting cascade, either extrinsically by the release of large amounts of tissue thromboplastin or intrinsically by widespread damage to vascular integrity.

In the obstetric population DIC is most often triggered by the release of large amounts of tissue thromboplastin, which occurs in placental abruption (the most common cause of severe consumptive coagulopathy in obstetrics), the retained dead fetus syndrome, and the amniotic fluid embolus (anaphylactoid syndrome of pregnancy). Severe preeclampsia, HELLP syndrome, and gram-negative sepsis are examples of conditions that can trigger DIC because of widespread damage to vascular integrity (Cunningham, Leveno, Bloom, et al., 2010; Gilbert, 2011). DIC is an overactivation of the clotting cascade and the fibrinolytic system, resulting in depletion of platelets and clotting factors, which causes the formation of multiple fibrin clots throughout the vasculature of the body, even in the microcirculation. Blood cells are destroyed as they pass through these fibrin-choked vessels. Thus DIC results in a clinical picture of clotting, bleeding, and ischemia (Cunningham, Leveno, Bloom, et al., 2010). Clinical manifestations and laboratory test results are summarized in Box 12-6.

Management. Medical management in all cases of DIC involves correction of the underlying cause (e.g., removal of the dead fetus, treatment of existing infection or of preeclampsia or eclampsia, or removal of an abrupted placenta). Volume expansion, rapid replacement of blood products and clotting factors, optimization of oxygenation, achievement of normal body temperature, and continued reassessment of laboratory parameters are the usual forms of treatment. Vitamin K administration, recombinant activated factor VIIa, fibrinogen concentrate, and hemostatic agents should be considered as additional therapies (Francois and Foley, 2012).

Nursing interventions include assessing for signs of bleeding (see Box 12-6) and complications from the administration of blood and blood products, administering fluid or blood replacement as ordered, cardiac and hemodynamic monitoring, and protecting the woman from injury. Because renal failure is one consequence of DIC, urinary output is monitored closely by using an indwelling catheter. Urinary output must be maintained at more than 30 mL/hr (Gilbert, 2011). Vital signs are assessed frequently. If DIC develops before birth, continuous EFM is necessary. The woman should be maintained in a side-lying tilt to maximize blood flow to the uterus. Oxygen may be administered through a nonrebreather face mask at 10 L/min or per hospital protocol or health care provider order. DIC usually is "cured" with the birth and as coagulation abnormalities resolve.

The woman and her family will be anxious and concerned about her condition and prognosis. The nurse offers explanations about care and provides emotional support to them through this critical time.

INFECTIONS ACQUIRED DURING PREGNANCY

Sexually Transmitted Infections

Sexually transmitted infections (STIs) in pregnancy are responsible for significant morbidity rates. Some consequences of maternal infection, such as infertility and sterility, last a lifetime. Psychosocial sequelae may include altered interpersonal relationships and lowered self-esteem. Congenitally acquired infections may affect the length and quality of a child's life. Chapter 4 discusses the diagnosis and management of STIs.

Urinary Tract Infections

UTIs are a common medical complication of pregnancy, occurring in approximately 20% of all pregnancies. They are also responsible for 10% of all hospitalizations during pregnancy (Duff, Sweet, and Edwards, 2009). UTIs include asymptomatic bacteriuria, cystitis, and pyelonephritis. They are usually caused by coliform organisms that are a normal part of the perineal flora. By far the most common cause is *Escherichia coli,* a gram-negative bacterium responsible for 85% of cases. Another gram-negative bacterium that causes UTIs is *Klebsiella pneumoniae*. The gram-positive organisms group B streptococci, enterococci, and staphylococci account for approximately 3% to 7% of all infections (Gilbert, 2011).

Asymptomatic Bacteriuria

Asymptomatic bacteriuria refers to the persistent presence of bacteria within the urinary tract of women who have no symptoms. A clean-voided urine specimen containing more than 100,000 colonies per milliliter of a single organism is diagnostic. If asymptomatic bacteriuria is not treated, up to 40% of infected women will subsequently develop symptomatic infection during the pregnancy (Colombo, 2012). Therefore the ACOG recommends that all women be screened for asymptomatic bacteriuria at their first prenatal visit (Colombo, 2012). It has been associated with preterm labor and birth and low-birth-weight infants (AAP and ACOG, 2012; Cunningham, Leveno, Bloom, et al., 2010).

Asymptomatic bacteriuria should be treated with an antibiotic. Antibiotics that are often prescribed include amoxicillin, ampicillin, cephalexin (Keflex), ciprofloxacin (Cipro), levofloxacin (Levaquin), nitrofurantoin (Macrodantin), and trimethoprim-sulfamethoxazole (Bactrim DS). Several different regimens, including single dose or 3-, 7-, and 10-day treatment may be used (Cunningham, Leveno, Bloom, et al., 2010). A repeat urine culture is usually ordered 1 to 2 weeks after completing therapy because approximately 15% of women do not respond to therapy or have a reinfection (Colombo, 2012). Women who have persistent or frequent recurrences of bacteriuria may be placed on suppressive therapy, often nitrofurantoin, each night at bedtime for the remainder of the pregnancy (Cunningham, Leveno, Bloom, et al., 2010).

Cystitis

Cystitis (bladder infection) is characterized by dysuria, urgency, and frequency, along with lower abdominal or suprapubic pain. Usually white blood cells (WBCs) and bacteria are found in the urine. Microscopic or gross hematuria may also be present. Typically symptoms are confined to the bladder rather than becoming systemic. Cystitis is usually uncomplicated, but it may lead to ascending UTI if untreated. Approximately 40% of pregnant women with pyelonephritis experienced symptoms of bladder infection before developing pyelonephritis (Cunningham, Leveno, Bloom, et al., 2010).

Cystitis is often treated with a 3-day course of antibiotic therapy, which is usually 90% effective in curing the infection. Antibiotics often prescribed include amoxicillin, ampicillin, cephalexin (Keflex), ciprofloxacin (Cipro), levofloxacin (Levaquin), nitrofurantoin (Macrodantin), and trimethoprim-sulfamethoxazole (Bactrim DS) (Cunningham, Leveno, Bloom, et al., 2010). Phenazopyridine (Pyridium), a urinary analgesic, is often prescribed along with an antibiotic for relief of symptoms caused by irritation of the urinary tract. Although phenazopyridine is effective at relieving dysuria, urgency, and frequency, women should be taught that the medication colors urine and tears orange. Therefore they should be instructed to avoid wearing contact lenses while taking this medication and warned that it will stain underwear.

Pyelonephritis

Renal infection (pyelonephritis) is a common serious medical complication of pregnancy and the second most common nondelivery reason for hospitalization (Cunningham, Leveno, Bloom, et al., 2010). The most common maternal complications associated with pyelonephritis include anemia, septicemia, transient renal dysfunction, and pulmonary insufficiency. Women with pyelonephritis can develop urosepsis, sepsis syndrome, and renal dysfunction. In addition, pulmonary injury resembling ARDS can occur in pregnant women with acute pyelonephritis, most likely as the result of damage to alveolar tissue caused by the release of endotoxins from gram-negative bacteria (Colombo, 2012; Cunningham, Leveno, Bloom, et al., 2010). Recurrent pyelonephritis is thought to cause fetal death and IUGR. Acute pyelonephritis is associated with preterm labor (Colombo, 2012).

Pyelonephritis develops most often during the second trimester of pregnancy and is usually caused by the *E. coli* organism. Infection develops only in the right kidney in more than half of all cases. The onset of pyelonephritis is often abrupt, with fever, shaking chills, and aching in the lumbar area of the back. Anorexia and nausea and

vomiting also can be present. Usually one or both costovertebral angles are tender to palpation.

Women diagnosed with pyelonephritis are admitted to the hospital immediately. Treatment with IV antibiotics is started as soon as urine and blood samples for culture and sensitivity have been collected. Ampicillin, gentamicin, cefazolin (Ancef), or ceftriaxone (Rocephin) are often ordered initially because they are broad-spectrum antibiotics that are usually effective. The woman must be monitored closely for the possible development of sepsis (Cunningham, Leveno, Bloom, et al., 2010).

Clinical symptoms generally resolve within a couple of days after antibiotic therapy is begun. The antibiotic may need to be changed based on the results of the initial culture and sensitivity testing or if the woman has not responded to therapy within 48 hours (Gilbert, 2011). Most women become afebrile within 72 hours. If no clinical improvement is seen within 48 to 72 hours, an ultrasound should be performed to assess for a urinary tract obstruction. Once the woman is afebrile, she is changed from IV to oral antibiotics (Cunningham, Leveno, Bloom, et al., 2010).

Usually oral antibiotic therapy is continued for 10 to 14 days after IV therapy has been completed (Colombo, 2012). A urine culture will likely be repeated 1 to 2 weeks after antibiotic therapy has been completed. Recurrent infection develops in 30% to 40% of women after completion of treatment for pyelonephritis. Therefore urine cultures should be obtained each trimester for the remainder of the pregnancy. Many women are maintained on a prophylactic antibiotic (often nitrofurantoin once or twice daily) for the remainder of the pregnancy (Colombo, 2012; Cunningham, Leveno, Bloom, et al., 2010).

Patient Education

Nurses are often responsible for teaching pregnant women about taking medications safely and effectively. This education is especially important in regard to antibiotics because this type of medication is so often misused by the general public. The woman should be instructed to finish the entire course of prescribed antibiotic therapy rather than stopping the medication as soon as she feels better. Failure to complete the entire course can lead to the creation of additional drug-resistant organisms. Antibiotics should be taken on time and around the clock so medication levels in the body remain constant. Finally, many women develop a yeast infection while taking antibiotics because the medication kills normal flora in the genitourinary tract as well as pathologic organisms. Therefore they should be encouraged to include yogurt, cheese, or milk containing active acidophilus cultures in their diet while on antibiotics.

The woman should also be taught simple ways to prevent future UTIs. See the Patient Teaching box on p. 97 for several suggestions.

SURGICAL EMERGENCIES DURING PREGNANCY

Approximately 1 in 500 women require nonobstetric surgery during pregnancy. However, pregnancy can make the diagnosis more difficult. An enlarged uterus and displaced internal organs can make abdominal palpation more difficult, alter the position of an affected organ, and/or change the usual signs and symptoms associated with a particular disorder. Two common nonobstetric abdominal conditions requiring surgery during pregnancy are appendicitis and symptomatic cholelithiasis (Schwartz, Adamczak, and Ludmir, 2012).

Appendicitis

The most common nonobstetric surgical emergency during pregnancy is appendicitis, occurring in about 1 in 1000 pregnancies (Cappell, 2012). The diagnosis of appendicitis is often delayed because the usual signs and symptoms mimic some normal changes of pregnancy such as nausea and vomiting and increased WBC count. As pregnancy progresses the appendix is pushed upward and to the right from its usual anatomic location (Cunningham, Leveno, Bloom, et al., 2010). Because of these changes, rupture of the appendix and the subsequent development of peritonitis occur in up to 25% of pregnant women with appendicitis (Cappell, 2012).

The most common symptom of appendicitis in pregnant women, regardless of gestational age, is right lower-quadrant abdominal pain. Nausea and vomiting are often present, but loss of appetite is not a reliable indicator of appendicitis. Fever, tachycardia, a dry tongue, and localized abdominal tenderness are commonly found in nonpregnant people with appendicitis, but they are less likely indicators for the disorder in pregnant women. Because of the physiologic increase in WBCs that occurs in pregnancy, this test is not helpful in making the diagnosis. A urinalysis and chest x-ray should be performed to rule out UTI and right lower-lobe pneumonia, given that both of these conditions can cause lower abdominal pain (Kelly and Savides, 2009). Appendicitis can also be confused with other disorders such as cholecystitis, preterm labor, pyelonephritis, or placental abruption (Cunningham, Leveno, Bloom, et al., 2010).

Radiologic imaging is necessary if appendicitis is suspected after history, physical examination, and laboratory studies have been completed. Although computed tomography (CT) is the imaging test of choice in nonpregnant patients because it is highly accurate, the use of ultrasound during pregnancy is preferred to avoid fetal exposure to radiation from CT (Cappell, 2012). Magnetic resonance imaging (MRI) may be used if appendicitis has not been confirmed by other imaging techniques (Cappell, 2012; Kelly and Savides, 2009).

Prompt surgical intervention to remove the appendix is still the standard treatment (Kelly and Savides, 2009). Laparoscopic surgery may be performed during the first and second trimesters of pregnancy if the appendix has not ruptured or the diagnosis is uncertain. Antibiotics are often administered for uncomplicated appendicitis and are definitely necessary if rupture, abscess, or peritonitis has occurred. Clindamycin and gentamicin are often prescribed because they are considered both effective and safe. The maternal mortality rate from ruptured appendix is about 4%. The fetal mortality rate from ruptured appendix is much higher, more than 30% (Cappell, 2012).

Cholelithiasis and Cholecystitis

Cholelithiasis (the presence of gallstones in the gallbladder) occurs more often in women than in men. Its incidence increases during pregnancy, probably because of increased hormone levels and pressure from the enlarged uterus that interferes with the normal circulation and drainage of the gallbladder. Most gallstones are asymptomatic during pregnancy. Usually the first symptom of cholelithiasis is biliary colic, epigastric or right upper-quadrant pain that can radiate to the back or shoulders. Pain may occur spontaneously or after eating a high-fat meal. Approximately two thirds of patients with biliary colic have recurrent attacks (Cappell, 2012).

Cholecystitis (inflammation of the gallbladder) is usually caused when a gallstone obstructs a cystic duct. As in biliary colic that occurs with cholelithiasis, epigastric or right upper-quadrant pain is present, but the pain is usually more severe and prolonged. Nausea, vomiting, and fever may also be present. Acute cholecystitis is the third most common indication for nonobstetric surgical

intervention in pregnancy, occurring in about 4 cases per 10,000 pregnancies (Cappell, 2012).

Often gallbladder surgery is postponed until the puerperium. The woman can usually be managed conservatively for the remainder of the pregnancy (see Patient Teaching box). However, women with recurrent biliary colic or acute cholecystitis generally require immediate cholecystectomy. Although the second trimester has traditionally been considered the safest time for this surgery, it is increasingly performed at any time during pregnancy because of improved surgical techniques and outcomes. Both laparoscopic and open cholecystectomy procedures are acceptable during pregnancy (Cappell, 2012; Cunningham, Leveno, Bloom, et al., 2010). Preoperative care includes IV fluids, discontinuing oral intake, analgesia, and usually antibiotics (Cappell, 2012).

Gynecologic Problems

Pregnancy predisposes a woman to ovarian problems, especially during the first trimester. Ovarian cysts and twisting (torsion) of ovarian cysts or twisting of adnexal tissues may occur. Other problems include retained or enlarged cystic corpus luteum of pregnancy and bacterial invasion of reproductive or other intraperitoneal organs. Serial ultrasounds, MRIs, and transvaginal color Doppler are used to diagnose most ovarian abnormalities (Cunningham, Leveno, Bloom, et al., 2010). Ovarian masses generally regress by 16 to 20 weeks of gestation. If they do not, elective surgery may be performed to remove masses. Laparotomy or laparoscopy may be required to discriminate between ovarian problems and early ectopic pregnancy, appendicitis, or an infectious process.

CARE MANAGEMENT

Initial assessment of the pregnant woman requiring surgery focuses on her presenting signs and symptoms. A thorough history and physical examination are performed. Laboratory testing includes, at a minimum, a complete blood count with differential and a urinalysis. Additional laboratory and other diagnostic tests may be necessary to reach a diagnosis. In addition, FHR and activity and uterine activity should be monitored, and constant vigilance for symptoms of impending obstetric complications maintained. The extent of preoperative assessment is determined by the immediacy of surgical intervention and the specific disorder that requires surgery.

Hospital Care

When surgery becomes necessary during pregnancy, the woman and her family are concerned about the effects of the procedure and medication on fetal well-being and the course of pregnancy. An important aspect of preoperative nursing care is encouraging the woman to express her fears, concerns, and questions.

PATIENT TEACHING

Nutrition Counseling for the Pregnant Woman with Cholecystitis or Cholelithiasis

- Assess your diet for foods that cause discomfort and gas and omit foods that trigger episodes.
- Reduce dietary fat intake to 40 to 50 g/day.
- Limit protein to 10% to 12% of total calories.
- Choose foods so most of the calories come from carbohydrates.
- Prepare food without adding fats or oils as much as possible.
- Avoid fried foods.

Preoperative procedures such as preparation of the operative site and time of insertion of IV lines and urinary retention catheters vary with the physician and the facility. However, in every instance there is a total restriction of solid foods and liquids or a clear specification of the type, amount, and time at which clear liquids may be taken before surgery. Some bowel preparation such as clear liquids and laxatives may be required before surgery. Food by mouth is restricted for several hours before a scheduled procedure. Even if she has had nothing by mouth but, more important, if surgery is unexpected, the woman is in danger of vomiting and aspirating; special precautions are taken before anesthetic is administered (e.g., administering an antacid).

Intraoperatively perinatal nurses may collaborate with the surgical staff to increase their knowledge about the special needs of pregnant women undergoing surgery. One intervention to improve fetal oxygenation is positioning the woman on the operating table with a lateral tilt to avoid compression of the maternal vena cava. Continuous FHR and uterine contraction monitoring during surgery may be performed if the fetus is considered viable. Monitoring may be accomplished by using sterile Aquasonic gel and a sterile sleeve for the transducer. During abdominal surgery uterine contractions may be palpated manually. However, many practitioners simply monitor the fetus before and after the procedure.

