- Caloric test, or oculovestibular response (RS)—Elicited with the child's head up (head of bed is elevated 30 degrees) by irrigating the external auditory canal with 10 mL of ice water for 20 seconds, which normally causes conjugate movement of the eyes toward the side of stimulation. This movement is lost when the pontine centers are impaired, thus providing important information in assessment of the comatose patient.

! NURSING ALERT

The caloric test is painful and is never performed on a child who is awake or an individual with a ruptured tympanic membrane.

- Funduscopic examination—Reveals additional clues. **Papilledema** is not evident early in the course of unconsciousness because it takes 24 to 48 hours to develop, if it develops at all. It is characterized by optic disc swelling, indistinct optic disc margins, hemorrhage, tortuosity of vessels, and absence of venous pulsations. The presence of preretinal (subhyaloid) hemorrhages in children is almost invariably a result of acute trauma with intracranial bleeding, usually subarachnoid or subdural hemorrhage.

Motor Function

Observing spontaneous activity, gait, and response to painful stimuli provides clues to the location and extent of cerebral dysfunction. Even subtle movements (e.g., the outward rotation of a hip) should be noted, and the child observed for other signs. Asymmetric movements of the limbs or absence of movement suggests paralysis. In hemiplegia the affected limb lies in external rotation and falls uncontrollably when lifted and allowed to drop. In patients with cerebellum abnormalities heel-to-toe walking is difficult. Patients with cerebellar ataxia have an unsteady, broad-based gait. All motor functions should be described rather than labeled.

In the deeper comatose states there is little or no spontaneous movement, and the musculature tends to be flaccid. There is considerable variability in the motor behavior in lesser degrees of coma. For example, the child may be relatively immobile or restless and hyperkinetic; muscle tone may be increased or decreased. Tremors, twitching, and spasms of muscles are common observations. The patient may display purposeless movements. Combative or negativistic behavior is common. Hyperactivity is more common in toxic states than in cases of increased ICP. Seizures are common in children and may be present from any cause. Any repetitive or seizure movements should be described precisely.

Posturing

Primitive postural reflexes emerge as cortical control over motor function is lost in brain dysfunction. These reflexes are evident in posturing and motor movements directly related to the area of the brain involved. Posturing reflects a balance between the lower exciting and the higher inhibiting influences and strong muscles overcoming weaker ones. Decorticate or **flexion posturing** (Fig. 45-4, *A*) is seen with severe dysfunction of the cerebral cortex or lesions to corticospinal tracts above the brainstem. Typical posturing includes rigid flexion with the arms held tightly to the body; flexed elbows, wrists, and fingers; plantar flexed feet; legs extended and internally rotated; and possibly the presence of fine tremors or intense stiffness. Decerebrate posture or **extension posturing** (see Fig. 45-4, *B*) is a sign of dysfunction at the level of the midbrain or lesions to the brainstem. It is characterized by rigid extension and pronation of the arms and legs, flexed wrists and fingers, a clenched jaw, an extended neck, and possibly an arched back. Unilateral decerebrate posture is often caused by tentorial herniation.

Posturing may not be evident when the child is quiet but can usually be elicited by applying painful stimuli such as a blunt object pressed on the base of the nail. Nurses should avoid applying thumb pressure to the supraorbital region of the frontal bone (risk of orbital damage). Noxious stimuli (e.g., suctioning) elicits a response,

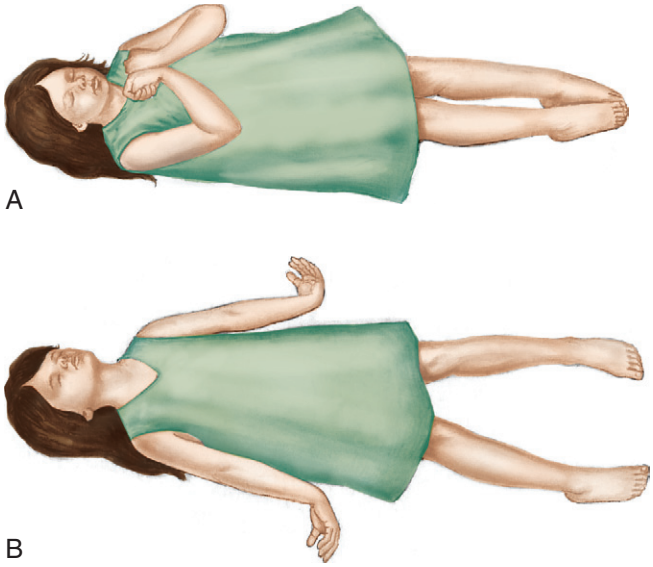

FIG 45-4 **A,** Flexion posturing. **B,** Extension posturing.

as may turning or touching. When the nurse is describing posturing, the stimulus needed to provoke the response is as important as the reaction.

Reflexes

Testing of some reflexes may be of limited value. In general the corneal, pupillary, muscle-stretch, superficial, and plantar reflexes tend to be absent in deep coma. The state of reflexes varies in lighter grades of unconsciousness and depends on the underlying pathologic process and the location of the lesion. Absence of corneal reflexes and presence of a tonic neck reflex are associated with severe brain damage. The Babinski reflex (see Extremities, Chapter 29) may be of value if it is found to be present consistently in children older than 18 months. A positive Babinski reflex is significant in assessment of pyramidal tract lesions when it is unilateral and associated with other pyramidal signs.

! NURSING ALERT

Three key reflexes that demonstrate neurologic health in young infants are the Moro, tonic neck, and withdrawal reflexes.

Special Diagnostic Procedures

Numerous diagnostic procedures are used for the assessment of cerebral function. Laboratory tests that may help delineate the cause of unconsciousness include blood glucose, urea nitrogen, and electrolyte (pH, sodium, potassium, chloride, calcium, and bicarbonate) tests; blood ammonia levels; clotting studies, hematocrit, and a complete blood count; liver function tests; blood cultures if there is fever; and urine toxicology screen and blood lead levels if clinically indicated.

An electroencephalogram (EEG) may provide important information. For example, generalized random, slow activity suggests suppressed cortical function; and localized slow activity suggests a space-occupying issue such as a hematoma, tumor, or infectious process. A flat tracing is one of the criteria used as evidence of brain death.

Examination of spinal fluid is performed when toxic encephalopathy or infection is suspected. Lumbar puncture ordinarily is delayed if intracranial hemorrhage is suspected and is contraindicated in the presence of ICP because of the potential for tentorial herniation.

Auditory and visual evoked potentials are sometimes used in neurologic evaluation of infants and very young children. Visual evoked potentials are useful in evaluating visual abnormalities from the retina to the visual cortex, and brainstem auditory evoked potentials are useful for assessing hearing acuity and brainstem function. Both are particularly useful for detecting demyelinating disease and neoplasms.

Highly sophisticated tests are carried out with specialized equipment. Two imaging techniques, computed tomography (CT) and magnetic resonance imaging (MRI), assist in diagnosis by scanning both soft tissues and solid matter. Most of these tests are outlined in Table 45-1. Because such tests can be threatening to children, the nurse needs to prepare patients for them and provide support and reassurance during them (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 39). Children who are old enough to understand require careful explanation of the procedure, reason for it, what they will experience, and how they can help. School-age children usually appreciate a more detailed description of why contrast material is injected. The importance of lying still for tests needs to be stressed. Children unfamiliar with the machines can be shown a picture beforehand.

Although radiographic examinations are not painful, the appearance of the machinery is often so frightening that the child protests because of anxiety. This is especially true of CT and MRI, both of which require that the child's head be placed within a special immobilizing device. Chin and cheek pads are sometimes used to prevent the slightest head movement, and straps are applied to the body to prevent a slight change in body position. The nurse can explain these events to a frightened child by comparing them to an astronaut's

TABLE 45-1 NEUROLOGIC DIAGNOSTIC PROCEDURES

TEST	DESCRIPTION	PURPOSE	COMMENTS
LP	Spinal needle is inserted between L3-L4 or L4-L5 vertebral spaces into subarachnoid space; CSF pressure is measured, and sample is collected.	Diagnostic—Measures spinal fluid pressure, obtains CSF for laboratory analysis Therapeutic—Injection of medication	Contraindicated in patients with increased ICP or infected skin over puncture site.
Subdural tap	Needle is inserted into anterior fontanel or coronal suture (midline to pupil).	Helps rule out subdural effusions Removes CSF to relieve pressure	Place infant in semi-erect position after subdural tap to minimize leakage from site; prevent child from crying if possible. Check site frequently for evidence of leakage.
Ventricular puncture	Needle is inserted into lateral ventricle via coronal suture (midline to pupil).	Removes CSF to relieve pressure	Risk of intracerebral or ventricular hemorrhage.
EEG	EEG records changes in electrical potential of brain. Electrodes are placed at various points to assess electrical function in a particular area. Impulses are recorded by electromagnetic pen or digitally.	Detects spikes, or bursts of electrical activity that indicate the potential for seizures Used to determine brain death	Patient should remain quiet during procedure; may require sedation. Minimize external stimuli during procedure.

TABLE 45-1 NEUROLOGIC DIAGNOSTIC PROCEDURES—cont'd

TEST	DESCRIPTION	PURPOSE	COMMENTS
Nuclear brain scan	Radioisotope is injected intravenously and then counted and recorded after fixed time intervals. Radioisotope accumulates in areas where blood-brain barrier is defective.	Identifies focal brain lesions (e.g., tumors, abscesses) Positive uptake of material with encephalitis and subdural hematoma Visualizes CSF pathways	Requires IV access; patient may require sedation. In normal children or noncommunicating hydrocephalus, no retrograde filling of ventricles occurs. Areas of concentrated uptake of material are termed *hot spots*.
Endocephalography	Pulses of ultrasonic waves are beamed through head; echoes from reflecting surfaces are recorded graphically.	Identifies shifts in midline structures from their normal positions as a result of intracranial lesions May show ventricular dilation	Simple, safe, rapid procedure. Fontanel must be patent.
RTUS	Similar to CT but uses ultrasound instead of ionizing radiation.	Allows high-resolution anatomic visualization in variety of imaging planes	Produces images similar to CT scan. Especially useful in neonatal CNS problems. Anterior fontanel must be patent.
Radiography	Skull films are taken from different views—lateral, posterolateral, axial (submentoventricular), half-axial.	Shows fractures, dislocations, spreading suture lines, craniosynostosis Shows degenerative changes, bone erosion, calcifications	Simple, noninvasive procedure.
CT scan	Pinpoint x-ray beam is directed on horizontal or vertical plane to provide series of images that are fed into computer and assembled in image displayed on video screen. CT uses ionizing radiation.	Visualizes horizontal and vertical cross section of brain in three planes (axial, coronal, sagittal) Distinguishes density of various intracranial tissues and structures—congenital abnormalities, hemorrhage, tumors, demyelinating and inflammatory processes, calcification	Requires IV access if contrast agent is used. Patient may require sedation. Rapid.
MRI	MRI produces radiofrequency emissions from elements (e.g., hydrogen, phosphorus), which are converted to visual images by computer.	Permits visualization of morphologic feature of target structures Permits tissue discrimination unavailable with many techniques	MRI is noninvasive procedure except when IV contrast agent is used. No exposure to radiation occurs. Patient may require sedation. Parent or attendant can remain in room with child. MRI does not visualize bone detail or calcifications. No metal can be present in scanner.
PET	PET involves IV injection of positron-emitting radionucleotide; local concentrations are detected and transformed into visual display by computer.	Detects and measures blood volume and flow in brain, metabolic activity, and biochemical changes within tissue	Requires lengthy period of immobility. Minimum exposure to radiation occurs. Patient may require sedation.
DSA	Contrast dye is injected intravenously; computer "subtracts" all tissues without contrast medium, leaving clear image of contrast medium in vessels studied.	Visualizes vasculature of target tissue Visualizes finite vascular abnormalities	Safe alternative to angiography. Patient must remain still during procedure; may require sedation.
SPECT	Involves IV injection of photon-emitting radionuclide; radionuclides are absorbed by healthy tissue at different rate than by diseased or necrotic tissue; data are transferred to computer that converts image to film.	Provides information regarding blood flow to tissues; analyzing blood flow to organ may help determine how well it is functioning	Requires lengthy period of immobility. Minimum exposure to radiation occurs. Patient may require sedation.

preparation for a space flight. It is important to emphasize to the child that at no time is the procedure painful.