In the immediate recovery period general observations and care pertinent to postoperative recovery are initiated. Frequent assessments are carried out for several hours after surgery. Whether the woman is cared for in the surgical postanesthesia recovery area or in a labor and birth unit, continuous fetal and uterine monitoring are likely to be initiated or resumed because of the potential risk for preterm labor. Tocolysis may be necessary if preterm labor occurs (see Chapter 17).

Home Care

Plans for the woman's return home and for convalescent care should be completed as early as possible before discharge. Depending on her insurance coverage, nursing care can be provided through a home health agency. If not, the woman and other support persons must be taught necessary skills and procedures such as wound care. Ideally the woman and other caregivers should have opportunities for supervised practice before discharge so they can feel comfortable with their knowledge and ability before being totally responsible for providing care. Box 12-7 lists information that should be included in discharge teaching for the postoperative patient. The woman also

BOX 12-7 DISCHARGE TEACHING FOR HOME CARE AFTER SURGERY

- Care of incision site
- Diet and elimination related to gastrointestinal function
- Signs and symptoms of developing complications (wound infection, thrombophlebitis, pneumonia)
- Equipment needed and technique for assessing temperature
- Recommended schedule for resumption of activities of daily living
- Treatments and medications ordered
- List of resource persons and their telephone numbers
- Schedule of follow-up visits
- If birth has not occurred:
  - Assessment of fetal activity (kick counts)
  - Signs of preterm labor

may need referrals to various community agencies for evaluation of the home situation, child care, home health care, and financial or other assistance.

TRAUMA DURING PREGNANCY

Trauma remains a common complication during pregnancy because most pregnant women in the United States continue their usual activities. Approximately 30,000 pregnant women in the United States experience treatable injuries each year because of trauma (Mozurkewich and Pearlman, 2012).

Significance

Trauma is estimated to occur in approximately 5% to 15% of pregnancies (Ruth and Miller, 2013). As pregnancy progresses the risk of trauma increases, because more cases of trauma are reported in the third trimester than earlier in gestation. Most maternal injuries are a result of motor vehicle accidents (MVAs) and falls (Martin and Foley, 2009), and most maternal deaths are caused by MVAs (Ruth and Miller, 2013). Serious injuries are more likely to occur in an MVA if the woman is not wearing a seat belt with a shoulder harness and is ejected from the vehicle. Therefore, to improve chances of survival for mother and fetus, pregnant women should wear properly positioned restraints at all times when in a motor vehicle (see Fig. 8-17) (Cunningham, Leveno, Bloom, et al., 2010). Other sources of trauma include intimate partner violence, assaults, and suicide attempts (Martin and Foley, 2009).

Trauma is the leading cause of death among women of childbearing age. It is also the leading cause of nonobstetric maternal death in the United States (Ruth and Miller, 2013). Fetal morbidity and mortality are also significantly impacted by maternal trauma. In fact, trauma causes fetal death more often than maternal death (Gilbert, 2011). Fetal death rates related to maternal trauma are reported to be as high as 65% (Ruth and Miller, 2013), and this information is probably underreported (Mozurkewich and Pearlman, 2012). Fortunately most trauma injuries during pregnancy are minor and have no effect on pregnancy outcome. However, each case must be evaluated carefully because pregnancy can mask signs of severe injury.

The effect of trauma on pregnancy is influenced by the length of gestation, type and severity of the trauma, and degree of disruption of uterine and fetal physiologic features. Trauma increases the incidence of preterm labor and birth, placental abruption, and fetal or neonatal death (Martin and Foley, 2009). Other common fetal effects of trauma include PROM, fetomaternal transfusion, skull injuries, and hypoxia because of maternal respiratory compromise (Gilbert, 2011).

Special considerations for mother and fetus are necessary when trauma occurs during pregnancy because of the physiologic alterations that accompany pregnancy and because of the presence of the fetus.

Maternal Physiologic Characteristics

Optimal care for the pregnant woman after trauma depends on understanding the physiologic state of pregnancy and its effects on trauma. The pregnant woman's body exhibits responses different from those of a nonpregnant person to the same traumatic insults. Because of the different responses to injury during pregnancy, management strategies must be adapted for appropriate resuscitation, fluid therapy, positioning, assessments, and most other interventions. Significant maternal adaptations and the relation to trauma are summarized in Table 12-8.

TABLE 12-8 MATERNAL ADAPTATIONS DURING PREGNANCY AND RELATION TO TRAUMA

SYSTEM	ALTERATION	CLINICAL RESPONSES
Respiratory	↑ Oxygen consumption	↑ Risk of acidosis
	↑ Tidal volume	↑ Risk of respiratory mismanagement
	↓ Functional residual capacity	
	Chronic compensated alkalosis ↓ $PaCO_2$ ↓ Serum bicarbonate	↓ Blood-buffering capacity
Cardiovascular	↑ Circulating volume, 1600 mL	Can lose 1000 mL blood
	↑ CO	No signs of shock until blood loss >30% total blood volume
	↑ Heart rate	
	↓ SVR	↓ Placental perfusion in supine position
	↓ Arterial blood pressure	
	Heart displaced upward to left	Point of maximal impulse, fourth intercostal space
Renal	↑ Renal plasma flow	
	Dilation of ureters and urethra	↑ Risk of stasis, infection
	Bladder displaced forward	↑ Risk of bladder trauma
Gastrointestinal	↓ Gastric motility	↑ Risk of aspiration
	↑ Hydrochloric acid production	
	↓ Competency of gastroesophageal sphincter	Passive regurgitation of stomach acid if head lower than stomach
Reproductive	↑ Blood flow to organs	Source of ↑ blood loss
	Uterine enlargement	Vena caval compression in supine position
Musculoskeletal	Displacement of abdominal viscera	↑ Risk of injury, altered rebound response
	Pelvic venous congestion	Altered pain referral
	Cartilage softened	↑ Risk of pelvic fracture
		Center of gravity changed
	Fetal head in pelvis	↑ Risk of fetal injury
Hematologic	↑ Clotting factors	↑ Risk of thrombus formation
	↓ Fibrinolytic activity	

CO, Cardiac output; *$PaCO_2$,* arterial partial pressure of carbon dioxide; *SVR,* systemic vascular resistance.

The uterus and bladder are confined to the bony pelvis during the first trimester of pregnancy and are at reduced risk for injury in cases of abdominal trauma. After pregnancy progresses beyond the 14th week, the uterus becomes an abdominal organ, and the risk for injury in cases of abdominal trauma increases. During the second and third trimesters the distended bladder becomes an abdominal organ and is at increased risk for injury and rupture. Bowel injuries occur less often during pregnancy because of the protection provided by the enlarged uterus.

The elevated levels of progesterone that accompany pregnancy relax smooth muscle and profoundly affect the gastrointestinal tract. Gastrointestinal motility decreases, with a resultant increased time required for gastric emptying; whereas the production of hydrochloric acid increases in the last trimester, and the gastroesophageal sphincter relaxes (Ruth and Miller, 2013). Because of these changes, airway management of the unconscious pregnant woman is critically important.

! NURSING ALERT

The unconscious pregnant woman is at increased risk for regurgitation of gastric contents and aspiration whenever her head is positioned lower than her stomach or if abdominal pressure is applied.

A pregnant woman has decreased tolerance for hypoxia and apnea because of her decreased functional residual capacity and increased renal loss of bicarbonate. Acidosis develops more quickly in the pregnant than in the nonpregnant state.

Cardiac output increases 30% to 50% over prepregnancy values and is position dependent in the third trimester. Because of compression of the inferior vena cava and descending aorta by the pregnant uterus, cardiac output decreases dramatically if the woman is placed in the supine position. Therefore the supine position must be avoided, even in women with cervical spine injuries. It is a primary priority that lateral uterine displacement be accomplished without any head movement. As soon as the neck is immobilized, the stretcher should be tilted laterally (Mozurkewich and Pearlman, 2012; Ruth and Miller, 2013).

Circulating blood volume increases 40% to 50% during gestation, and pregnant women can tolerate a 1000-mL blood loss readily without demonstrating clinical signs. Hemodynamic instability that indicates the need for transfusion may not be apparent until blood loss exceeds 1500 mL (Martin and Foley, 2009).

Fetal Physiologic Characteristics

Perfusion of the uterine arteries, which provide the primary blood supply to the uteroplacental unit, depends on adequate maternal arterial pressure because these vessels lack autoregulation. Therefore maternal hypotension decreases uterine and fetal perfusion. Maternal shock results in splanchnic and uterine artery vasoconstriction, which decreases blood flow and oxygen transport to the fetus. EFM tracings can help in the evaluation of maternal status after trauma. They reflect fetal cardiac responses to hypoxia and hypoperfusion, including tachycardia or bradycardia, minimal or absent baseline variability, and/or late decelerations.

Careful monitoring of fetal status assists greatly in maternal assessment because the fetal monitor tracing works as an "oximeter" of internal maternal well-being. Hypoperfusion can be present in the pregnant woman before the onset of clinical signs of shock. The EFM tracings may show the first signs of maternal compromise (e.g., when maternal heart rate, BP, and color appear normal yet the EFM printout shows signs of fetal hypoxia) (Miller, Miller, and Tucker, 2013).

Mechanisms of Trauma

Blunt Abdominal Trauma

Blunt abdominal trauma is most commonly the result of MVAs but also may be the result of battering or falls. Maternal and fetal mortality and morbidity rates are directly correlated with whether the mother remains inside the vehicle or is ejected. Maternal death is usually the result of a head injury or exsanguination from a major vessel rupture. Serious retroperitoneal hemorrhage after lower abdominal and pelvic trauma is reported more frequently during pregnancy. Serious maternal abdominal injuries are usually the result of splenic rupture or liver or renal injury.

When the mother survives, placental abruption is the most common cause of fetal death (Gilbert, 2011). Placental separation is thought to be a result of deformation of the elastic myometrium around the relatively inelastic placenta. Shearing of the placental edge from the underlying decidua basalis results and is worsened by the increased intrauterine pressure resulting from the impact. It is critical that all pregnant victims be evaluated carefully for signs and symptoms of placental abruption after even minor blunt abdominal trauma.

! NURSING ALERT

Signs and symptoms of placental abruption include uterine tenderness or pain, uterine irritability, uterine contractions, vaginal bleeding, leaking of amniotic fluid, or a change in FHR characteristics.

Pelvic fracture may result from severe injury and produce bladder trauma or retroperitoneal bleeding with the two-point displacement of pelvic bones that usually occurs. One point of displacement is commonly at the symphysis pubis, and the second point is posterior because of the structure of the pelvis. Careful evaluation for clinical signs of internal hemorrhage is indicated.

Direct fetal injury as a complication of trauma during pregnancy most often involves the fetal skull and brain. Most commonly this injury accompanies maternal pelvic fracture in late gestation, after the fetal head becomes engaged. When the force of the impact is great enough to fracture the maternal pelvis, the fetus often sustains a skull fracture. Evaluation for fetal skull fracture or intracranial hemorrhage is indicated.

Uterine rupture as a result of trauma is rare, occurring in less than 1% of severe cases. Rupture is more likely to occur in a previously scarred uterus. When uterine rupture occurs, it is usually associated with a direct blow delivered with substantial force (Cunningham, Leveno, Bloom, et al., 2010). Traumatic uterine rupture almost always results in fetal death. Maternal death occurs less frequently, in about 30% of cases (Ruth and Miller, 2013).

Penetrating Abdominal Trauma

Bullet wounds are the most frequent cause of penetrating abdominal injury, followed by stab wounds. When the uterus sustains penetrating wounds, the fetus is more likely than the mother to be injured seriously. The enlarged uterus may protect other maternal organs, particularly the bowel, but the fetus is more vulnerable (Cunningham, Leveno, Bloom, et al., 2010; Martin and Foley, 2009).

Numerous factors determine the extent and severity of maternal and fetal injury from a bullet wound, including size and velocity of the bullet, anatomic region penetrated, angle of entry, path of the

bullet, organs damaged, gestational age, and exit wound. Once the bullet enters the body, it may ricochet several times as it encounters organs or bone, or it may sever a large blood vessel. During the second half of pregnancy the fetus usually sustains a direct injury from the bullet. Gunshot wounds require surgical exploration to determine the extent of injury and repair damage as needed.

Stab wounds are limited by the length and width of the penetrating object and are usually confined to the pathway of the weapon. Maternal and fetal injury is less if the stab wound is located in the upper abdomen and is from movement of the penetrating object from above the head downward toward the abdomen rather than from movement from the ground upward toward the lower abdomen. Stab wounds usually require surgical exploration to clean out debris, determine extent of injury, and repair damage.

Thoracic Trauma

Thoracic trauma is reported to produce 25% of all trauma deaths. Pulmonary contusion results from nearly 75% of blunt thoracic trauma and is a potentially life-threatening condition. Pulmonary contusion can be difficult to recognize, especially if flail chest also is present or if there is no evidence of thoracic injury. Pulmonary contusion should be suspected in cases of thoracic injury, especially after blunt acceleration or deceleration trauma such as that occurring when a rapidly moving vehicle crashes into an immovable object.

Penetrating wounds into the chest can result in pneumothorax or hemothorax. This type of injury is usually caused by an MVA that results in impalement by the steering column or a loose article in the vehicle that became a projectile with the force of impact. Stab wounds into the chest also may occur as a result of violence.

Management

Immediate Stabilization

Immediate priorities for stabilization of the pregnant woman after trauma should be identical to those of the nonpregnant trauma patient. Pregnancy should not result in any restriction of the usual diagnostic, pharmacologic, or resuscitative procedures or maneuvers (AAP and ACOG, 2012). The initial response of many trauma team members when caring for the pregnant woman is to assess fetal status first because of the concern for a healthy neonate. Instead the trauma team should follow a methodic evaluation of maternal status to ensure complete assessment and stabilization of the mother. Fetal survival depends on maternal survival, and stabilization of the mother improves the chance of fetal survival.

! NURSING ALERT

Priorities of care for the pregnant woman after trauma must be to resuscitate the woman and stabilize her condition first and then consider fetal needs.

Primary Survey

The systematic evaluation begins with a *primary survey* and the initial *CABDs* of resuscitation: *compressions*, *airway*, *breathing*, and *defibrillation*. Increased oxygen needs during gestation necessitate a rapid response. The presence of a cervical spine injury is always assumed.

! NURSING ALERT

Hyperextension of the neck is avoided; instead jaw thrust is used to establish an airway for the trauma victim.

Once an airway is established, assessment should focus on adequacy of oxygenation. The chest wall is observed for movement. If breathing is absent, ventilations and endotracheal intubation are initiated. Supplemental oxygen should be administered with a tight-fitting, nonrebreather face mask at 10 to 12 L/min to maintain adequate oxygen availability to the fetus. The chest wall is assessed for penetrating chest wound or flail chest. Breathing with a flail chest is rapid and labored; chest wall movements are uncoordinated and asymmetric; crepitus from bony fragments may be palpated.

Rapid placement of two large-bore (14- to 16-gauge) IV lines is necessary in the majority of seriously injured women. It is important to place the lines while veins are still distended. Cardiac arrest during the immediate stabilization period is usually the result of profound hypovolemia, necessitating massive fluid resuscitation. 1 to 2 L of warmed crystalloid solutions should be infused. Ringer's solution and normal saline solution are the fluids of choice for volume resuscitation (Ruth and Miller, 2013). Because of the 50% increase in blood volume during pregnancy, published formulas for nonpregnant adults used for estimating crystalloid and blood replacement to counter blood loss must be adjusted upward.

Replacement of red blood cells and other blood components is anticipated; and blood is drawn for type, crossmatch, complete blood cell count, and platelet count. Infusion of type-specific whole blood or packed red blood cells is usually necessary to improve fetal oxygenation status and replace blood loss. During an extreme emergency type O Rh-negative blood may be administered without matching.

Administering vasopressor drugs to treat maternal hypotension should be avoided if possible. These medications may significantly reduce uterine blood flow and thus decrease oxygen delivery to the fetus. In addition, their use does not address the cause of the hypovolemia (Ruth and Miller, 2013).

After 20 weeks of gestation venous return to the heart is best accomplished by positioning the uterus to one side to eliminate the weight of the uterus compressing the inferior vena cava or the descending aorta. This facilitates efforts to establish the forward flow of blood through resuscitation and stabilization.

Cardiopulmonary Resuscitation of the Pregnant Woman. Trauma, cardiac abnormalities, embolism, magnesium overdose, sepsis, intracranial hemorrhage, anesthetic complications, eclampsia, and uterine rupture are the most common causes of cardiac arrest in a pregnant woman (Martin and Foley, 2009). Special modifications are necessary when cardiopulmonary resuscitation (CPR) is performed during the second half of pregnancy. In nonpregnant women chest compressions produce a cardiac output of only about 30% of normal. Cardiac output in pregnant women may be even less as a result of aortocaval compression caused by the gravid uterus. Therefore uterine displacement during resuscitation efforts is critical (Cunningham, Leveno, Bloom, et al., 2010). The uterus may be displaced laterally either manually or by placing a wedge, rolled blanket, or towel under one of the woman's hips. If defibrillation is needed, the paddles must be placed one rib interspace higher than usual because the heart is displaced slightly by the enlarged uterus (see Emergency box).

Complications, including laceration of the liver, rupture of the spleen or uterus, hemothorax, hemopericardium, or fracture of ribs or sternum may be associated with CPR on a pregnant woman. Fetal complications, including cardiac arrhythmia or asystole related to maternal defibrillation and medications and CNS depression related to antiarrhythmic drugs and inadequate uteroplacental perfusion, with possible fetal hypoxemia and acidemia, also may occur.

EMERGENCY

Cardiopulmonary Resuscitation for the Pregnant Woman

Assessment
- Determine unresponsiveness and no breathing or no normal breathing.
- Activate emergency medical system and get AED if available.
- Return to victim and check for pulse.
- Begin chest compressions if no pulse is felt.

Compressions
- Position the woman on a flat, firm surface with her uterus displaced laterally with a wedge (e.g., a rolled towel placed under her hip) or manually or place her in a lateral position.
- Begin chest compressions at a rate of 100/min. Push hard and push fast! At the end of each compression allow chest to recoil (reexpand) completely.
  - Chest compressions may be performed slightly higher on the sternum if the uterus is enlarged enough to displace the diaphragm into a higher position.
- After five cycles of 30 compressions and two breaths (or approximately 2 min), check for a pulse. If no pulse is present, continue CPR.

Airway
- Open airway using head tilt-chin lift maneuver.

Breathing
- Deliver breaths using a face mask or bag-mask device if possible.
- Deliver each breath over 1 second, watching for chest rise.
- Deliver breaths using a ratio of 30 chest compressions to 2 breaths.

Defibrillation
- Use an AED according to standard protocol to analyze heart rhythm and deliver shock if indicated.

Data from Aufderheide TP, Cave DM, Hazinski MF, et al: Part 5: Adult Basic Life Support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science, *Circulation* 122(suppl 3):S685–S705. *AED,* Automated external defibrillator; *CPR,* cardiopulmonary resuscitation.

If the resuscitation is successful, the woman must be monitored carefully afterward. She remains at increased risk for recurrent cardiac arrest and arrhythmias (e.g., ventricular tachycardia, supraventricular tachycardia, bradycardia). Therefore her cardiovascular, pulmonary, and neurologic status should be assessed continuously. If the pregnancy remains intact, uterine activity and resting tone must be monitored. Fetal status and gestational age should also be determined and used in decision making regarding the continuation of the pregnancy or the timing and route of birth.

Another common reason for performing CPR on a pregnant woman is airway obstruction caused by choking. Clearing an airway obstruction is usually accomplished by performing abdominal thrusts. However, during the second and third trimesters of pregnancy, chest thrusts rather than abdominal thrusts should be used (see Emergency box and Fig. 12-20).

Secondary Survey

After immediate resuscitation and successful stabilization measures, a more detailed *secondary survey* of the mother and fetus should be completed. A complete physical assessment, including all body systems, is performed.

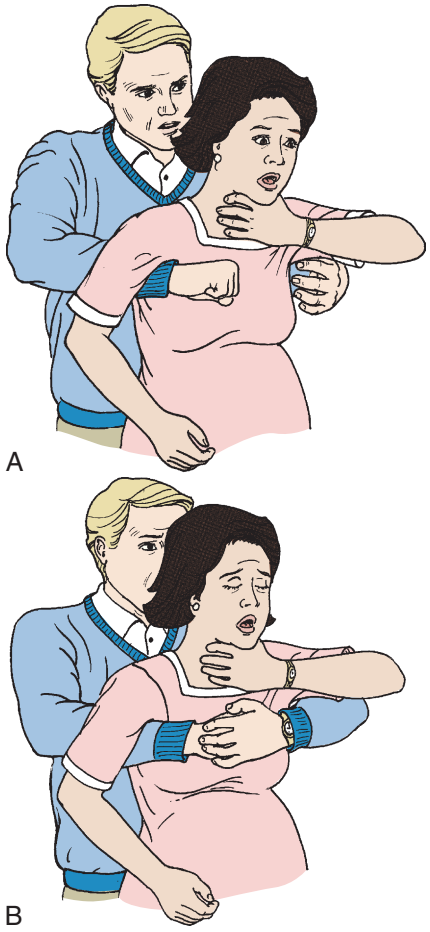

FIG 12-20 Clearing airway obstruction in woman in late stage of pregnancy. **A,** Standing behind victim, place your arms under woman's armpits and across chest. Place thumb side of your clenched fist against middle of sternum, and place other hand over fist. **B,** Perform backward chest thrusts until foreign body is expelled or woman becomes unconscious (see Emergency box below).

EMERGENCY

Relief of Foreign Body Airway Obstruction

If the pregnant woman is unable to speak or cough, perform chest thrusts. Stand behind the woman and place your arms under her armpits to encircle her chest. Press backward with quick thrusts until the foreign body is expelled (see Fig. 12-20). If the woman becomes unconscious, carefully support her to the ground, immediately activate EMS, and begin CPR.

Data from Aufderheide TP, Cave DM, Hazinski MF, et al: Part 5: Adult Basic Life Support: 2010 American Heart Association Guidelines for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care Science, *Circulation* 122(suppl 3):S685–S705. *EMS,* Emergency medical services; *CPR,* cardiopulmonary resuscitation.

The maternal abdomen should be evaluated carefully because a large percentage of serious injuries involve the uterus, intraperitoneal structures, and the retroperitoneum. The greatest clinical concern after severe abdominal trauma is placental abruption because as many as 40% of these women have an abruption. If

placental abruption occurs, the associated fetal mortality rate can be as high as 50% to 80% (Mozurkewich and Pearlman, 2012). Assessments should focus on recognition of this complication, with careful evaluation of fetal monitor tracings, uterine tenderness, labor, or vaginal bleeding. Ultrasound examination may be performed to determine gestational age, viability of the fetus, and placental location. However, ultrasound studies cannot exclude placental abruption. Most cases of abruption that occur as a result of trauma are associated with relatively minor injuries (Cunningham, Leveno, Bloom, et al., 2010; Martin and Foley, 2009).

If trauma is the result of a penetrating wound, the woman should be undressed completely and examined carefully for all entrance and exit wounds. Ultrasonography and CT scan should be performed to assess for the likelihood of intraabdominal bleeding. Peritoneal lavage can be performed on hemodynamically stable women if ultrasound and CT findings do not provide a clear diagnosis. Under direct visualization the peritoneum is incised, and a peritoneal dialysis catheter is positioned. If aspiration yields free-flowing blood, the test is considered positive, and a laparotomy is warranted (Cunningham, Leveno, Bloom, et al., 2010; Martin and Foley, 2009).

Exploratory laparotomy is necessary after a gunshot wound to assess the abdominal cavity for organ damage and repair any damage, with careful examination of all organs, the entire bowel, and posterior vessels. If uterine injury is found, a careful evaluation of the risks and benefits of cesarean birth is quickly accomplished. A cesarean birth is desirable if the fetus is alive and near term and may be necessary for the preterm fetus because of the high incidence of direct fetal injury in these cases. The fetus usually tolerates surgery and anesthesia if adequate uterine perfusion and oxygenation are maintained. Tetanus prophylaxis guidelines are not changed by pregnancy.

Trauma may affect numerous systems in the maternal body and more than the pregnancy. External signs of maternal trauma should suggest the possibility of internal trauma. Back and neck pain suggest spine injury, abrasions on the chest suggest chest injury, and limb pain and malposition suggest limb fractures. If head injury results in nonresponsiveness, suspect spinal, thoracic, and abdominal injuries. Hypovolemic shock can occur with internal hemorrhage, fracture of long bones, ruptured liver or spleen, hemothorax, or arterial dissection.

All female trauma victims of childbearing age should be considered pregnant until proven otherwise. Determination of the health history and a history of the events preceding the trauma are important components of care. If the pregnant woman was involved in an MVA, it should be determined whether she was the driver or a passenger and if she was ejected from the vehicle or used a restraining device and remained within the vehicle.

Electronic Fetal Monitoring. External FHR and contraction monitoring is recommended after blunt trauma in a viable gestation for a minimum of 4 hours, regardless of injury severity. Fetal monitoring should be initiated soon after the woman is stable (Cunningham, Leveno, Bloom, et al., 2010; Martin and Foley, 2009). Continuous EFM may show early signs of placental abruption, including a change in baseline rate; loss of accelerations; or the presence of late decelerations, especially when accompanied by absent or minimal variability. The external device to monitor uterine activity, the tocodynamometer, is unable to measure pressures; the pattern made with this device shows the frequency and duration of contractions only. Palpation is required to evaluate the intensity of contractions and the uterine resting tone. It is important to palpate between contractions to verify that the uterus is well relaxed. If it does not relax between contractions, placental abruption could be present.

The exact duration of FHR and contraction monitoring required after blunt abdominal trauma is not known. Monitoring should be continued indefinitely if uterine contractions, abnormal FHR characteristics, vaginal bleeding, uterine tenderness or irritability, serious maternal injury, or ruptured membranes are present. Most physicians recommend continuous monitoring for at least 24 hours. Most abruptions develop soon after the traumatic event, although in rare cases abruption has developed days afterward (Cunningham, Leveno, Bloom, et al., 2010; Martin and Foley, 2009).

LEGAL TIP: Care of the Pregnant Woman Involved in a Minor Trauma Situation

After minor trauma the pregnant woman may be discharged after an adequate period of EFM that demonstrates a normal (category I) tracing (see Chapter 15) and absence of uterine contractions. However, clear instructions must be given for immediate return if vaginal bleeding, leaking of amniotic fluid, decreased fetal movement, or severe abdominal pain occurs.

Fetal-Maternal Hemorrhage. The potential for fetal-maternal hemorrhage exists after trauma. Hemorrhage can lead to fetal anemia, distress, or even death. If the pregnant trauma victim is Rh negative, fetal-maternal hemorrhage can result in sensitization and hemolytic disease of the neonate. The KB assay is often performed in women following blunt abdominal trauma to estimate the amount of fetal blood within the maternal circulation. However, because most cases have less than 30 mL of hemorrhage, KB test results seldom alter management (Cunningham, Leveno, Bloom, et al., 2010; Martin and Foley, 2009). Usually the routine administration of 300 mcg of Rh_o(D) immunoglobulin is sufficient to protect almost all Rh-negative pregnant trauma patients from isoimmunization (Morzurkewich and Pearlman, 2012).

Ultrasound. Ultrasound after trauma is not as sensitive as EFM for diagnosing placental abruption. It may be useful to help establish gestational age, locate the placenta, evaluate cardiac activity (to determine whether the fetus is alive), and determine amniotic fluid volume. It may also be used to evaluate the presence of intraabdominal fluid that would suggest the presence of intraabdominal hemorrhage.

Radiation Exposure. If the pregnant woman has sustained serious injuries, any necessary radiographic examination should be performed, regardless of fetal exposure. If radiographic examination would be performed for the nonpregnant trauma victim, it also should be performed for the pregnant woman. Abdominal or pelvic CT scanning can be used to visualize extraperitoneal and retroperitoneal structures and the genitourinary tract. Radiation exposure of less than 5 rads has not been associated with fetal abnormalities or pregnancy loss, and the radiation level associated with abdominal or pelvic CT scans is far below this amount (Martin and Foley, 2009). Blunt head trauma and loss of consciousness necessitate skull films and CT assessment with neurosurgical consultation. MRI can also be used safely to assess injuries because it does not produce ionizing radiation (Martin and Foley, 2009).

Perimortem Cesarean Birth

In the presence of multisystem trauma, *perimortem cesarean birth* may be indicated. Removal of the stressor of pregnancy early in the

process of resuscitation may increase the chance for maternal survival. Therefore, to facilitate resuscitative efforts, a cesarean birth should be performed after 4 minutes of resuscitative efforts if there is no evidence of a maternal pulse (Martin and Foley, 2009; Mozurkewich and Pearlman, 2012; Ruth and Miller, 2013). It should be emphasized that perimortem cesarean birth is rarely successful, especially when the maternal arrest is related to trauma (Ruth and Miller, 2013).

KEY POINTS

- Hypertensive disorders during pregnancy are a leading cause of maternal and perinatal morbidity and mortality worldwide.
- The cause of preeclampsia is unknown, and there are no known reliable tests for predicting women at risk for developing preeclampsia.
- Preeclampsia is a multisystem disease, and the pathologic changes are present long before clinical manifestations such as hypertension are evident.
- HELLP syndrome, which is usually diagnosed during the third trimester, is a variant of severe preeclampsia, not a separate illness.
- Magnesium sulfate, the anticonvulsant of choice for preventing or controlling eclamptic seizures, requires careful monitoring of reflexes, respirations, and renal function.
- The intent of emergency interventions for eclampsia is to prevent self-injury, enhance oxygenation, reduce aspiration risk, and establish control with magnesium sulfate.
- The woman with hyperemesis gravidarum may have significant weight loss and dehydration; management focuses on restoring fluid and electrolyte balance and preventing recurrence of nausea and vomiting.
- Some miscarriages occur for unknown reasons, but fetal or placental maldevelopment and maternal factors account for many others.
- The type of miscarriage and signs and symptoms direct care management.
- Ectopic pregnancy is a significant cause of maternal morbidity and mortality.
- Placental abruption and placenta previa are differentiated by type of bleeding, uterine tonicity, and presence or absence of pain.
- Pyelonephritis is a serious medical complication of pregnancy and the second most common nondelivery reason for hospitalization.
- Perioperative care for a pregnant woman differs from that for a nonpregnant woman in one significant aspect: the presence of at least one other person—the fetus.
- Most maternal trauma results from MVAs and falls. Most maternal deaths are caused by MVAs.
- Fetal survival depends on maternal survival. After trauma the first priority is resuscitation and stabilization of the mother before consideration of the fetus.
- Maternal trauma can be associated with major complications for the pregnancy, including placental abruption, fetomaternal hemorrhage, preterm labor and birth, and fetal death.

CHAPTER

13

Labor and Birth Processes

Kitty Cashion

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Explain the five major factors that affect the labor process.
- Describe the anatomic structure of the bony pelvis.
- Recognize the normal measurements of the diameters of the pelvic inlet, cavity, and outlet.
- Explain the significance of the size and position of the fetal head during labor and birth.
- Summarize the cardinal movements of the mechanism of labor for a vertex presentation.
- Examine the maternal anatomic and physiologic adaptations to labor.
- Describe factors thought to contribute to the onset of labor.
- Describe fetal adaptations to labor.

During late pregnancy the woman and fetus prepare for the labor process. The fetus has grown and developed in preparation for extrauterine life. The woman has undergone various physiologic adaptations during pregnancy that prepare her for giving birth and motherhood. Labor and birth represent the end of pregnancy, the beginning of extrauterine life for the newborn, and a change in the lives of the family. This chapter discusses the factors affecting labor, the processes involved, the normal progression of events, and the adaptations made by both the woman and fetus.

FACTORS AFFECTING LABOR

At least five factors affect the process of labor and birth. These are easily remembered as the five *Ps*: ***p***assenger (fetus and placenta), ***p***assageway (birth canal), ***p***owers (contractions), ***p***osition of the mother, and ***p***sychologic response. The first four factors are presented here as the basis of understanding the physiologic process of labor. The fifth factor is discussed in Chapter 16. Other factors that may be a part of the woman's labor experience may be important as well. VandeVusse (1999) identified external forces, including place of birth, preparation, type of provider (especially nurses), and procedures. Physiology (sensations) was identified as an internal force. These factors are discussed generally in Chapter 16 as they relate to nursing care during labor. Further research investigating essential forces of labor is recommended.

Passenger

The movement of the passenger, or fetus, through the birth canal is determined by several interacting factors: the size of the fetal head, fetal presentation, fetal lie, fetal attitude, and fetal position. Because the placenta also must pass through the birth canal, it can be considered a passenger along with the fetus; however, the placenta rarely impedes the process of labor in normal vaginal birth. An exception is the case of placenta previa (see Chapter 12).

Size of the Fetal Head

Because of its size and relative rigidity, the fetal head has a major effect on the birth process. The fetal skull is composed of two parietal bones, two temporal bones, the frontal bone, and the occipital bone (Fig. 13-1, *A*). These bones are united by membranous sutures: the sagittal, lambdoidal, coronal, and frontal (see Fig. 13-1, *B*). Membrane-filled spaces called *fontanels* are located where the sutures intersect. During labor after rupture of membranes, palpation of fontanels and sutures during vaginal examination reveals fetal presentation, position, and attitude.

The two most important fontanels are the anterior and posterior (see Fig. 13-1, *B*). The larger of these, the anterior fontanel, is diamond shaped, about 3 cm by 2 cm, and lies at the junction of the sagittal, coronal, and frontal sutures. It closes by 18 months after birth. The posterior fontanel lies at the junction of the sutures of the two parietal bones and the occipital bone, is triangular, and is about 1 cm by 2 cm. It closes 6 to 8 weeks after birth.

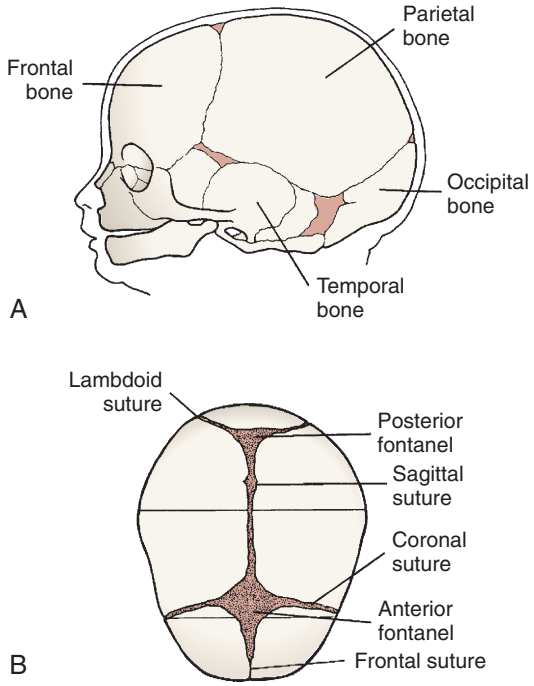

FIG 13-1 Fetal head at term. **A,** Bones. **B,** Sutures and fontanels.