The nurse should not expect cooperation from a young child. Sedation may be required. Many different agents are currently used for sedation of children undergoing neurologic diagnostic procedures. Chloral hydrate, pentobarbital, or benzodiazepines have been used for decades as short-term sedative agents and remain safe methods of pediatric outpatient sedation (Mason, 2008). Chloral hydrate and pentobarbital have no analgesic proprieties but can provide successful sedation for nonpainful procedures such as CT and MRI (Mason, 2008). In recent years propofol has been used as a sedation agent for diagnostic procedures because of its short induction and recovery time, but this medication should be used with caution because it can cause respiratory depression and apnea with little warning (Machata, Willschke, Kabon, et al., 2008; Mason, 2008). (See Pain Management, Chapter 30.)

Physical preparation for the diagnostic test may involve administration of a sedative. If so, children should be helped through the preparation and administration and assured that someone will remain with them (if possible). Children need continual support and reinforcement during procedures in which they remain conscious. Vital signs and physiologic responses to the procedure are monitored throughout. Many diagnostic procedures performed on an outpatient basis require sedation, and children need recovery time and observation. The nurse should review written instructions with parents if the child is discharged after a procedure. Children who have undergone a procedure with a general anesthetic require postanesthesia care, including positioning, to prevent aspiration of secretions and frequent assessment of the vital signs and LOC. In addition, other neurologic functions such as pupillary responses, motor strength, and movement are tested at regular intervals. Any surgical wound resulting from the test is checked for bleeding, CSF leakage, and other complications. Children who undergo repeated subdural taps should have their hematocrit monitored to detect excessive blood loss from the procedure.

NURSING CARE OF THE UNCONSCIOUS CHILD

The unconscious child requires nursing attention, with observation, recording, and evaluation of changes in objective signs. These observations provide valuable information regarding the patient's progress. Often they serve as a guide to the diagnosis and treatment. Therefore careful and detailed observations are essential for the patient's welfare. In addition, vital functions must be maintained, and complications prevented through conscientious and meticulous nursing care. The outcome of unconsciousness may be early and complete recovery, death within a few hours or days, persistent and permanent unconsciousness, or recovery with varying degrees of residual mental or physical disability. The outcome and recovery of the unconscious child may depend on the level of nursing care and observational skills.

Emergency measures are directed toward ensuring a patent airway, breathing, and circulation; stabilizing the spine when indicated; treating shock; and reducing ICP if present. Delayed treatment often leads to increased damage. As soon as emergency measures have been implemented, and in many cases concurrently, therapies for specific causes are begun. Because nursing care is closely related to medical management, both are considered here.

Continual observation of LOC, pupillary reaction, and vital signs is essential to manage CNS disorders. Regular assessment of neurologic status is an essential part of nursing comatose children. The assessment frequency depends on the cause of unconsciousness, the LOC, and the progression of cerebral involvement. Intervals may be as short as every 15 minutes or as long as every 2 hours. Significant alterations must be reported immediately.

Vital signs provide important information about the status of the unconscious child. Hypothalamic and brainstem disorders may affect the patient's thermoregulation; thus frequent monitoring is needed. The temperature is taken every 2 to 4 hours, depending on the patient's condition. Hypothermia is defined as a core body temperature less than 35° C (95° F). EEG slowing is noted at 30° C, and loss of pupillary light reflex is lost at 28° C (Young, 2009). Hyperthermia is defined as a core body temperature greater than 38.5° C (101.3° F); and temperatures greater than 42° C can cause EEG slowing, seizures, and encephalopathy (Young, 2009).

The neurologic examination is performed periodically and includes evaluating pupillary abnormalities, brainstem function, LOC, and motor response (Sharma, Kochar, Sankhyan, et al., 2010). Pupils are observed for their size, symmetry, and reaction to light. Signs of meningeal irritation such as nuchal rigidity are also assessed. The presence of the oculovestibular response, corneal (blink) response, and cough and gag reflexes is evaluated. Aspects of LOC assessment include response to vocal commands, resistance to care, and response to painful stimuli. Spontaneous movement, changes in muscle tone or strength, and body position are noted. Seizure activity is described according to the duration and body areas involved.

Pain management for the comatose child requires astute nursing observation and management. Responses to pain include motor reactions such as increased agitation or posturing; facial changes such as grimaces; and physiologic reactions such as tachycardia, tachypnea, diaphoresis, or hypertension (Schnakers and Zasler, 2007). Because these findings may not be specific for pain, the nurse should observe for their appearance during times of induced or suspected pain and their disappearance after the end of the inciting procedure or the administration of analgesia. A pain assessment record should be used to document indications of pain and the effectiveness of interventions (see Pain Assessment, Chapter 30).

The use of opioids such as morphine to relieve pain is controversial because they may mask signs of altered consciousness or depress respirations. However, unrelieved pain activates the stress response, which can elevate ICP. To block the stress response, some authorities advocate the use of analgesics; sedatives; and in some cases paralyzing agents via continuous intravenous (IV) infusion. A frequently used combination is fentanyl, midazolam, and vecuronium (Norcuron). If there are concerns about assessing the LOC or respiratory depression, naloxone (Narcan) can be used to reverse the opioid effects. Regardless of which drugs are used, adequate dosage and regular administration are essential to provide optimal pain relief (see Pain Management, Chapter 30).

Other measures to relieve discomfort include providing a quiet, dimly lit environment; limiting visitors; preventing any sudden, jarring movement such as banging into the bed; and preventing an increase in ICP. The last is most effectively achieved by proper positioning and prevention of straining such as during coughing, vomiting, suctioning, and defecating.