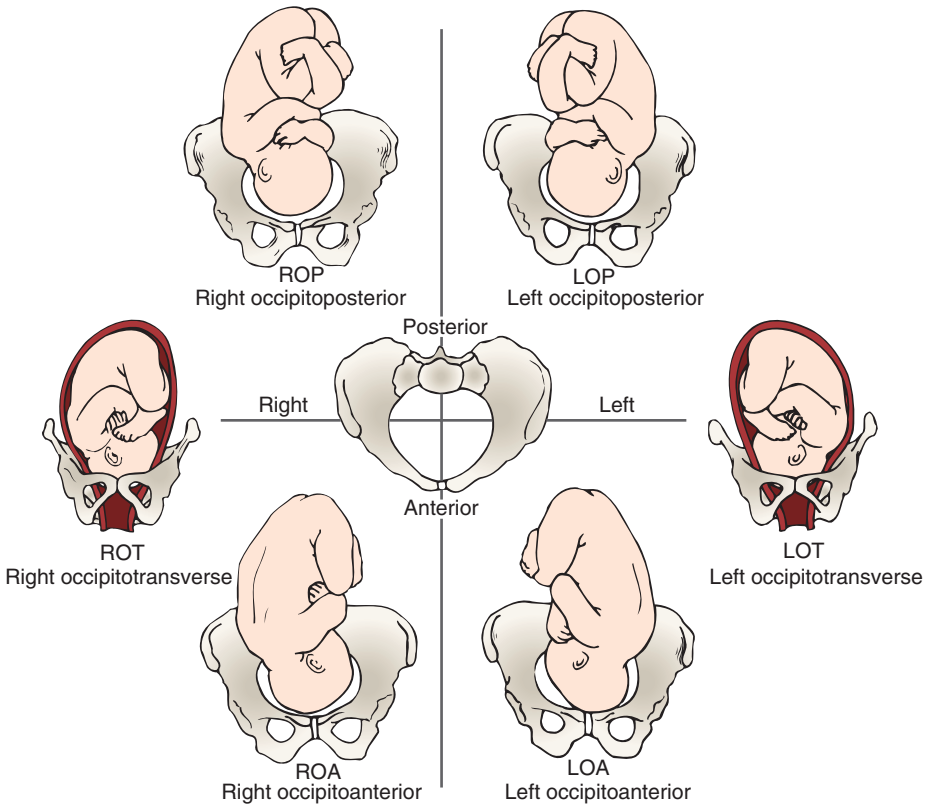
Sutures and fontanels make the skull flexible to accommodate the infant brain, which continues to grow for some time after birth. However, because the bones are not firmly united, slight overlapping, or molding of the shape of the head, occurs during labor. This capacity of the bones to slide over one another also permits adaptation to the various diameters of the maternal pelvis. Molding can be extensive, but the heads of most newborns assume their normal shape within 3 days after birth.

Although the size of the fetal shoulders may affect passage, their position can be altered relatively easily during labor so one shoulder may occupy a lower level than the other. This creates a shoulder diameter that is smaller than the skull, facilitating passage through the birth canal. The circumference of the fetal hips is usually small enough to not create problems.

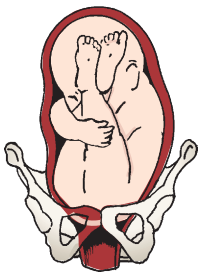
Fetal Presentation

Presentation refers to the part of the fetus that enters the pelvic inlet first and leads through the birth canal during labor at term. The three main presentations are *cephalic presentation* (head first), occurring in 96% of births (Fig. 13-2); *breech presentation* (buttocks, feet, or both first), occurring in 3% of births (Fig. 13-3, *A-C*); and *shoulder presentation*, seen in 1% of births (see Fig. 13-3, *D*). The presenting part is that part of the fetus that lies closest to the internal os of the cervix. It is the part of the fetal body first felt by the examining finger during a vaginal examination. In a cephalic presentation the presenting part is usually the occiput; in a breech



Lie: Longitudinal or vertical
Presentation: Vertex
Reference point: Occiput
Attitude: General flexion

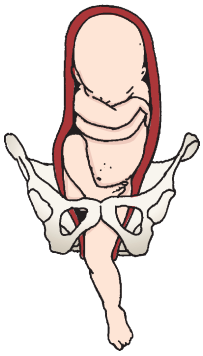
FIG 13-2 Examples of fetal vertex (occiput) presentations in relation to front, back, or side of maternal pelvis.



A

Frank breech

Lie: Longitudinal or vertical
Presentation: Breech (incomplete)
Presenting part: Sacrum
Attitude: Flexion, except for legs at knees



B

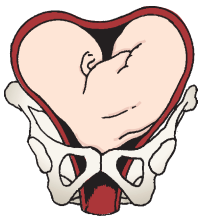
Single footling breech

Lie: Longitudinal or vertical
Presentation: Breech (incomplete)
Presenting part: Sacrum
Attitude: Flexion, except for one leg extended at hip and knee

C

Complete breech

Lie: Longitudinal or vertical
Presentation: Breech (sacrum and feet presenting)
Presenting part: Sacrum (with feet)
Attitude: General flexion



D

Shoulder presentation

Lie: Transverse or horizontal
Presentation: Shoulder
Presenting part: Scapula
Attitude: Flexion

FIG 13-3 Fetal presentations. **A** to **C,** Breech (sacral) presentation. **D,** Shoulder presentation.

presentation it is the sacrum; in the shoulder presentation it is the scapula. When the presenting part is the occiput, the presentation is noted as vertex (see Fig. 13-2). Factors that determine the presenting part include fetal lie, fetal attitude, and extension or flexion of the fetal head.

Fetal Lie

Lie is the relation of the long axis (spine) of the fetus to the long axis (spine) of the mother. The two primary lies are longitudinal, or vertical, in which the long axis of the fetus is parallel with the long axis of the mother (see Fig. 13-2); and transverse, horizontal, or oblique, in which the long axis of the fetus is at a right angle diagonal to the long axis of the mother (see Fig. 13-3, *D*). Longitudinal lies are either cephalic or breech presentations, depending on the fetal structure that first enters the mother's pelvis. Vaginal birth cannot occur when the fetus stays in a transverse lie. An oblique lie (i.e., one in which the long axis of the fetus is lying at an angle to the long axis of the mother) is less common and usually converts to a longitudinal or transverse lie during labor (Cunningham, Leveno, Bloom, et al., 2010).

Fetal Attitude

Attitude is the relation of the fetal body parts to one another. The fetus assumes a characteristic posture (attitude) in utero partly because of the mode of fetal growth and partly because of the way the fetus conforms to the shape of the uterine cavity. Normally the back of the fetus is rounded so the chin is flexed on the chest, the thighs are flexed on the abdomen, and the legs are flexed at the knees. The arms are crossed over the thorax, and the umbilical cord lies between the arms and the legs. This attitude is termed *general flexion* (see Fig. 13-2).

Deviations from the normal attitude may cause difficulties in childbirth. For example, in a cephalic presentation the fetal head may be extended or flexed in a manner that presents a head diameter that exceeds the limits of the maternal pelvis, leading to prolonged labor, forceps- or vacuum-assisted birth, or cesarean birth.

Certain critical diameters of the fetal head are usually measured. The **biparietal diameter,** which is about 9.25 cm at term, is the largest transverse diameter and an important indicator of fetal head size (Fig. 13-4, *B*). In a well-flexed cephalic presentation the biparietal diameter is the widest part of the head entering the pelvic inlet. Of the several anteroposterior diameters, the smallest and most critical one is the suboccipitobregmatic diameter (about 9.5 cm at term). When the fetal head is in complete flexion, this diameter allows it to pass through the true pelvis easily (see Fig. 13-4, *A*; Fig. 13-5, *A*). As the head is more extended, the anteroposterior diameter widens, and the head may not be able to enter the true pelvis (see Fig. 13-5, *B* and *C*).

Fetal Position

The presentation or presenting part indicates the portion of the fetus that overlies the pelvic inlet. **Position** is the relationship of a

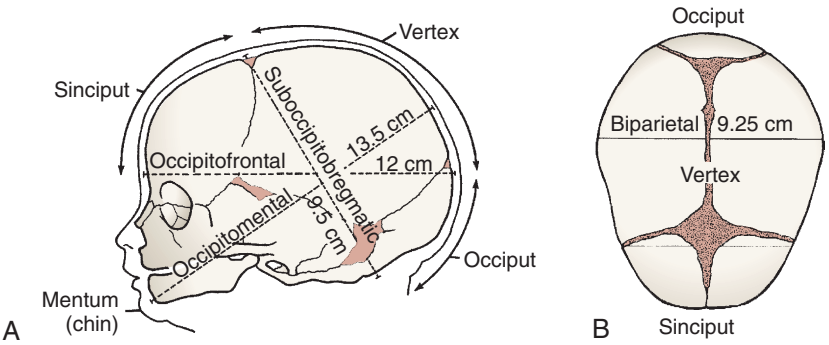


FIG 13-4 Diameters of fetal head at term. **A,** Cephalic presentations: occiput, vertex, and sinciput; and cephalic diameters: suboccipitobregmatic, occipitofrontal, and occipitomental. **B,** Biparietal diameter.

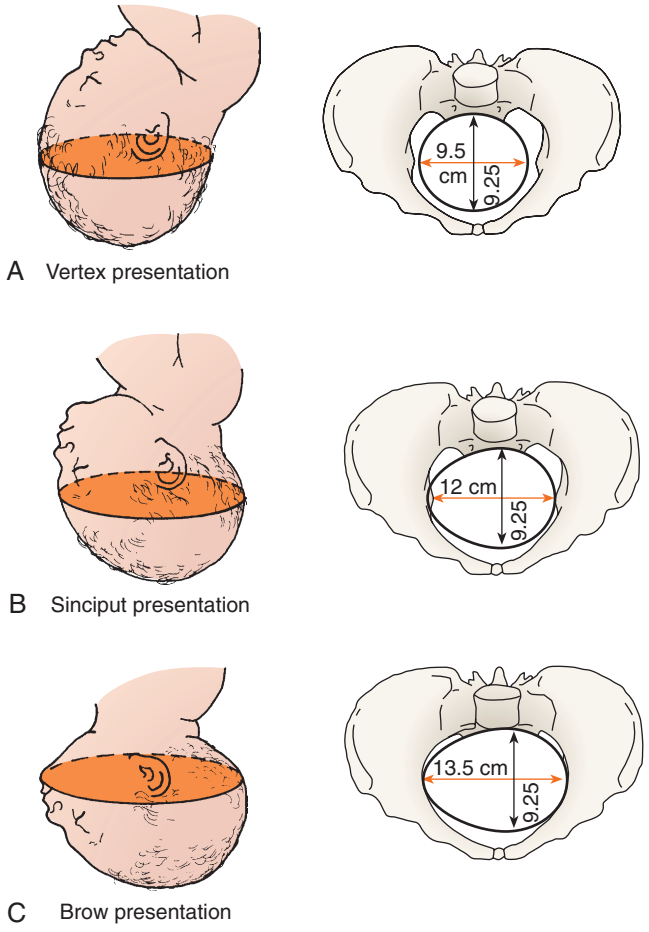

FIG 13-5 Head entering pelvis. Biparietal diameter is indicated with shading (9.25 cm). **A,** Suboccipitobregmatic diameter: complete flexion of head on chest so smallest diameter enters. **B**, Occipitofrontal diameter: moderate extension (military attitude) so large diameter enters. **C,** Occipitomental diameter: marked extension (deflection) so largest diameter, which is too large to permit head to enter pelvis, is presenting.

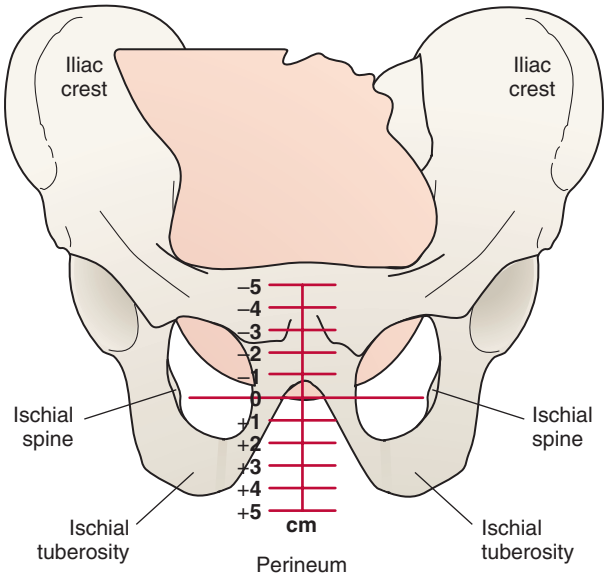

FIG 13-6 Stations of presenting part, or degree of descent. Lowermost portion of presenting part is at level of ischial spines, station 0.

reference point on the presenting part (occiput, sacrum, mentum [chin] or sinciput [deflexed vertex]) to the four quadrants of the mother's pelvis (see Fig. 13-2). Position is denoted by a three-letter abbreviation. The first letter of the abbreviation denotes the location of the presenting part in the right (R) or left (L) side of the mother's pelvis. The middle letter stands for the specific presenting part of the fetus (O for occiput, S for sacrum, M for mentum [chin], and Sc for scapula [shoulder]). The third letter stands for the location of the presenting part in relation to the anterior (A), posterior (P), or transverse (T) portion of the maternal pelvis. For example, ROA means that the occiput is the presenting part and is located in the right anterior quadrant of the maternal pelvis (see Fig. 13-2). LSP means that the sacrum is the presenting part and is located in the left posterior quadrant of the maternal pelvis (see Fig. 13-3).

Station is the relationship of the presenting fetal part to an imaginary line drawn between the maternal ischial spines and is a measure of the degree of descent of the presenting part of the fetus through the birth canal. The placement of the presenting part is measured in centimeters above or below the ischial spines (Fig. 13-6). For example, when the lowermost portion of the presenting part is 1 cm above the spines, it is noted as being minus (−)1. At the level of the spines the station is referred to as 0 (zero). When the presenting part is 1 cm below the spines, the station is said to be plus (+)1. Birth is imminent when the presenting part is at +4 to +5 cm. The station of the presenting part should be determined when labor begins so the rate of descent of the fetus during labor can be determined accurately.

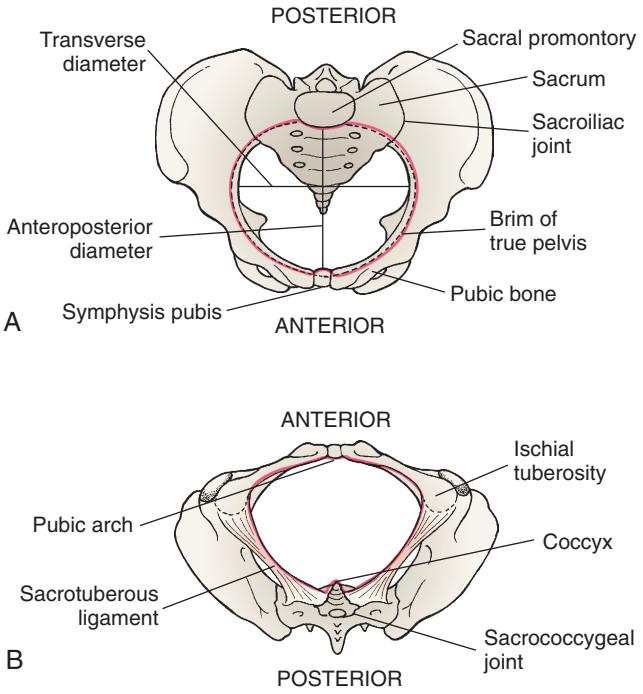

FIG 13-7 Female pelvis. **A,** Pelvic brim as viewed from above. **B,** Pelvic outlet from below, as seen by health care provider when the woman is lying supine.

Engagement is the term used to indicate that the largest transverse diameter of the presenting part (usually the biparietal diameter) has passed through the maternal pelvic brim or inlet into the true pelvis and usually corresponds to station 0. It often occurs in the weeks just before labor begins in nulliparas and may occur before or during labor in multiparas. Engagement can be determined by abdominal or vaginal examination.

Passageway

The passageway, or birth canal, is composed of the mother's rigid bony pelvis and the soft tissues of the cervix, the pelvic floor, the vagina, and the introitus (the external opening to the vagina). Although the soft tissues, particularly the muscular layers of the pelvic floor, contribute to vaginal birth of the fetus, the maternal pelvis plays a far greater role in the labor process because the fetus must successfully accommodate itself to this relatively rigid passageway. The size and shape of the pelvis can be determined at the initial prenatal visit or on admission in labor. This information can then be used in the assessment of labor progress (Thorp, 2009).

Bony Pelvis

The anatomy of the bony pelvis is described in Chapter 3. The following discussion focuses on the importance of pelvic configurations as they relate to the labor process. (It may be helpful to refer to Figs. 3-4 and 3-5.)

The bony pelvis is formed by the fusion of the ilium, ischium, pubis, and sacral bones. The four pelvic joints are the symphysis pubis, the right and left sacroiliac joints (Fig. 13-7, *A*), and the sacrococcygeal joint (Fig. 13-7, *B*). The bony pelvis is separated by the brim, or inlet, into two parts: the false and the true pelves. The false pelvis is the part above the brim and plays no part in childbearing. The true pelvis, the part involved in birth, is divided into three planes: the inlet, or brim; the midpelvis, or cavity; and the outlet.

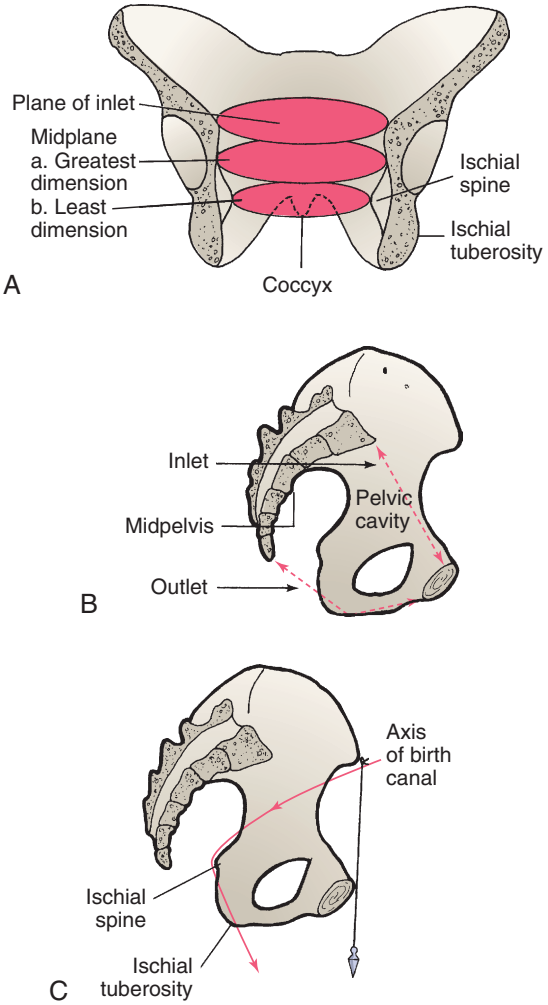

FIG 13-8 Pelvic cavity. **A,** Inlet and midplane. Outlet not shown. **B,** Cavity of true pelvis. **C,** Note curve of sacrum and axis of birth canal.

The pelvic inlet, which is the upper border of the true pelvis, is formed anteriorly by the upper margins of the pubic bone, laterally by the iliopectineal lines along the innominate bones, and posteriorly by the anterior upper margin of the sacrum and the sacral promontory.

The pelvic cavity, or midpelvis, is a curved passage with a short anterior wall and a much longer concave posterior wall. It is bounded by the posterior aspect of the symphysis pubis, the ischium, a portion of the ilium, the sacrum, and the coccyx.

The pelvic outlet is the lower border of the true pelvis. Viewed from below it is ovoid; somewhat diamond shaped; and bounded by the pubic arch anteriorly, the ischial tuberosities laterally, and the tip of the coccyx posteriorly (see Fig. 13-7, *B*). In the latter part of pregnancy the coccyx is movable unless it has been broken (e.g., in a fall during skiing or skating) and has fused to the sacrum during healing.

The pelvic canal varies in size and shape at various levels. The diameters at the plane of the pelvic inlet, midpelvis, and outlet plus the axis of the birth canal (Fig. 13-8) determine whether vaginal birth is possible and the manner by which the fetus may pass down the birth canal.

The subpubic angle, which determines the type of pubic arch, together with the length of the pubic rami and the intertuberous

FIG 13-9 Estimation of angle of subpubic arch. With both thumbs examiner externally traces descending rami down to tuberosities. (From Barkauskas VH, Baumann LC, Darling-Fisher CS: *Health and physical assessment*, ed 3, St Louis, 2002, Mosby.)

diameter, is of great importance. Because the fetus must first pass beneath the pubic arch, a narrow subpubic angle is less accommodating than a rounded wide arch. The method of measurement of the subpubic arch is shown in Fig. 13-9. A summary of obstetric measurements is given in Table 13-1.

The four basic types of pelvis are classified as follows:

1. Gynecoid (the classic female type)
2. Android (resembling the male pelvis)
3. Anthropoid (resembling the pelvis of anthropoid apes)
4. Platypelloid (the flat pelvis)

The gynecoid pelvis is the most common, with major gynecoid pelvic features present in 50% of all women. Anthropoid and android features are less common, and platypelloid pelvic features are the least common. Mixed types of pelves are more common than are pure types (Cunningham, Leveno, Bloom, et al., 2010). Examples of pelvic variations and their effects on mode of birth are given in Table 13-2.

Assessment of the bony pelvis can be performed during the first prenatal evaluation and need not be repeated if the pelvis is of adequate size and suitable shape. In the third trimester of pregnancy the examination of the bony pelvis may be more thorough, and the results more accurate because there is relaxation and increased mobility of the pelvic joints and ligaments as a result of hormonal influences. Widening of the joint of the symphysis pubis and the resulting instability may cause pain in any or all of the pelvic joints.

Because the examiner does not have direct access to the bony structures and because the bones are covered with varying amounts of soft tissue, estimates of size and shape are approximate. Precise bony pelvis measurements can be determined by use of computed tomography, ultrasound, or x-ray films. However, radiographic examination is rarely done during pregnancy because the x-ray may damage the developing fetus.

Soft Tissues

The soft tissues of the passageway include the distensible lower uterine segment, the cervix, the pelvic floor muscles, the vagina, and the introitus. Before labor begins the uterus is composed of the uterine body (corpus) and the cervix (neck). After labor has begun, uterine contractions cause the uterine body to have a thick and muscular upper segment and a thin-walled, passive, muscular lower segment. A *physiologic retraction ring* separates the two segments (Fig. 13-10). The lower uterine segment gradually distends to accommodate the intrauterine contents as the wall of the upper segment thickens and its accommodating capacity is reduced. The contractions of the uterine body thus exert downward pressure on the fetus, pushing it against the cervix.

The cervix effaces (thins) and dilates (opens) sufficiently to allow the first fetal portion to descend into the vagina. As the fetus descends, the cervix is actually drawn upward and over this first portion.

The pelvic floor is a muscular layer that separates the pelvic cavity above from the perineal space below. This structure helps the fetus rotate anteriorly as it passes through the birth canal. As noted earlier, the soft tissues of the vagina develop throughout pregnancy until at term the vagina can dilate to accommodate the fetus and permit its passage to the external world.

Powers

Involuntary and voluntary powers combine to expel the fetus and placenta from the uterus. Involuntary uterine contractions, called the *primary powers,* signal the beginning of labor. Once the cervix has dilated, voluntary bearing-down efforts by the woman, called the *secondary powers,* augment the force of the involuntary contractions.

Primary Powers

The involuntary contractions originate at certain pacemaker points in the thickened muscle layers of the upper uterine segment. From the pacemaker points contractions move downward over the uterus in waves, separated by short rest periods. Terms used to describe these involuntary contractions include *frequency* (the time from the beginning of one contraction to the beginning of the next), *duration* (length of contraction), and *intensity* (strength of contraction at its peak).

The primary powers are responsible for the effacement and dilation of the cervix and descent of the fetus. **Effacement** means the shortening and thinning of the cervix during the first stage of labor. The cervix, normally 2 to 3 cm long and about 1 cm thick, is obliterated or "taken up" by a shortening of the uterine muscle bundles during the thinning of the lower uterine segment that occurs in advancing labor. Only a thin edge of the cervix can be palpated when effacement is complete. Effacement generally is advanced in first-time term pregnancy before more than slight dilation occurs. In subsequent pregnancies effacement and dilation of the cervix tend to progress together. Degree of effacement is expressed in percentages, from 0% to 100% (e.g., a cervix is 50% effaced) (Fig. 13-11, *A* to *C*).

Dilation of the cervix is the enlargement or widening of the cervical opening and the cervical canal that occurs once labor has begun. The diameter of the cervix increases from less than 1 cm to full dilation (approximately 10 cm) to allow birth of a term fetus. When the cervix is fully dilated (and completely retracted), it can no longer be palpated (see Fig. 13-11, *D*). Full cervical dilation marks the end of the first stage of labor.

Dilation of the cervix occurs by the drawing upward of the musculofibrous components of the cervix caused by strong uterine contractions. Pressure exerted by the amniotic fluid while the membranes are intact or by the force applied by the presenting part can promote cervical dilation. Scarring of the cervix as a result of prior infection or surgery may slow cervical dilation.

TABLE 13-1 OBSTETRIC MEASUREMENTS

PLANE	DIAMETER	MEASUREMENTS
Inlet (Superior Strait)		
Conjugates		
Diagonal	12.5-13 cm	
Obstetric: measurement that determines whether presenting part can engage or enter superior strait	1.5-2 cm less than diagonal (radiographic)	
True (vera) (anteroposterior)	≥11 cm (12.5) (radiographic)	
		 Length of diagonal conjugate (solid colored line), obstetric conjugate (broken colored line), and true conjugate (blue line)*
Midplane		
Transverse diameter (interspinous diameter)	10.5 cm	
The midplane of the pelvis normally is its largest plane and the one of greatest diameter		 Measurement of interspinous diameter*
Outlet		
Transverse diameter (intertuberous diameter) (biischial)	≥8 cm	
The outlet presents the smallest plane of the pelvic canal		 Use of Thom's pelvimeter to measure intertuberous diameter*

TABLE 13-2 COMPARISON OF PELVIC TYPES

	GYNECOID *(50% of Women)*	ANDROID *(23% of Women)*	ANTHROPOID *(24% of Women)*	PLATYPELLOID *(3% of Women)*
Brim	Slightly ovoid or transversely rounded	Heart shaped, angulated	Oval, wider anteroposteriorly	Flattened anteroposteriorly, wide transversely
Shape	Round	Heart	Oval	Flat
Depth	Moderate	Deep	Deep	Shallow
Side walls	Straight	Convergent	Straight	Straight
Ischial spines	Blunt, somewhat widely separated	Prominent, narrow interspinous diameter	Prominent, often with narrow interspinous diameter	Blunted, widely separated
Sacrum	Deep, curved	Slightly curved, terminal portion often beaked	Slightly curved	Slightly curved
Subpubic arch	Wide	Narrow	Narrow	Wide
Usual mode of birth	Vaginal Spontaneous Occipitoanterior position	Cesarean Vaginal Difficult, with forceps	Vaginal Forceps/spontaneous Spontaneous Occipitoposterior or occipitoanterior position	Vaginal Spontaneous

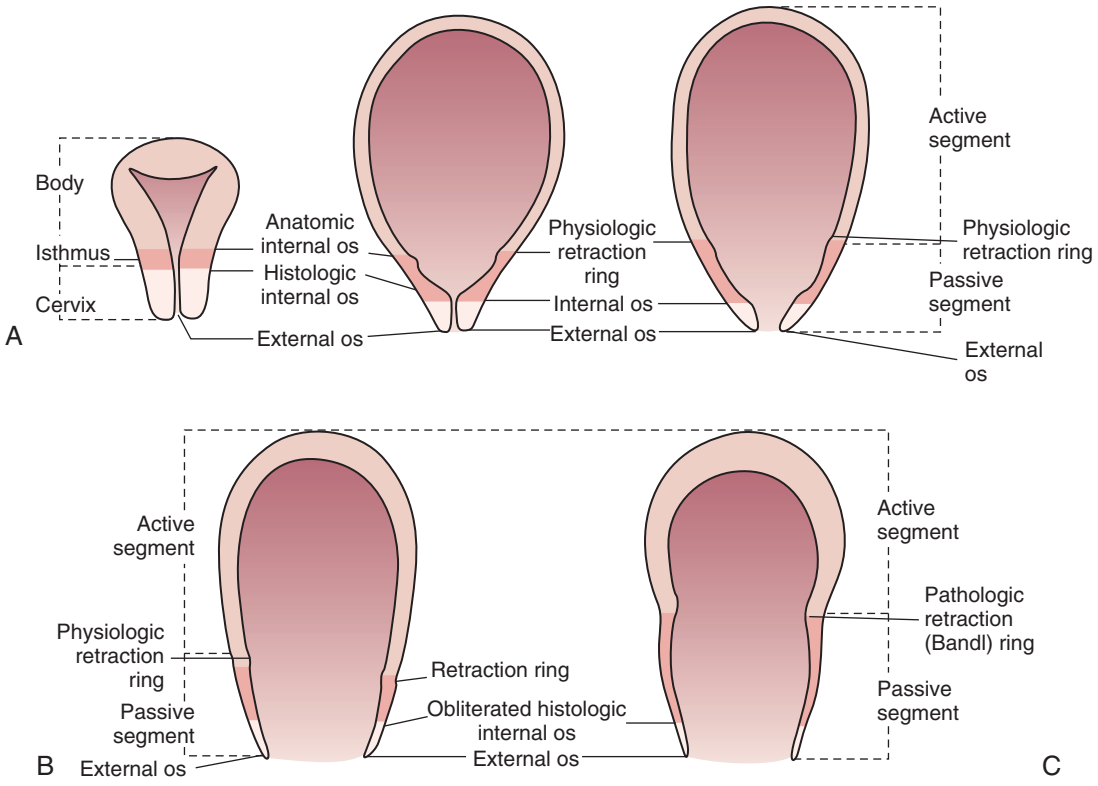

FIG 13-10 Uterus in normal labor **A,** in early first stage; and **B,** in second stage. Passive segment is derived from lower uterine segment (isthmus) and cervix, and physiologic retraction ring is derived from anatomic internal os. **C,** Uterus in abnormal labor in second-stage dystocia. Pathologic retraction (Bandl) ring that forms under abnormal conditions develops from physiologic ring.

In the first and second stages of labor increased intrauterine pressure caused by contractions exerts pressure on the descending fetus and the cervix. When the presenting part of the fetus reaches the perineal floor, mechanical stretching of the cervix occurs. Stretch receptors in the posterior vagina cause release of endogenous oxytocin that triggers the maternal urge to bear down, or the *Ferguson reflex*.

Uterine contractions are usually independent of external forces. For example, laboring women who are paralyzed because of spinal cord lesions above the twelfth thoracic vertebra have normal but

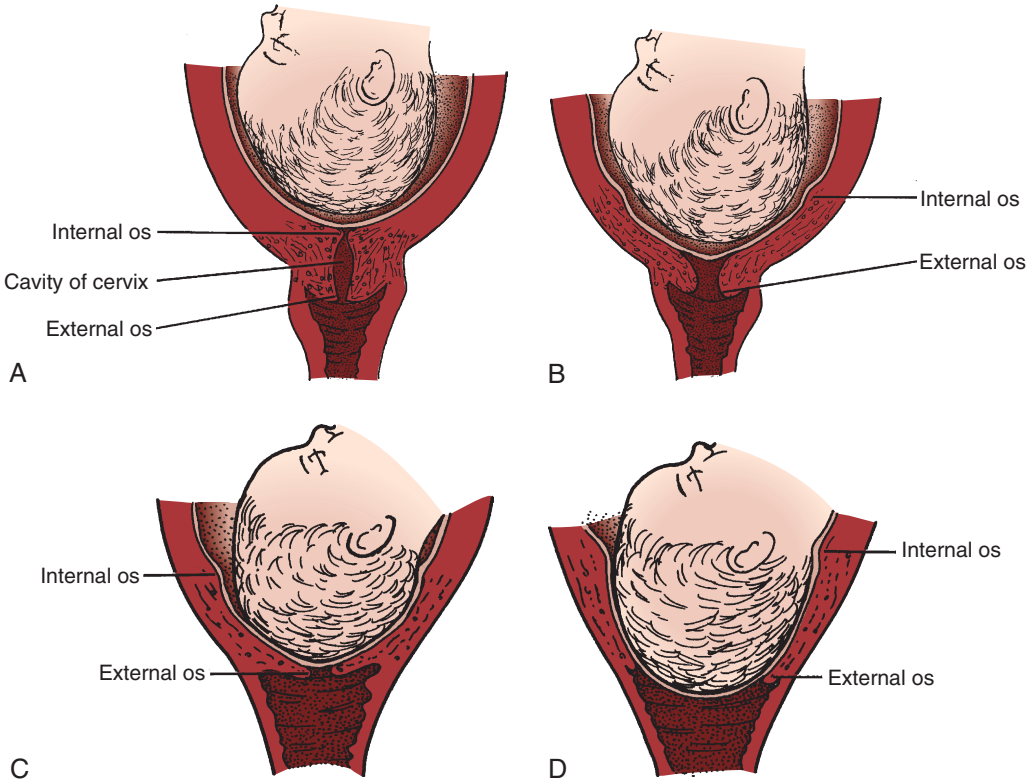

FIG 13-11 Cervical effacement and dilation. Note how cervix is drawn up around presenting part (internal os). Membranes are intact, and head is not well applied to cervix. **A,** Before labor. **B,** Early effacement. **C,** Complete effacement (100%). Head is well applied to cervix. **D,** Complete dilation (10 cm). Cranial bones overlap somewhat, and membranes are still intact.

painless uterine contractions (Cunningham, Leveno, Bloom, et al., 2010). However, uterine contractions may decrease in frequency and intensity temporarily if narcotic analgesic medication is given early in labor. Studies of effects of epidural analgesia have demonstrated lengthening of both the first and second stages of labor and slowing of the rate of fetal descent (Cunningham, Leveno, Bloom, et al., 2010).