MEDICATION ALERT

When opioids are used, bowel elimination must be monitored closely because of the potential constipating effect. Stool softeners should be given with laxatives as needed to prevent constipation.

Respiratory Management

Respiratory effectiveness is the primary concern in the care of the unconscious child, and establishing an adequate airway is *always* the first priority. Carbon dioxide has a potent vasodilating effect and increases cerebral blood flow (CBF) and ICP. Cerebral hypoxia that lasts longer than 4 minutes nearly always causes irreversible brain damage.

Children in lighter states of coma may be able to cough and swallow; but those in deeper states are unable to handle secretions, which tend to pool in the throat and pharynx. Dysfunction of cranial nerves IX and X places the child at risk for aspiration and cardiac arrest; therefore the child is positioned to prevent aspiration of secretions, and the stomach is emptied to reduce the likelihood of vomiting. In infants blockage of air passages from secretions can happen in seconds. In addition, upper airway obstruction from laryngospasm is a frequent complication in comatose children.

An oral airway can be used for children who have a temporary loss of consciousness such as after a contusion, seizure, or anesthesia. For children who remain unconscious for a longer time, a nasotracheal or orotracheal tube is inserted to maintain the open airway and facilitate removal of secretions. Endotracheal intubation should be considered in children with a GCS score of less than 8, evidence of herniation, apnea, or inability to maintain an airway (Sankhyan, Raju, Sharma, et al., 2010). A tracheostomy is performed in cases in which laryngoscopy for introduction of an endotracheal tube would be difficult or for a child who needs long-term ventilatory support. Suctioning is used only as needed to clear the airway, exerting care to prevent increasing ICP. Respiratory status is observed and evaluated regularly. Signs of respiratory distress may be an indication for ventilatory assistance.

When the respiratory center is involved, mechanical ventilation is usually indicated (see Chapter 39). Blood gas analysis is performed regularly, and oxygen is administered as indicated. Moderately severe hypoxia and respiratory acidosis are often present but not always evident from clinical manifestations. Hyperventilation frequently accompanies unconsciousness and may lead to respiratory alkalosis, or it may represent the attempt by the body to compensate for metabolic acidosis. Therefore blood gas and pH determinations are essential guides for therapy. Chest physiotherapy is carried out on a regular basis, and the child's position is changed at least every 2 hours to prevent pulmonary complications.

Intracranial Pressure Monitoring

An acute rise in ICP can cause secondary brain injury (Singhi and Tiwari, 2009), and management of the child with increased ICP is a complex and important task. ICP monitoring is used to guide therapy to reduce ICP and provides information on intracranial compliance, cerebrovascular status, and cerebral perfusion (Sankhyan, Raju, Sharma, et al., 2010). Nonetheless ICP monitoring is an invasive procedure that has associated risks, including infection, hemorrhage, malfunction, and obstruction (Singhi and Tiwari, 2009). Indications for inserting an ICP monitor are as follows:

- GCS evaluation of less than 8:
  - Traumatic brain injury with an abnormal head CT scan
  - Deterioration of condition
- Subjective judgment regarding clinical appearance and response

Four major types of ICP monitors are:

1. Intraventricular catheter with fibroscopic sensors attached to a monitoring system
2. Subarachnoid bolt (Richmond screw)
3. Epidural sensor
4. Anterior fontanel pressure monitor.

Direct ventricular pressure measurement with an intraventricular catheter remains the gold standard of ICP monitoring (Singhi and Tiwari, 2009). Subarachnoid and epidural monitoring can be used when a catheter cannot be cannulated in the ventricle, but they often must be replaced after several days because of measurement drift (Singhi and Tiwari, 2009). Transducers for both ventricular and subarachnoid monitoring should be set up without the use of a flush device.

Placement of the intraventricular catheter and subarachnoid bolt occurs through a burr hole in the skull. The intraventricular method involves introduction of a catheter into the lateral ventricle on the nondominant side, if known. The subarachnoid bolt involves placement of a bolt in the subarachnoid space, and the epidural sensor involves placement of a sensor between the dura and the skull. The intraventricular catheter has the advantage of providing a means for recalibration when measurement drift occurs, but both the catheter and the bolt can be used for therapeutic CSF drainage to reduce pressure. A drainage bag attached to the system is kept at the level of the ventricles and can be lowered to decrease ICP (see Critical Thinking Case Study).

! NURSING ALERT

If the external ventricular drain is unclamped for CSF drainage, carefully monitor the level of the collection container. If the container is too low, improper CSF decompression could lower ICP too rapidly, causing bleeding and pain.

! NURSING ALERT

The bolt is stabilized with dressings, and these are not changed or disturbed, even to check the site.

CRITICAL THINKING CASE STUDY

Hydrocephalus

Three-year-old Emma had a posterior fossa tumor removed 5 days ago. Although an EVD was placed to treat her hydrocephalus, she continues to demonstrate signs of increased ICP, including holding the back of her head, anorexia, crying when moved or when strangers enter the room, and intermittent lethargy. On examination fluid drainage is noted on the mother's clothes, and Emma is experiencing repetitive, rapid eyelid blinking.

1. Evidence—Is there sufficient evidence to draw conclusions about Emma's behavior, physical assessment findings, and ICP?
2. Assumptions—Describe any underlying assumption about each of the following:
   a. A preschool-age child who had a posterior fossa tumor removed 5 days ago
   b. A preschool-age child who has an EVD placed to treat the hydrocephalus
   c. A preschool-age child with an EVD who continues to demonstrate physical signs associated with increased ICP after recent surgery
3. What priorities for nursing care should be established?
4. Does the evidence support your nursing intervention?

EVD, External ventricular drain; *ICP,* intracranial pressure.

Placement of the subarachnoid bolt is not adjusted by anyone except the neurosurgeon who placed the device. The neurosurgeon is notified if a satisfactory waveform on the ICP monitoring is not observed.