Secondary Powers

As soon as the presenting part reaches the pelvic floor, the contractions change in character and become expulsive. The laboring woman experiences an involuntary urge to push. She uses secondary powers (bearing-down efforts) to aid in expulsion of the fetus as she contracts her diaphragm and abdominal muscles and pushes. These bearing-down efforts result in increased intraabdominal pressure that compresses the uterus on all sides and adds to the power of the expulsive forces.

The secondary powers have no effect on cervical dilation, but they are of considerable importance in the expulsion of the infant from the uterus and vagina after the cervix is fully dilated. When and how a woman pushes in the second stage of labor are much-debated topics. Continued study is needed to determine the effectiveness and appropriateness of strategies used by nurses to teach pushing techniques, the suitability and effectiveness of various pushing techniques related to abnormal fetal heart patterns, and the standards for length of pushing in terms of maternal and fetal outcomes. See Chapter 16 for further discussion regarding pushing during the second stage of labor.

Position of the Laboring Woman

Position affects the woman's anatomic and physiologic adaptations to labor. Frequent changes in position relieve fatigue, increase comfort, and improve circulation. Therefore a laboring woman should be encouraged to find positions that are most comfortable to her.

Positioning for second-stage labor may be determined by the woman's preference, but it is constrained by the condition of the woman or fetus, the environment, and the health care provider's confidence in assisting in a birth in a specific position. See Chapter 16 for further discussion of positioning during labor and birth.

PROCESS OF LABOR

The term *labor* refers to the process of moving the fetus, placenta, and membranes out of the uterus and through the birth canal. Various changes take place in the woman's reproductive system in the days and weeks before labor begins. Labor itself can be discussed in terms of the mechanisms involved in the process and the stages through which the woman moves.

Signs Preceding Labor

In first-time pregnancies the uterus sinks downward and forward about 2 weeks before term, when the presenting part of the fetus (usually the fetal head) descends into the true pelvis. This settling is called lightening, or "dropping," and usually happens gradually. After lightening women feel less congested and breathe more easily, but usually more bladder pressure results from this shift;

BOX 13-1 SIGNS PRECEDING LABOR

- Lightening
- Return of urinary frequency
- Backache
- Stronger Braxton Hicks contractions
- Weight loss of 0.5 to 1.5 kg
- Surge of energy
- Increased vaginal discharge; bloody show
- Cervical ripening
- Possible rupture of membranes

consequently there is a return of urinary frequency. In a multiparous pregnancy lightening may not take place until after uterine contractions are established and true labor is in progress.

The woman may complain of persistent low backache and sacroiliac distress as a result of relaxation of the pelvic joints. She may identify strong, frequent, but irregular uterine (Braxton Hicks) contractions.

The vaginal mucus becomes more profuse in response to the extreme congestion of the vaginal mucous membranes. Brownish or blood-tinged cervical mucus may be passed **(bloody show).** The cervix becomes soft (ripens) and partially effaced and may begin to dilate. The membranes may rupture spontaneously.

Other phenomena are common in the days preceding labor: (1) loss of 0.5 to 1.5 kg in weight caused by water loss resulting from electrolyte shifts that in turn are produced by changes in estrogen and progesterone levels; and (2) a surge of energy. Women speak of having a burst of energy that they often use to clean the house and put everything in order. Less commonly some women have diarrhea, nausea, vomiting, and indigestion. Box 13-1 lists signs that may precede labor.

Onset of Labor

The onset of true labor cannot be ascribed to a single cause. Many factors, including changes in the maternal uterus, cervix, and pituitary gland, are involved. Hormones produced by the normal fetal hypothalamus, pituitary, and adrenal cortex probably contribute to the onset of labor. Progressive uterine distention and increasing intrauterine pressure seem to be associated with increasing myometrial irritability. This is a result of increased concentrations of estrogen, oxytocin, and prostaglandins and decreasing progesterone levels. The mutually coordinated effects of these factors result in the occurrence of strong, regular, rhythmic uterine contractions (Blackburn, 2013; Kilpatrick and Garrison, 2012). The outcome of these factors working together is normally the birth of the fetus and the expulsion of the placenta; however, how certain alterations trigger others and the ways in which proper checks and balances are maintained are not known.

Stages of Labor

The course of labor at or near term gestation in a woman without complications and a fetus in vertex presentation consists of: (1) regular progression of uterine contractions, (2) effacement and progressive dilation of the cervix, and (3) progress in descent of the presenting part. Four stages of labor are recognized. An overview of these stages is included here. They are discussed in greater detail, along with nursing care for the laboring woman and family, in Chapter 16.

The *first stage of labor* is considered to last from the onset of regular uterine contractions to full dilation of the cervix. Commonly the onset of labor is difficult to establish because the woman may be admitted to the labor unit just before birth and the beginning of labor may be only an estimate. The first stage is much longer than the second and third combined. However, great variability is the rule, depending on the factors discussed previously in this chapter. The first stage of labor is divided into three phases: a latent phase, an active phase, and a transition phase. During the latent phase there is more progress in effacement of the cervix and little increase in descent. During the active and transition phases there is more rapid dilation of the cervix and increased rate of descent of the presenting part.

The *second stage of labor* lasts from the time the cervix is fully dilated to the birth of the fetus. It is composed of two phases: the latent phase and the active pushing (descent) phase. During the latent phase the fetus continues to descend passively through the birth canal and rotate to an anterior position as a result of ongoing uterine contractions. The urge to bear down during this phase is not strong, and some women do not experience it at all. During the active pushing phase the woman has strong urges to bear down as the presenting part of the fetus descends and presses on the stretch receptors of the pelvic floor.

The *third stage of labor* lasts from the birth of the fetus until the placenta is delivered. The placenta normally separates with the third or fourth strong uterine contraction after the infant has been born. After it has separated, the placenta can be delivered with the next uterine contraction.

The *fourth stage of labor* arbitrarily lasts about 2 hours after delivery of the placenta. It is the period of immediate recovery when homeostasis is reestablished. The fourth stage of labor is also the time when parent-child bonding and attachment begins and breastfeeding is initiated. It is an important period of observation for complications such as abnormal bleeding (see Chapter 21).

Mechanism of Labor

As already discussed, the female pelvis has varied contours and diameters at different levels, and the presenting part of the passenger is large in proportion to the passage. Therefore for vaginal birth to occur the fetus must adapt to the birth canal during the descent. The turns and other adjustments necessary in the human birth process are termed the *mechanism of labor* (Fig. 13-12). The seven cardinal movements of the mechanism of labor that occur in a vertex presentation are engagement, descent, flexion, internal rotation, extension, external rotation (restitution), and finally birth by expulsion. Although these movements are discussed separately, in actuality a combination of movements occurs simultaneously. For example, engagement involves both descent and flexion.

Engagement

When the biparietal diameter of the head passes the pelvic inlet, the head is said to be engaged in the pelvic inlet (see Fig. 13-12, *A*). In most nulliparous pregnancies this occurs before the onset of active labor because the firmer abdominal muscles direct the presenting part into the pelvis. In multiparous pregnancies in which the abdominal musculature is more relaxed, the head often remains freely movable above the pelvic brim until labor is established.

Asynclitism. The head usually engages in the pelvis in a synclitic position (i.e., one that is parallel to the anteroposterior plane of the pelvis). Frequently asynclitism occurs (the head is deflected anteriorly or posteriorly in the pelvis), which can facilitate descent because the head is being positioned to accommodate to the pelvic cavity (Fig. 13-13). Extreme asynclitism can cause cephalopelvic

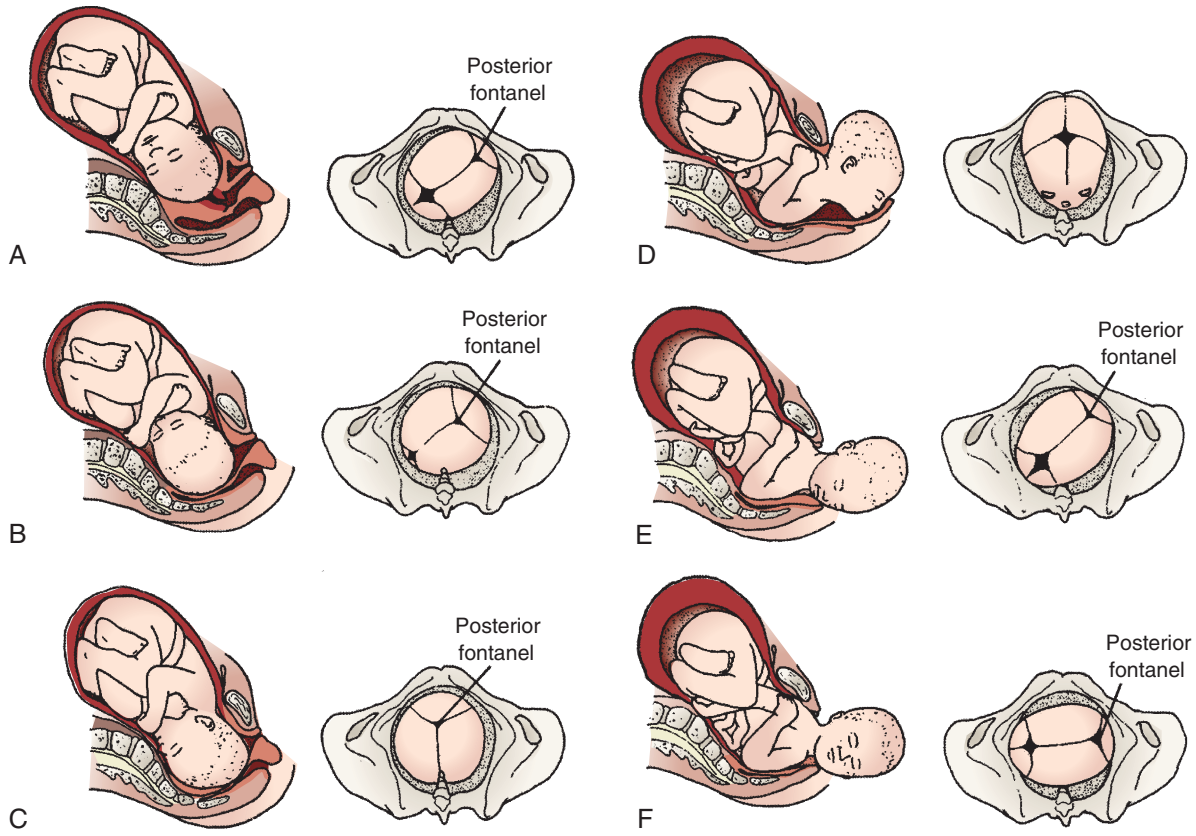

FIG 13-12 Cardinal movements of the mechanism of labor. Left occipitoanterior *(LOA)* position. Pelvic figures show position of fetal head as seen by birth attendant. **A,** Engagement and descent. **B,** Flexion. **C,** Internal rotation to occipitoanterior *(OA)* position. **D,** Extension. **E,** External rotation beginning (restitution). **F,** External rotation.

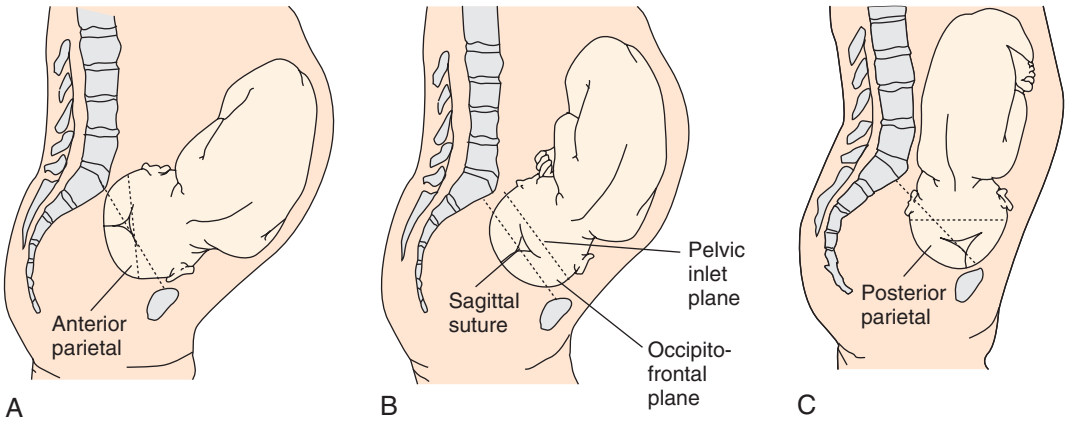

FIG 13-13 Synclitism and asynclitism. **A,** Anterior asynclitism. **B,** Normal synclitism. **C,** Posterior asynclitism.

disproportion, even in a normal-size pelvis, because the head is positioned so it cannot descend.

Descent

Descent refers to the progress of the presenting part through the pelvis. It depends on at least four forces: (1) pressure exerted by the amniotic fluid, (2) direct pressure exerted by the contracting fundus on the fetus, (3) force of the contraction of the maternal diaphragm and abdominal muscles in the second stage of labor, and (4) extension and straightening of the fetal body. The effects of these forces are modified by the size and shape of the maternal pelvic planes and the size of the fetal head and its capacity to mold.

The degree of descent is measured by the station of the presenting part (see Fig. 13-6). As mentioned, little descent occurs during the latent phase of the first stage of labor. Descent accelerates in the active phase when the cervix has dilated to 5 to 7 cm. It is especially apparent when the membranes have ruptured.

In a first-time pregnancy descent is usually slow but steady; in subsequent pregnancies descent may be rapid. Progress in descent of the presenting part is determined by abdominal palpation and vaginal examination until the presenting part can be seen at the introitus (see Chapter 16).

Flexion

As soon as the descending head meets resistance from the cervix, pelvic wall, or pelvic floor, it normally flexes so the chin is brought into closer contact with the fetal chest (see Fig. 13-12, *B*). Flexion permits the smaller suboccipitobregmatic diameter (9.5 cm) rather than the larger diameters to present to the outlet.

Internal Rotation

The maternal pelvic inlet is widest in the transverse diameter; therefore the fetal head passes the inlet into the true pelvis in the occipitotransverse position. The outlet is widest in the anteroposterior diameter; for the fetus to exit the head must rotate. Internal rotation begins at the level of the ischial spines but is not completed until the presenting part reaches the lower pelvis. As the occiput rotates anteriorly, the face rotates posteriorly. With each contraction the fetal head is guided by the bony pelvis and the muscles of the pelvic floor. Eventually the occiput will be in the midline beneath the pubic arch. The head is almost always rotated by the time it reaches the pelvic floor (see Fig. 13-12, *C*). Both the levator ani muscles and the bony pelvis are important for achieving anterior rotation. A previous childbirth injury or regional anesthesia may compromise the function of the levator sling.

Extension

When the fetal head reaches the perineum for birth, it is deflected anteriorly by the perineum. The occiput passes under the lower border of the symphysis pubis first, and the head emerges by extension: first the occiput, then the face, and finally the chin (see Fig. 13-12, *D*).

Restitution and External Rotation

After the head is born, it rotates briefly to the position it occupied when it was engaged in the inlet. This movement is referred to as restitution (see Fig. 13-12, *E*). The 45-degree turn realigns the infant's head with her or his back and shoulders. The head can then be seen to rotate further. This external rotation occurs as the shoulders engage and descend in maneuvers similar to those of the head (see Fig. 13-12, *F*). As noted earlier, the anterior shoulder descends first. When it reaches the outlet, it rotates to the midline and is delivered from under the pubic arch. The posterior shoulder is guided over the perineum until it is free of the vaginal introitus.

Expulsion

After birth of the shoulders, the head and shoulders are lifted up toward the mother's pubic bone, and the trunk of the baby is born by flexing it laterally in the direction of the symphysis pubis. When the baby has emerged completely, birth is complete, and the second stage of labor ends.

PHYSIOLOGIC ADAPTATION TO LABOR

In addition to the maternal and fetal anatomic adaptations that occur during birth, physiologic adaptations must occur. Accurate assessment of the laboring woman and fetus requires knowledge of these expected adaptations.

Fetal Adaptation

Several important physiologic adaptations occur in the fetus. These changes occur in fetal heart rate (FHR), fetal circulation, respiratory movements, and other behaviors.

Fetal Heart Rate

FHR monitoring provides reliable and predictive information about the condition of the fetus related to oxygenation. The average FHR at term is 140 beats/min. The normal range is 110 to 160 beats/min. Earlier in gestation the FHR is higher, with an average of approximately 160 beats/min at 20 weeks of gestation. The rate decreases progressively as the maturing fetus reaches term. However, temporary accelerations and slight early decelerations of the FHR can be expected in response to spontaneous fetal movement, vaginal examination, fundal pressure, uterine contractions, abdominal palpation, and fetal head compression. Stresses to the uterofetoplacental unit result in characteristic FHR patterns (see Chapter 15 for further discussion).

Fetal Circulation

Fetal circulation can be affected by many factors, including maternal position, uterine contractions, blood pressure, and umbilical cord blood flow. Uterine contractions during labor tend to decrease circulation through the spiral arterioles and subsequent perfusion through the intervillous space. Most healthy fetuses are well able to compensate for this stress and exposure to increased pressure while moving passively through the birth canal during labor. Usually the umbilical cord moves freely in the amniotic fluid. However, it can be compressed during uterine contractions (Blackburn, 2013; Miller, Miller, and Tucker, 2013).