An epidural sensor provides a readout of the ICP with a stopcock assembly and transducer. Although less invasive, ICP measurements may be inconsistent. In infants a fontanel transducer can be used to detect impulses from a pressure sensor and convert them to electrical energy. The electrical energy is then converted to visible waves or numeric readings on an oscilloscope. ICP measurement from the anterior fontanel is noninvasive but may prove to be inaccurate if the equipment is poorly placed or recalibrated inconsistently.

ICP can be increased by instilling solutions; therefore antibiotics are administered systemically if a positive CSF culture is obtained. CSF is a body fluid; therefore Standard Precautions are implemented according to hospital policy (see Infection Control, Chapter 39).

Nurses caring for patients with intracranial monitoring devices must be acquainted with the system, assist with insertion, interpret the monitor readings, and be able to distinguish between danger signals and mechanical dysfunction.

For sustained ICP elevations greater than 20 to 25 mm Hg, several medical measures are available. Osmotic diuretics may provide rapid relief in emergency situations. Although their effect is transient, lasting only about 6 hours, they can be lifesaving in emergencies. These substances are rapidly excreted by the kidneys and carry with them large quantities of sodium and water. Mannitol (or sometimes urea) administered intravenously is the drug most frequently used for rapid reduction and can lower ICP in 1 to 5 minutes. The infusion is generally given slowly but may be pushed rapidly in cases of herniation or impending herniation. Hypertonic saline in concentrations of 3% to 23% has been shown to reduce ICP by its osmotic force and can be beneficial for hypovolemic and hypotensive patients by increasing intravascular volume and blood pressure (Singhi and Tiwari, 2009). Adrenocorticosteroids are not recommended for cerebral edema secondary to head trauma. $Paco_2$ should be maintained at 25 to 30 mm Hg to produce vasoconstriction, which reduces CSF, thereby decreasing ICP; but this effect is sustained only 11 to 20 hours because the CSF equilibrates to the new $Paco_2$ level (Singhi and Tiwari, 2009).

Nursing Activities

In cases of high levels of increased ICP, procedures tend to trigger reactive pressure waves in many patients. For example, increased intrathoracic or abdominal pressure is transmitted to the cranium. Particular care should be taken in positioning these patients to avoid neck vein compression, which may further increase ICP by interfering with venous return.

The child can be propped to one side or the other, and the use of an alternating-pressure mattress reduces the chance of prolonged pressure to vulnerable areas. Frequent clinical assessment of the child cannot be replaced by an ICP monitoring device.

! NURSING ALERT

The head of the bed is elevated to 30 degrees, and the child is positioned so the head is maintained in midline to facilitate venous drainage and avoid jugular compression (Sankhyan, Raju, Sharma, et al., 2010). Turning side to side is contraindicated because of the risk of jugular compression.

It is important to avoid activities that may increase ICP by causing pain or emotional stress. Gentle range-of-motion exercises can be carried out but should not be performed vigorously. Nontherapeutic touch can cause an increase in ICP. Any disturbing procedures to be performed should be scheduled to take advantage of therapies such as osmotherapy and sedation that reduce ICP. Efforts are taken to minimize or eliminate environmental noise. Assessment and intervention to relieve pain are important nursing functions to decrease ICP. Individualizing nursing activities and minimizing environmental stimuli by decreasing elective procedures help control ICP (Sankhyan, Raju, Sharma, et al., 2010).

Suctioning

Suctioning and percussion are poorly tolerated and therefore are contraindicated unless concurrent respiratory problems exist. Hypoxia and the Valsalva maneuver associated with cough both acutely elevate ICP. Vibration, which does not increase ICP, accomplishes excellent results and should be tried first if treatment is needed. If suctioning is necessary, it should be brief and proceeded by hyperventilation with 100% oxygen, which can be monitored during suctioning with a pulse oxygen sensor reading to determine oxygen saturation.

Nutrition and Hydration

In the unconscious child fluids and calories are supplied initially by the IV route (see Chapter 39). An IV infusion is started early, and the type of fluid administered is determined by the patient's general condition. Fluid therapy requires careful monitoring and adjustment based on neurologic signs and electrolyte determinations. The goal of fluid therapy is euvolemia. Often comatose children are unable to cope with the same amounts of fluid they can tolerate when they are healthy, and overhydration must be avoided to prevent fatal cerebral edema. When cerebral edema is a threat, fluids may be restricted to reduce the chance of fluid overload. Skin and mucous membranes are examined for signs of dehydration. Observation for signs of altered fluid balance related to abnormal pituitary secretions is a part of nursing care.

Long-term nutrition is provided with a balanced formula via a nasogastric or gastrostomy tube. Most children have continuous feedings; but, if bolus feedings are used, the tube is rinsed with water after each feeding. Avoid overfeeding to prevent vomiting and the risk of aspiration.

Altered Pituitary Secretion

An altered ability to handle fluid loads is attributed in part to the syndrome of inappropriate antidiuretic hormone secretion (SIADH) and diabetes insipidus (DI) resulting from hypothalamic dysfunction (see Chapter 46). SIADH frequently accompanies CNS diseases such as head injury, meningitis, encephalitis, brain abscess, brain tumor, and subarachnoid hemorrhage. In patients with SIADH, scant quantities of urine are excreted, electrolyte analysis reveals hyponatremia and hyposmolality, and manifestations of overhydration are evident. It is important to evaluate all parameters because the reduced urinary output might be erroneously interpreted as a sign of dehydration. The treatment of SIADH consists of restriction of fluids until serum electrolytes and osmolality return to normal levels.

DI may occur after intracranial trauma. In DI there are large amounts of diluted urine and the accompanying danger of dehydration. Adequate replacement of fluids is essential, and observation of electrolyte balance is necessary to detect signs of hypernatremia and hyperosmolality. Exogenous vasopressin may be administered.

Medications

The cause of unconsciousness determines specific drug therapies. Children with infectious processes are given antibiotics appropriate to the disease and the infecting organism. Corticosteroids are prescribed for inflammatory conditions and edema. Cerebral edema is an indication for osmotherapy. Sedatives or antiepileptics are prescribed for seizure activity (see p. 1449).