Fetal Respiration

Certain changes stimulate chemoreceptors in the aorta and carotid bodies to prepare the fetus for initiating respirations immediately after birth (Blackburn, 2013; Rozance and Rosenberg, 2012). These changes include the following:

- Fetal lung fluid is cleared from the air passages as the infant passes through the birth canal during labor and (vaginal) birth.
- Fetal oxygen pressure (Po_2) decreases.
- Arterial carbon dioxide pressure (Pco_2) increases.
- Arterial pH decreases.
- Bicarbonate level decreases.
- Fetal respiratory movements decrease during labor.

Maternal Adaptation

As the woman progresses through the stages of labor, various body system adaptations cause her to exhibit both objective and subjective symptoms (Box 13-2).

Cardiovascular Changes

During each contraction an average of 400 mL of blood is emptied from the uterus into the maternal vascular system. By the end of the first stage of labor cardiac output during contractions is increased by 51% above baseline pregnancy values at term. Cardiac output peaks about 10 to 30 minutes after both vaginal and cesarean birth and returns to its prelabor baseline within the first postpartum hour. A drop in maternal heart rate accompanies this increase in cardiac output (Gordon, 2012).

Changes in blood pressure also occur. In general, both systolic and diastolic pressures increase during contractions and return to baseline levels between contractions. Systolic values increase more than diastolic values (Blackburn, 2013).

BOX 13-2 MATERNAL PHYSIOLOGIC CHANGES DURING LABOR

- Cardiac output increases 10% to 15% in first stage; 30% to 50% in second stage.
- Heart rate increases slightly in first and second stages.
- Systolic blood pressure increases during uterine contractions in first stage; systolic and diastolic pressures increase during uterine contractions in second stage.
- White blood cell count increases.
- Respiratory rate increases.
- Temperature may be slightly elevated.
- Proteinuria may occur.
- Gastric motility and absorption of solid food are decreased; nausea and vomiting may occur during transition to second-stage labor.
- Blood glucose level decreases.

CRITICAL THINKING CASE STUDY

Anxiety in a Multipara in Active Labor

Jody was admitted in active labor to an LDR room 2 hours ago. She is a 24-year-old G2 P1 at 39 weeks of gestation. She is noticeably anxious and tells you that her first pregnancy ended at term but that the labor was "terrible. It was 22 hours long. I had an epidural but had to push and push to get the baby out." Which interventions are appropriate?

1. Evidence—Is there sufficient evidence to draw any conclusions about which intervention is needed?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Effect of anxiety on progress in labor
   b. Effect of parity on labor
   c. Effect of epidural analgesia on length of labor
   d. Effect of epidural analgesia on ability to push
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

LDR, Labor, delivery, and recovery.

Supine hypotension (see Fig. 16-5) occurs when the ascending vena cava and descending aorta are compressed. The laboring woman is at greater risk for supine hypotension if the uterus is particularly large because of multifetal pregnancy or polyhydramnios or if she is obese, dehydrated, or hypovolemic. In addition, anxiety, pain, and some medications can cause hypotension.

The woman should be discouraged from using the Valsalva maneuver (holding one's breath and tightening abdominal muscles) for pushing during the second stage. This activity increases intrathoracic pressure, reduces venous return, and increases venous pressure. Cardiac output and blood pressure increase, and the pulse slows temporarily. During the Valsalva maneuver fetal hypoxia may occur. The process is reversed when the woman takes a breath.

The white blood cell (WBC) count can increase (Blackburn, 2013). Although the mechanism leading to this increase in WBCs is unknown, it may be secondary to physical or emotional stress or tissue trauma. Labor is strenuous, and physical exercise alone can increase the WBC count.

Some peripheral vascular changes occur, perhaps in response to cervical dilation or compression of maternal vessels by the fetus passing through the birth canal. Flushed cheeks, hot or cold feet, and eversion of hemorrhoids may result.

Respiratory Changes

Increased physical activity with greater oxygen consumption is reflected in an increase in the respiratory rate. Hyperventilation may cause respiratory alkalosis (an increase in pH), hypoxia, and hypocapnia (decrease in carbon dioxide). In the unmedicated woman in the second stage oxygen consumption almost doubles. Anxiety also increases oxygen consumption.

Renal Changes

During labor spontaneous voiding may be difficult for various reasons: tissue edema caused by pressure from the presenting part, discomfort, analgesia, and embarrassment. Proteinuria of 1+ is a normal finding because it can occur in response to the breakdown of muscle tissue from the physical work of labor.

Integumentary Changes

The integumentary system changes are evident, especially in the great distensibility (stretching) in the area of the vaginal introitus. The degree of distensibility varies with the individual. Despite this ability to stretch, even in the absence of episiotomy or lacerations, minute tears in the skin around the vaginal introitus occur.

Musculoskeletal Changes

The musculoskeletal system is stressed during labor. Diaphoresis, fatigue, proteinuria (1+), and possibly an increased temperature accompany the marked increase in muscle activity. Backache and joint ache (unrelated to fetal position) occur as a result of increased joint laxity at term. The labor process itself and the woman's pointing her toes can cause leg cramps.

Neurologic Changes

Sensorial changes occur as the woman moves through the phases of the first stage of labor and from one stage to the next. Initially she may be euphoric. Euphoria gives way to increased seriousness, then to amnesia between contractions during the second stage, and finally to elation or fatigue after giving birth. Endogenous endorphins (morphinelike chemicals produced naturally by the body) raise the pain threshold and produce sedation. In addition, physiologic anesthesia of perineal tissues caused by pressure of the presenting part decreases perception of pain (see Critical Thinking Case Study).

Gastrointestinal Changes

During labor gastrointestinal motility and absorption of solid foods are decreased, and stomach-emptying time is slowed. Nausea and vomiting of undigested food eaten after the onset of labor are common. Nausea and belching also occur as a reflex response to full cervical dilation. The woman may state that diarrhea accompanied the onset of labor, or the nurse may palpate the presence of hard or impacted stool in the rectum.

Endocrine Changes

The onset of labor may be triggered by decreasing levels of progesterone and increasing levels of estrogen, prostaglandins, and oxytocin (Norwitz and Lye, 2009). Metabolism increases, and blood glucose levels may decrease with the work of labor.

KEY POINTS

- Labor and birth are affected by the five Ps: *p*assenger, *p*assageway, *p*owers, *p*osition of the woman, and *p*sychologic response.
- Because of its size and relative rigidity, the fetal head is a major factor in determining the course of birth.
- The diameters at the plane of the pelvic inlet, the midpelvis, and the outlet plus the axis of the birth canal determine whether vaginal birth is possible and the manner in which the fetus passes down the birth canal.
- Involuntary uterine contractions act to expel the fetus and placenta during the first stage of labor; these are augmented by voluntary bearing-down efforts during the second stage.
- The first stage of labor lasts from the time dilation begins to the time when the cervix is fully dilated.
- The second stage of labor lasts from the time of full cervical dilation to the birth of the infant.
- The third stage of labor lasts from the infant's birth to the expulsion of the placenta.
- The fourth stage of labor is the first 2 hours after birth.
- The cardinal movements of the mechanism of labor are engagement, descent, flexion, internal rotation, extension, restitution and external rotation, and expulsion of the infant.
- Although the events precipitating the onset of labor are unknown, many factors, including changes in the maternal uterus, cervix, and pituitary gland, are thought to be involved.
- A healthy fetus with an adequate uterofetoplacental circulation is able to compensate for the stress of uterine contractions.
- As the woman progresses through labor, various body systems adapt to the birth process.

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe breathing and relaxation techniques used for each stage of labor.
- Identify nonpharmacologic strategies to enhance relaxation and decrease pain during labor.
- Compare pharmacologic methods used to relieve pain in different stages of labor and for vaginal or cesarean birth.
- Describe nursing responsibilities appropriate in providing care for a woman receiving analgesia and anesthesia during labor.

Pain is an unpleasant, complex, highly individualized phenomenon with sensory and emotional components. Pregnant women commonly worry about the pain they will experience during labor and birth and about how they will react to and deal with that pain. A variety of nonpharmacologic and pharmacologic methods can help the woman or the couple cope with the pain of labor. The methods selected depend on the situation, the availability, and the preferences of the woman and her health care provider. This chapter will discuss sources of intrapartum pain and factors that affect women's response to pain. It will also describe nonpharmacologic and pharmacologic methods commonly used for pain relief.

PAIN DURING LABOR AND BIRTH

Neurologic Origins

The pain and discomfort of labor have two origins—visceral and somatic. During the first stage of labor, uterine contractions cause cervical dilation and effacement. Uterine ischemia (decreased blood flow and therefore local oxygen deficit) results from compression of the arteries supplying the myometrium during uterine contractions. Pain impulses during the first stage of labor are transmitted via the T10 to T12 and L1 spinal nerve segments and accessory lower thoracic and upper lumbar sympathetic nerves. These nerves originate in the uterine body and cervix (Blackburn, 2013).

The pain from distention of the lower uterine segment, stretching of cervical tissue as it effaces and dilates, pressure and traction on adjacent structures (e.g., uterine tubes, ovaries, ligaments) and nerves, and uterine ischemia during the first stage of labor is visceral pain. It is located over the lower portion of the abdomen. Referred pain occurs when pain that originates in the uterus radiates to the abdominal wall, lumbosacral area of the back, iliac crests, gluteal area, thighs, and lower back (Blackburn, 2013; Zwelling, Johnson, and Allen, 2006).

During most of the first stage of labor, the woman usually has discomfort only during contractions and is free of pain between contractions. Some women, especially those whose fetus is in a posterior position, experience continuous contraction-related low back pain, even in the interval between contractions. As labor progresses and pain becomes more intense and persistent, women become fatigued and discouraged, often experiencing difficulty coping with contractions (Creehan, 2008; Zwelling, Johnson, and Allen, 2006).

During the second stage of labor, the woman has somatic pain, which is often described as intense, sharp, burning, and well localized. This pain results from:

- Distention and traction on the peritoneum and uterocervical supports during contractions
- Pressure against the bladder and rectum
- Stretching and distention of perineal tissues and the pelvic floor to allow passage of the fetus
- Lacerations of soft tissue (e.g., cervix, vagina, and perineum)

As women concentrate on the work of bearing down to give birth to their baby, they may report a decrease in pain intensity (Blackburn, 2013; Creehan, 2008). Pain impulses during the second stage of labor are transmitted via the pudendal nerve through S2 to S4 spinal nerve segments and the parasympathetic system (Blackburn, 2013).

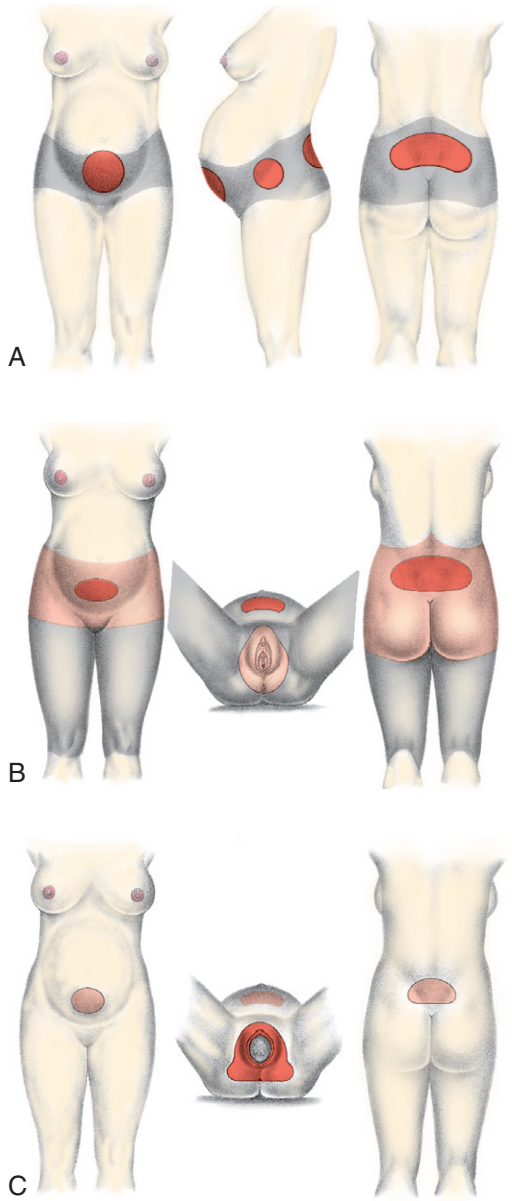

FIG 14-1 Pain during labor. **A,** Distribution of labor pain during first stage. **B,** Distribution of labor pain during transition and early phase of second stage. **C,** Distribution of pain during late second-stage and actual birth. (*Gray areas* indicate mild discomfort; *light pink areas* indicate moderate discomfort; *dark red areas* indicate intense discomfort.)

Pain experienced during the third stage of labor and the **afterpains** of the early postpartum period are uterine, similar to the pain experienced early in the first stage of labor. Areas of pain during labor are shown in Fig. 14-1.

Perception of Pain

Although the **pain threshold** is remarkably similar in everyone regardless of gender, social, ethnic, or cultural differences, these differences play a definite role in the person's perception of and behavioral responses to pain. The effects of factors such as culture, counterstimuli, and distraction in coping with pain are not fully understood. The meaning of pain and the verbal and nonverbal expressions given to pain are apparently learned from interactions within the primary social group. Cultural influences may impose certain behavioral expectations regarding acceptable and unacceptable behavior when experiencing pain.

Pain tolerance refers to the level of pain a laboring woman is willing to endure. When this level is exceeded, she will seek measures to relieve the pain. Factors that influence a woman's pain tolerance level and her request for pharmacologic pain relief measures include her desire for a natural, vaginal birth; her preparation for childbirth; the nature of her support during labor; and her willingness and ability to participate in nonpharmacologic measures for comfort (Creehan, 2008).

Expression of Pain

Pain results in physiologic effects and sensory and emotional (affective) responses. During childbirth, pain gives rise to identifiable physiologic effects. Sympathetic nervous system activity is stimulated in response to intensifying pain, resulting in increased catecholamine levels. Blood pressure and heart rate increase. Maternal respiratory patterns change in response to an increase in oxygen consumption. Hyperventilation, sometimes accompanied by respiratory alkalosis, can occur as pain intensifies and more rapid, shallow breathing techniques are used during contractions. Pallor and diaphoresis may be seen. Gastric acidity increases, and nausea and vomiting are common in the active and transition phases of the first stage of labor. Placental perfusion may decrease, and uterine activity may diminish, potentially prolonging labor and affecting fetal well-being.

Certain emotional (affective) expressions of pain often are seen. Such changes include increasing anxiety with lessened perceptual field, writhing, crying, groaning, gesturing (hand clenching and wringing), and excessive muscular excitability throughout the body.

FACTORS INFLUENCING PAIN RESPONSE

Pain during childbirth is unique to each woman. How she perceives or interprets that pain is influenced by a variety of physiologic, psychologic, emotional, social, cultural, and environmental factors (Zwelling, Johnson, and Allen, 2006).

Physiologic Factors

A variety of physiologic factors can affect the intensity of childbirth pain. Women with a history of dysmenorrhea may experience increased pain during childbirth as a result of higher prostaglandin levels. Back pain associated with menstruation also may increase the likelihood of contraction-related low back pain. Other physical factors that affect pain intensity include fatigue, the interval and duration of contractions, fetal size and position, rapidity of fetal descent, and maternal position (Zwelling, Johnson, and Allen, 2006).

Beta (β) endorphins are endogenous opioids secreted by the pituitary gland that act on the central and peripheral nervous systems to reduce pain. The level of β endorphins increases during pregnancy and birth in humans. β endorphins are associated with feelings of euphoria and analgesia. The pain threshold may rise as β endorphin levels increase, enabling women in labor to tolerate acute pain (Blackburn, 2013).

Culture

The population of pregnant women reflects the increasingly multicultural nature of society in the United States. As nurses care for women and families from a variety of cultural backgrounds, they must have knowledge and understanding of how culture mediates pain. Although all women expect to experience at least some pain

and discomfort during childbirth, it is their culture and religious belief system that determines how they will perceive, interpret, and respond to and manage the pain. For example, women with strong religious beliefs often accept pain as a necessary and inevitable part of bringing a new life into the world (Callister, Khalaf, Semenic, et al., 2003). An understanding of the beliefs, values, expectations, and practices of various cultures will narrow the cultural gap and help the nurse assess the laboring woman's pain experience more accurately. The nurse can then provide appropriate, culturally sensitive care by using pain relief measures that preserve the woman's sense of control and self-confidence (see Cultural Competence box). Recognize that although a woman's behavior in response to pain may vary according to her cultural background, it may not accurately reflect the intensity of the pain she is experiencing. Assess the woman for the physiologic effects of pain, and listen to the words she uses to describe the sensory and affective qualities of her pain (see Community Focus box).

Anxiety

Anxiety is commonly associated with increased pain during labor. Mild anxiety is considered normal for a woman during labor and birth. However, excessive anxiety and fear cause more catecholamine secretion, which increases the stimuli to the brain from the pelvis because of decreased blood flow and increased muscle tension. This action, in turn, magnifies **pain perception.** Thus as anxiety and fear heighten, muscle tension increases, the effectiveness of uterine contractions decreases, the experience of discomfort increases, and a cycle of increased fear and anxiety begins (Blackburn, 2013). Ultimately this cycle will slow the progress of labor. The woman's confidence in her ability to cope with pain will be diminished, potentially resulting in reduced effectiveness of the pain relief measures being used.

Previous Experience

Previous experience with pain and childbirth may affect a woman's description of her pain and her ability to cope with the pain. Childbirth for a healthy young woman may be her first experience with significant pain, and as a result, she may not have developed effective pain coping strategies. She may describe the intensity of even early labor pain as pain "as bad as it can be." The nature of previous childbirth experiences also may affect a woman's responses to pain. For women who have had a difficult and painful previous birth experience, anxiety and fear from this past experience may lead to increased pain perception.

Sensory pain for nulliparous women is often greater than that for multiparous women during early labor (dilation less than 5 cm) because their reproductive tract structures are less supple. During the transition phase of the first stage of labor and during the second stage of labor, multiparous women may experience greater sensory pain than nulliparous women because their more supple tissue increases the speed of fetal descent and thereby intensifies pain. The firmer tissue of nulliparous women results in a slower, more gradual descent. Affective pain is usually greater for nulliparous women throughout the first stage of labor but decreases for both nulliparous and multiparous women during the second stage of labor (Lowe, 2002). Parity may also influence the perception of labor pain because nulliparous women often have longer labors and therefore greater fatigue.

Fatigue and sleep deprivation magnify pain. Most women have a decrease in quality of sleep over the last few days of pregnancy, and the spontaneous onset of labor occurs most often during the night (Beebe and Lee, 2007). Thus many women have an increased perception of the intensity of pain during labor.

Gate-Control Theory of Pain

Even particularly intense pain stimuli can at times be ignored. This is possible because certain nerve cell groupings within the spinal cord, brainstem, and cerebral cortex have the ability to modulate the pain impulse through a blocking mechanism. This gate-control theory of pain helps explain the way hypnosis and the pain relief techniques taught in childbirth preparation classes work to relieve the pain of labor. According to this theory, pain sensations travel along sensory nerve pathways to the brain but only a limited number of sensations, or messages, can travel through these nerve pathways at one time. Using distraction techniques such as massage or stroking, music, focal points, and imagery reduces or completely blocks the capacity of nerve pathways to transmit pain. These distractions are thought to work by closing down a hypothetic gate in the spinal cord, thus preventing pain signals from reaching the brain. The perception of pain is thereby diminished.

In addition, when the laboring woman engages in neuromuscular and motor activity, activity within the spinal cord itself further modifies the transmission of pain. Cognitive work involving

CULTURAL COMPETENCE

Some Cultural Beliefs About Pain

The following examples demonstrate how women of different cultural backgrounds may react to pain. Because they are generalizations, the nurse must assess each woman experiencing pain related to childbirth.

- Chinese women may not exhibit reactions to pain, although exhibiting pain during childbirth is acceptable. They consider accepting something when it is first offered as impolite; therefore pain interventions must be offered more than once. Acupuncture may be used for pain relief.
- Arab or Middle Eastern women may be vocal in response to labor pain. They may prefer medication for pain relief.
- Japanese women may be stoic in response to labor pain, but they may request medication when pain becomes severe.
- Southeast Asian women may endure severe pain before requesting relief.
- Hispanic women may be stoic until late in labor, when they may become vocal and request pain relief.
- Native-American women may use medications or remedies made from indigenous plants. They are often stoic in response to labor pain.
- African-American women may express pain openly. Use of medication for pain relief varies.

COMMUNITY FOCUS

Culture and Pain

Talk to a man and a woman from a culture different from your own who have experienced childbirth. Ask her to describe her reactions to pain, how she sought relief of pain, the atmosphere of the childbirth setting, and the attitudes of the health care providers. Ask him if he was present for the birth and what his role in the birth was. How did his culture influence his role and reaction to childbirth? How did her culture influence her response to labor and the associated pain? What expressions of pain are "acceptable" in her culture? If he was present, how did he help her deal with the pain? What is the role of support persons in the labor process? Are the responses of the couple different from your responses to those same questions?

BOX 14-1 SUGGESTED MEASURES FOR SUPPORTING A WOMAN IN LABOR

- Provide companionship and reassurance.
- Offer positive reinforcement and praise for her efforts.
- Encourage participation in distracting activities and nonpharmacologic measures for comfort.
- Give nourishment (if allowed by primary health care provider).
- Assist with personal hygiene.
- Offer information and advice.
- Involve the woman in decision making regarding her care.
- Interpret the woman's wishes to other health care providers and to her support group.
- Create a relaxing environment.
- Use a calm and confident approach.
- Support and encourage the woman's family members by role modeling labor support measures and providing time for breaks.

concentration on breathing and relaxation requires selective and directed cortical activity that activates and closes the gating mechanism as well. As labor intensifies, more complex cognitive techniques are required to maintain effectiveness. The gate-control theory underscores the need for a supportive birth setting that allows the laboring woman to relax and use various higher mental activities.

Comfort

Although the predominant medical approach to labor is that it is painful and the pain must be removed, an alternative view is that labor is a natural process and women can experience comfort and transcend the discomfort or pain to reach the joyful outcome of birth. Having needs and desires met promotes a feeling of comfort. The most helpful interventions in enhancing comfort are a caring nursing approach and a supportive presence.

Support

Current evidence indicates that a woman's satisfaction with her labor and birth experience is determined by how well her personal expectations of childbirth were met and the quality of support and interaction she received from her caregivers (Box 14-1). In addition, satisfaction is influenced by the degree to which she was able to stay in control of her labor and to participate in decision making regarding her labor, including the pain relief measures to be used (Albers, 2007; Zwelling, Johnson, and Allen, 2006).

The value of the continuous supportive presence of a person (e.g., doula, childbirth educator, family member, friend, nurse, or partner) during labor who provides physical comforting, facilitates communication, and offers information and guidance to the woman in labor has long been known. Emotional support is demonstrated by giving praise and reassurance and conveying a positive, calm, and confident demeanor when caring for the woman in labor (Creehan, 2008). It is interesting to note that research findings have concluded that a more positive effect is achieved when the continuous support is provided by people who are not hospital staff members (Hodnett, Gates, Hofmeyr, et al., 2011).

Environment

The quality of the environment can influence pain perception and the laboring woman's ability to cope with her pain. Environment includes the individuals present (e.g., how they communicate, their philosophy of care including a belief in the value of nonpharmacologic pain relief measures, practice policies, and quality of support) and the physical space in which the labor occurs (Creehan, 2008; Zwelling, Johnson, and Allen, 2006). Women usually prefer to be cared for by familiar caregivers in a comfortable, homelike setting. The environment should be safe and private, allowing a woman to feel free to be herself as she tries out different comfort measures. Stimuli such as light, noise, and temperature should be adjusted according to her preferences. The environment should have space for movement and equipment such as birth balls. Comfortable chairs, tubs, and showers should be readily available to facilitate participation in a variety of nonpharmacologic pain relief measures. The familiarity of the environment can be enhanced by bringing items from home such as pillows, objects for a focal point, music, and DVDs.

NONPHARMACOLOGIC PAIN MANAGEMENT

The alleviation of pain is important. Commonly it is not the amount of pain the woman experiences but whether she meets the goals she set for herself to cope with the pain that influences her perception of the birth experience as good or bad. The observant nurse looks for clues to the woman's desired level of control in the management of pain and its relief.

Nonpharmacologic measures are often simple and safe, have few if any major adverse reactions, are relatively inexpensive, and can be used throughout labor. In addition, they provide the woman with a sense of control over her childbirth as she makes choices about the measures that are best for her. During the prenatal period, she should explore a variety of nonpharmacologic measures. Techniques she usually finds helpful in relieving stress and enhancing relaxation (e.g., music, meditation, massage, warm baths) may be very effective as components of a plan for managing labor pain. The woman should be encouraged to communicate to her health care providers her preferences for relaxation and pain relief measures and to actively participate in their implementation.

Many of the nonpharmacologic methods for relief of discomfort are taught in different types of prenatal preparation classes, or the woman or couple may have read various books and magazine articles on the subject in advance. Many of these methods require practice for best results (e.g., hypnosis, patterned breathing and controlled relaxation techniques, biofeedback), although the nurse may use some of them successfully without the woman or couple having prior knowledge (e.g., slow-paced breathing, massage and touch, effleurage, counterpressure). Women should be encouraged to try a variety of methods. Often nonpharmacologic methods are used in combination with pharmacologic methods, particularly as labor progresses.

With the increasing use of epidural analgesia, nurses may be less likely to encourage women to use nonpharmacologic measures, in part because these methods may be viewed as more complex and time consuming than monitoring a woman receiving an epidural. In addition, new nurses may not have had the opportunity to develop skill in the implementation of these methods. It is imperative that perinatal nurses develop a commitment to and expertise in using a variety of nonpharmacologic pain relief strategies in order for women in labor to be comfortable using them. Although research data to support the effectiveness of many of these nonpharmacologic measures are limited, there are sufficient reports of their benefits from women and health care providers to recommend that nurses encourage their use (Creehan, 2008). The analgesic effect of many nonpharmacologic measures is comparable

BOX 14-2 NONPHARMACOLOGIC STRATEGIES TO ENCOURAGE RELAXATION AND RELIEVE PAIN

Cutaneous Stimulation Strategies
- Counterpressure
- Effleurage (light massage)
- Therapeutic touch and massage
- Walking
- Rocking
- Changing positions
- Application of heat or cold
- Transcutaneous electrical nerve stimulation (TENS)
- Acupressure
- Water therapy (showers, whirlpool baths)
- Intradermal water block

Sensory Stimulation Strategies
- Aromatherapy
- Breathing techniques
- Music
- Imagery
- Use of focal points

Cognitive Strategies
- Childbirth education
- Hypnosis
- Biofeedback

FIG 14-2 Expectant parents learning relaxation techniques. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

to or even superior to opioids that are administered parenterally (Box 14-2).

Childbirth Preparation Methods

The childbirth education movement began in the 1950s. Today most health care providers recommend or offer childbirth preparation classes for expectant parents. Historically, popular childbirth methods taught in the United States were the Dick-Read method, the Lamaze (psychoprophylaxis) method, and the Bradley (husband-coached childbirth) method. Although these three organizations continue to exist, they are now less focused on a "method" approach. Rather, women are assisted to develop their birth philosophy and inner knowledge and then choose from a variety of skills to use to cope with the labor process. Many childbirth educators teach a variety of techniques that originated in several different organizations or publications. Women are encouraged to choose the techniques that work best for them.

Gaining popularity are methods developed and promoted by Birthing From Within, Birthworks, Association of Labor Assistants and Childbirth Educators (ALACE), Childbirth and Postpartum Professional Association (CAPPA), and HypnoBirthing, to name a few. These methods offer classes and other services that focus on fostering a woman's confidence in her innate ability to give birth. The woman or couple are helped to recognize the uniqueness of their pregnancy and childbirth experience.

Relaxation and Breathing Techniques

Relaxation

Relaxation or reduction of body tension is a technique suggested by virtually all childbirth education organizations. Learning relaxation in childbirth education classes can help couples with the stresses of pregnancy, childbirth, and adjustment to parenting and can be a form of stress management throughout life (Fig. 14-2). Evidence suggests that relaxation may improve the management of labor pain (Jones, Othman, Dowswell, et al., 2012). Relaxation is ideally combined with activity such as walking, slow dancing, rocking, and position changes that help the baby rotate through the pelvis. Rhythmic motion stimulates mechanoreceptors in the brain, which decreases pain perception.

The nurse can assist the woman by providing a quiet and relaxed environment, offering cues as needed, and recognizing signs of tension (e.g., frowning, change in tone of voice, clenching of fists). A relaxed environment for labor is created by controlling sensory stimuli (e.g., light, noise, temperature) and reducing interruptions. Nurses should remain calm and unhurried in their approach and sit rather than stand at the bedside whenever possible (Creehan, 2008).

Imagery and Visualization

Imagery and visualization are useful techniques in preparation for birth and are often used in combination with relaxation. Although research on their use is scant, clinical reports suggest that imagery and visualization can be used to produce a sense of well-being during pregnancy, assist with cervical dilation, and decrease the experience of pain and tension during labor. Imagery involves techniques such as imagining a walk through a restful garden or breathing in light, energy, and healing color and breathing out worries and tension. A variety of skills taught in childbirth classes augment relaxation during pregnancy and labor. All can be taught as lifetime skills useful to the couple and can be used to teach their children to cope with the stresses of life.

Breathing Techniques

Different approaches to childbirth preparation stress varying breathing techniques to provide distraction, thereby reducing the perception of pain and helping the woman maintain control throughout contractions. In the first stage of labor, such breathing techniques can promote relaxation of the abdominal muscles and thereby increase the size of the abdominal cavity. This lessens discomfort generated by friction between the uterus and abdominal wall during contractions. Because the muscles of the genital area also become more relaxed, they do not interfere with fetal descent. In the second stage, breathing is used to increase abdominal pressure and thereby assist in expelling the fetus. Breathing also can be used to relax the pudendal muscles to prevent precipitate expulsion of the fetal head (Fig. 14-3).

For couples who have prepared for labor by practicing relaxing and breathing techniques, a simple review with occasional reminders may be all that is necessary to help them along. For those who

FIG 14-3 A laboring woman using breathing techniques during a uterine contraction with coaching from her partner. (Courtesy Marjorie Pyle, RNC, Lifecircle, Costa Mesa, CA.)

CRITICAL THINKING CASE STUDY

Laboring Without an Epidural

Jamie is a 16-year-old G1 P0 who has been admitted with severe preeclampsia (HELLP syndrome) at 34 weeks of gestation. Jamie's physician plans to induce labor and anticipates a vaginal birth. Jamie has not attended any childbirth preparation classes and has been planning to have an epidural for labor and birth. Unfortunately, because her platelet count is very low (28,000), the anesthesia care provider refuses to place an epidural block. Jamie bursts into tears and says, "I can't make it through labor without an epidural! It's going to hurt too much! Help me!!"

1. Evidence—Is there sufficient evidence regarding avoiding regional anesthesia in women who have low platelet counts?
2. Assumptions—Describe an underlying assumption about each of the following nonpharmacologic or pharmacologic methods for pain relief during labor.
   a. Breathing and relaxation techniques
   b. Application of heat and cold
   c. Systemic analgesia
   d. Presence of a support person to increase effectiveness of interventions for pain
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

HELLP, ***H****emolysis,* ***E****levated* ***L****iver enzymes,* ***L****ow* ***P****latelet count.*

have had no preparation, instruction and practice in simple breathing and relaxation techniques can be given early in labor and often is surprisingly successful. Nurses can also model breathing techniques and breathe in synchrony with the woman and her partner. Motivation is high and readiness to learn is enhanced by the reality of labor (see Critical Thinking Case Study).

Various breathing techniques can be used for controlling pain during contractions (Box 14-3). The nurse needs to determine what, if any, techniques the laboring couple know before giving them instruction. Simple patterns are more easily learned. Paced breathing is most associated with prepared childbirth and includes slow-paced, modified-paced, and patterned-paced breathing (pant-blow) techniques. Each labor is different, and nursing support includes

BOX 14-3 PACED BREATHING TECHNIQUES

Cleansing Breath

- Relaxed breath in through nose and out through mouth. Used at the beginning and end of each contraction.

Slow-Paced Breathing (Approximately 6 to 8 Breaths per Minute)

- Performed at approximately half the normal breathing rate (number of breaths per minute divided by 2)
- IN-2-3-4/OUT-2-3-4/IN-2-3-4/OUT-2-3-4 …

Modified-Paced Breathing (Approximately 32 to 40 Breaths per Minute)

- Performed at about twice the normal breathing rate (number of breaths per minute multiplied by 2)
- IN-OUT/IN-OUT/IN-OUT/IN-OUT …
- For more flexibility and variety, the woman may combine the slow and modified breathing by using the slow breathing for beginnings and ends of contractions and modified breathing for more intense peaks. This technique conserves energy, lessens fatigue, and reduces risk for hyperventilation.

Patterned-Paced or Pant-Blow Breathing (Same Rate as Modified)

- Enhances concentration
- 3:1 Patterned breathing IN-OUT/IN-OUT/IN-OUT/IN-BLOW (repeat through contraction)
- 4:1 Patterned breathing IN-OUT/IN-OUT/IN-OUT/IN-OUT/IN-BLOW (repeat through contraction)

Adapted from Nichols F: Paced breathing techniques. In Nichols FH, Humenick SS, editors: *Childbirth education: practice, research, and theory,* ed 2, Philadelphia, 2000, Saunders; Perinatal Education Associates: *Breathing,* 2008, www.birthsource.com/scripts/article.asp?articleid=211.

assisting couples to adapt breathing techniques to their individual labor experience.

All patterns begin with a deep, relaxing, **cleansing breath** to "greet the contraction" and end with another deep breath exhaled to "gently blow the contraction away." These deep breaths ensure adequate oxygen for mother and baby and signal that a contraction is beginning or has ended. As the breath is exhaled, respiratory and voluntary muscles relax (Creehan, 2008). In general, *slow-paced breathing* is performed at approximately half the woman's normal breathing rate and is initiated when she can no longer walk or talk through contractions. The woman should take no fewer than three or four breaths per minute. Slow-paced breathing aids in relaxation and provides optimum oxygenation. The woman should continue to use this technique for as long as it is effective in reducing the perception of pain and maintaining control. As contractions increase in frequency and intensity, the woman often needs to change to a more complex breathing technique, which is shallower and faster than her normal rate of breathing but should not exceed twice her resting respiratory rate. This *modified-paced breathing* pattern requires that she remain alert and concentrate more fully on breathing, thus blocking more painful stimuli than the simpler slow-paced breathing pattern (Perinatal Education Associates, 2008 [www.birthsource.com]).