MEDICATION ALERT

Sedation in the combative child provides amnesic and anxiolytic properties in conjunction with a paralytic agent. The combination decreases ICP and allows treatment of cerebral edema. Usual drugs include morphine, midazolam, and pancuronium (Pavulon). Midazolam is appealing because of its short half-life. Prolonged use of propofol should be avoided in children because of the risk of metabolic acidosis (Orliaguet, Meyer, and Baugnon, 2008).

Deep coma induced by administration of barbiturates is controversial in the management of ICP. Barbiturates are currently reserved for the reduction of increased ICP when all else has failed. They decrease the cerebral metabolic rate for oxygen and protect the brain during times of reduced **cerebral perfusion pressure.** Barbiturate coma requires extensive monitoring, cardiovascular and respiratory support, and ICP monitoring to assess response to therapy. Paralyzing agents such as pancuronium also may be needed to aid in performing diagnostic tests, improving effectiveness of therapy, and reducing risks of secondary complications. Elevation of ICP or heart rate of patients who are being given paralyzing agents or are under sedation may indicate the need for another dose of either or both medications.

Thermoregulation

Hyperthermia often accompanies cerebral dysfunction; if it is present, measures are implemented to reduce the temperature to prevent brain damage and reduce metabolic demands generated by the increased body temperature. Antipyretic agents are usually ineffective with hyperthermia as a result of traumatic brain injury; therefore external cooling should be used (Badjatia, 2009). External cooling consists of evaporation (sponge baths), conduction (ice packs, cooling blankets), convection (fans), and radiation (skin exposure) (Badjatia, 2009). Laboratory tests and other methods are used in an attempt to determine the cause of the hyperthermia.

Elimination

A urinary catheter is usually inserted in the acute phase, although diapers may be used and weighed to record urinary output. The child who formerly had bowel and bladder control is generally incontinent. If the child remains comatose for a long period, the indwelling catheter may be removed, and periodic bladder emptying can be accomplished by intermittent catheterization. Stool softeners are usually sufficient to maintain bowel function, but suppositories or enemas may be needed occasionally for adequate elimination and to prevent fecal impaction. The passage of liquid stool after a period of no bowel activity is usually a sign of an impaction. To avoid this preventable problem, daily recording of bowel activity is essential.

Hygienic Care

Routine measures for cleansing and maintaining skin integrity are an integral part of nursing care of the unconscious child (see Maintaining Healthy Skin, Chapter 39).

Mouth care is performed at least twice daily because the mouth tends to become dry or coated with mucus. The teeth are brushed carefully with a soft toothbrush or cleaned with gauze saturated with saline. Commercially prepared cleansing devices such as Toothettes are convenient for cleansing the mouth and teeth. Lips are coated with ointment or other preparations to protect them from drying, cracking, or blistering.

Unconscious children are susceptible to eye irritation. The corneal reflexes are absent; therefore the eyes are easily irritated or damaged by linen, dust, or other substances that may come in contact with them. Excessive dryness results from incomplete closure of the eyes or decreased secretions, especially if the child is undergoing osmotherapy to reduce or prevent cerebral edema.

NURSING ALERT

The eyes should be examined regularly and carefully for early signs of irritation or inflammation. Artificial tears or a lubricating ointment is placed in the eyes every 1 to 2 hours. Eye dressings may be necessary to protect the eyes from possible damage.

Positioning and Exercise

The unconscious child is positioned to minimize ICP and prevent aspiration of saliva, nasogastric secretions, and vomitus. The head of the bed is elevated, and the child is placed in a side-lying or semiprone position. A small, firm pillow is placed under the head, and the uppermost limbs are flexed and supported with pillows. The weight of the body should not rest on the dependent arm. In the semiprone position the child lies with the dependent arm at the side behind the body, the opposite side supported on pillows, and the uppermost arm and leg flexed and resting on the pillows. This position prevents undue pressure on the dependent extremities. The dependent position of the face encourages drainage of secretions and prevents the flaccid tongue from obstructing the airway.

Normal range-of-motion exercises help maintain function and prevent contractures of joints. Exercises should be performed gently and with full range of motion. A small rolled pad can be placed in the palms to help maintain proper position of fingers; footboards or high-top shoes can help prevent footdrop; and splinting may be needed to prevent severe contractures of the wrist, knee, or ankle in decerebrate children.

Stimulation

Sensory stimulation is important in the care of the unconscious child. It helps arouse a temporarily unconscious or semiconscious child to the conscious state and orient him or her to time and place. Auditory and tactile stimulation are especially valuable. Tactile stimulation is not appropriate for children in whom it may elicit an undesirable response. However, for other children it often has a relaxing and calming effect. When the child's condition permits, holding or rocking has a soothing effect and provides the body contact needed by young children. Involving family members with the sensory stimulation can create a positive effect on the child and allows the family to participate in the care (Abbasi, Mohammadi, and Rezayi, 2009).

The auditory sense is often intact in a state of coma. Hearing is the last sense to be lost and the first one to be regained; therefore the child should be spoken to as any other child. Conversation around the child should not include thoughtless or derogatory remarks. Soft music is used frequently to provide auditory

stimulation. Singing the child's favorite songs or reading a favorite story is a tactic used to maintain the child's contact with a familiar world. Playing songs or stories recorded in the parents' voices can provide a continuous source of familiar stimulation.

Regaining Consciousness

Awakening from a coma is a gradual process; however, sometimes children regain consciousness within a short time. Regaining orientation involves knowing person, place, and time in that order.

Certain behaviors have been observed when children awaken from the unconscious state. The stress and anxiety they appear to feel in a strange and unfamiliar environment can be expressed in silent, withdrawn behavior. They respond to basic questioning but usually do not display their prehospitalization personality and social behavior until they are transferred from the critical care area.

Family Support

Helping the parents of an unconscious child cope with the situation is especially difficult. They may demonstrate all of the guilt, fear, hostility, and anxiety of any parent of a seriously ill child (see Chapter 38). In addition, these parents are faced with the uncertain outcome of the cerebral dysfunction. The fear of death, intellectual disability, or other permanent disability is present. Nursing intervention with parents depends on the nature of the pathologic condition, the parents' personality, and the parent-child relationship before the injury or illness. Parents need the most intensive nursing intervention during the period of crisis and uncertainty. Throughout the treatment and recovery phase the nurse provides parents with information and encourages them to become involved in the child's care.

Probably the most difficult situations involve children who never regain consciousness. Family members often attempt to construct a representation of the child by bringing items that belong to him or her such as favorite toys or music. This is interpreted as an attempt to provide stimulation for the child in the hope of eliciting a response, to let the hospital staff know the child as the unique individual that he or she was, and to reconstitute an image of the child "lost" to them and for whom they mourn. Unlike losing a child through death, these situations lack finality, which often leaves family members in a state of prolonged grief and searching for signs of hope. An awareness of these behaviors and coping mechanisms provides nurses with the understanding that helps them support the parents in their grief process.

Superimposed on the process of grieving for the "lost" child, parents may be faced with difficult decisions. When the child's brain is so severely damaged that vital functions must be maintained by artificial means, the parents along with guidance from the health care team must make the final decision of whether to remove life-support systems. Nurses continue to provide specialty care during this time that maintains the patient's physiologic status while addressing informational and psychologic needs of the family (Ashwal and Serna-Fonseca, 2006). This decision is difficult for parents, but having an open and honest dialog about the child's medical condition and prognosis can help make patient-centered conclusions (Young, 2009). Parents' cultural, religious, and language needs along with their intellectual level, decision-making preferences, and emotional state are considered during the discussions (Truog, Campbell, Curtis, et al., 2008). Sometimes parents may choose to refuse or not initiate treatment if they believe it to be best for the child and the family (informed dissent). At other times they request that "everything possible" be done for the child.

When the child has survived the cerebral insult and is not comatose but physical or mental capacity is limited either minimally or severely, families must cope with the long and tedious rehabilitation process and the uncertain outcome. The drain on financial, emotional, and social resources can be enormous.

For parents who choose to care for their child at home, planning for home care begins early in the recovery process. The family should become involved with the child's care as soon as they indicate an interest and ability to do so. They need education and support in learning to care for the child, regular follow-up observation and assessment of the home management, and planning for some respite care of the child. Parents need to understand that it is important to plan for periodic relief from the continual care of the child (see Preparing for Discharge and Home Care, Chapter 38).

CEREBRAL TRAUMA

Head Injury

Head injury is a pathologic process involving the scalp, skull, meninges, or brain as a result of trauma. According to national statistics and Safe Kids Worldwide,* unintentional injuries are the number one health risk for children and the leading cause of death in children older than 1 year of age. Annually one in eight children in the United States will sustain an injury serious enough to require medical attention. Tragically 5100 children ages 1 to 14 years are killed every year by injuries (Safe Kids, 2009). It has been estimated that 500,000 children per year sustain a traumatic brain injury and that 2170 children per year die as a result of the brain injury (Faul, Xu, Wald, et al., 2010). Evidence demonstrates that a previous head injury increases a child's risk of having a subsequent head injury (Swaine, Tremblay, Platt, et al., 2007).

Etiology

The three major causes of brain damage in childhood, in order of importance, are falls, motor vehicle injuries, and bicycle or sports-related injuries. Neurologic injury accounts for the highest mortality rate, with boys affected twice as often as girls. In motor vehicle accidents children younger than 2 years of age are almost exclusively injured as passengers, but older children may also be injured as pedestrians or cyclists. The majority of deaths from brain trauma caused by bicycle injuries occur between the ages of 5 and 14 years. Bicycle helmet laws have been effective in reducing the risk of head injury by 85% and brain injury by 88% (Rivara and Grossman, 2011).

The exposed nature of the head renders it particularly vulnerable to trauma, and many of the physical characteristics of children predispose them to craniocerebral trauma. For example, infants can be left unattended on beds, in high chairs, and in other places from which they can fall. Because the head of an infant or toddler is proportionately larger and heavier in relation to other body parts, it is the most likely to be injured. Incomplete motor development contributes to falls at young ages, and the natural curiosity and exuberance of children also increase their risk of injury.

Pathophysiology

The pathology of brain injury is directly related to the force of impact. Intracranial contents (brain, blood, CSF) are damaged because the force is too great to be absorbed by the skull and

*1301 Pennsylvania Ave., NW, Suite 1000, Washington, DC 20004-1707, 202-662-0600, www.safekids.org.

musculoligamentous support of the head. Although nervous tissue is delicate, it usually requires a severe blow to cause significant damage.

Primary head injuries are those that occur at the time of trauma and include skull fracture, contusions, intracranial hematoma, and diffuse injury. Subsequent complications include hypoxic brain damage, increased ICP, infection, and cerebral edema. The predominant feature of a child's brain injury is the amount of diffuse swelling that occurs. Hypoxia and hypercapnia threaten the energy requirements of the brain and increase CBF. The added volume across the blood-brain barrier, along with the loss of **autoregulation,** exacerbates cerebral edema. Pressure inside the skull that is greater than arterial pressure results in inadequate perfusion.

A child's response to head injury is different from that of an adult. The larger head size and insufficient musculoskeletal support render the very young child particularly vulnerable to head injuries. Physical forces act on the head through acceleration, deceleration, or deformation. Acceleration or deceleration is responsible for most head injuries. When the stationary head receives a blow, the sudden acceleration causes deformation of the skull and mass movement of the brain. Continued movement of the intracranial contents allows the brain to strike parts of the skull (e.g., the sharp edges of the sphenoid or the irregular surface of the anterior fossa) or the edges of the tentorium. Sudden deceleration such as takes place during a fall causes the greatest cerebral injury at the point of impact.

Although the brain volume remains unchanged, significant distortion takes place as the brain changes shape in response to the force of impact to the skull. This movement can cause bruising at the point of impact (coup) or at a distance as the brain collides with the unyielding surfaces far removed from the point of impact (contrecoup) (Fig. 45-5). Thus a blow to the occipital region can cause severe injury to the frontal and temporal areas of the brain. Children with an acceleration-deceleration injury demonstrate diffuse

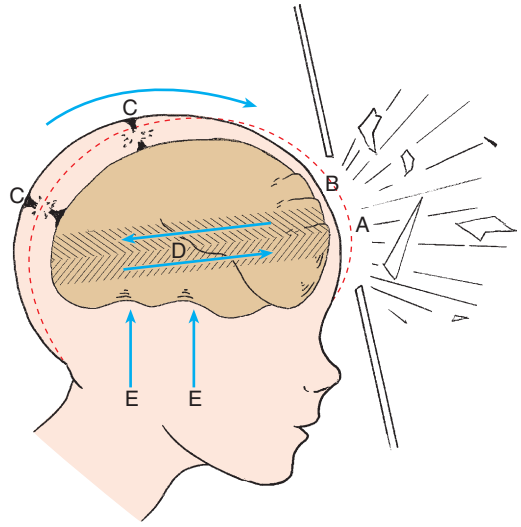

FIG 45-5 Mechanical distortion of the cranium during a closed head injury. **A,** Preinjury contour of the skull. **B,** Immediate postinjury contour of the skull. **C,** Torn subdural vessels. **D,** Shearing forces. **E,** Trauma from contact with the floor of the cranium. (Redrawn from Grubb RL, Coxe WS: Central nervous system trauma: cranial. In Eliasson SG, Presky AL, Hardin Jr WB, editors: *Neurological pathophysiology*, New York, 1974, Oxford University Press.)

generalized cerebral swelling produced by increased blood volume or a redistribution of cerebral blood volume (cerebral hyperemia) rather than by increased water content (edema) as seen in adults.

Another effect of brain movement is shearing stresses, which may tear small arteries and cause subdural hemorrhages. Damage can also occur when severe compression of the skull causes the brain to be forced through the tentorial opening. This can produce irreparable damage to the brainstem (see Fig. 45-6).

Concussion. The most common head injury is concussion, an alteration in neurologic or cognitive function with or without loss of consciousness, which occurs immediately after a head injury (Landry, 2011). Confusion and amnesia after head injury are the hallmarks of concussion; however, loss of consciousness is not an accurate indicator for the presence of a concussion (Meehan and Mannix, 2010). Concussions usually resolve in 7 to 10 days without complications; however, some individuals may require several months to recover (Lee, 2007).

The pathogenesis of concussion is still unclear but may be a result of shearing forces that cause stretching, compression, and tearing of nerve fibers, particularly in the area of the central brainstem, the seat of the reticular activating system. It has also been suggested that the anatomic alterations of nerve fibers cause the release of large quantities of acetylcholine into the CSF and a reduction in oxygen consumption with increased lactate production.

Contusion and Laceration. The terms contusion and laceration are used to describe visible bruising and tearing of cerebral tissue. Contusions represent petechial hemorrhages or localized bruising along the superficial aspects of the brain at the site of impact (coup injury) or a lesion remote from the site of direct trauma (contrecoup injury). In serious accidents there may be multiple sites of injury.

The major areas of the brain susceptible to contusion or laceration are the occipital, frontal, and temporal lobes. In addition, the irregular surfaces of the anterior and middle fossae at the base of the skull are capable of producing bruises or lacerations on forceful impact. Contusions may cause focal disturbances in strength, sensation, or visual awareness. The degree of brain damage in the contused areas varies according to the extent of vascular injury. Signs vary from mild, transient weakness of a limb to prolonged unconsciousness and paralysis. However, the signs and symptoms may be clinically indistinguishable from those of concussion.

The lower incidence of cerebral contusion in infancy has been attributed to infants' pliable skulls with less convolutional markings of the inner space between brain tissue and bone. However, infants who are shaken roughly (shaken baby syndrome) can sustain profound neurologic impairment, seizures, retinal hemorrhages, intracranial subarachnoid or subdural hemorrhages, high cervical spinal cord hemorrhages, and contusions (Walls, 2006).

Cerebral lacerations are generally associated with penetrating or depressed skull fractures. However, they may occur without fracture in small children. When brain tissue is actually torn, with bleeding into and around the tear, more severe and prolonged unconsciousness and paralysis occur, leaving permanent scarring and some degree of disability.

Fractures. Because of its flexibility, the immature skull is able to sustain a greater degree of deformation than the adult skull before it incurs a fracture. A great deal of force is required to produce a fracture in an infant's skull.

The types of skull fractures that occur are linear, depressed, comminuted, basilar, open, and growing. As a rule the faster the blow, the greater the likelihood of a depressed fracture; a low-velocity impact tends to produce a linear fracture.

A linear fracture is a single fracture line that starts at the point of maximum impact but does not cross suture lines. Linear fractures constitute the majority of childhood skull fractures. Most are associated with an overlying hematoma or soft-tissue swelling (Erlichman, Blumfield, Rajpathak, et al., 2010).

Depressed fractures are those in which the bone is broken locally, usually into several irregular fragments that are pushed inward, causing pressure on the brain. Depressed skull fractures may be associated with direct underlying parenchymal damage and should be suspected when a child's head appears misshapen. Surgery may be needed to elevate the depressed bone fragment if there is an associated intracranial hematoma or pressure.

Comminuted fractures consist of multiple associated linear fractures. They usually result from intense impact. These types of fractures often result from repeated blows against an object and may suggest child abuse.

Basilar fractures involve the basilar portion of the frontal, ethmoid, sphenoid, temporal, or occipital bones. Because of the proximity of the fracture line to structures surrounding the brainstem, a basal skull fracture is a serious head injury. Approximately 80% of the cases may include clinical features such as subcutaneous bleeding in the posterior neck area and over the mastoid process **(battle sign),** bleeding around the eyes (raccoon eyes), bleeding behind the tympanic membrane (hemotympanum), or CSF leakage from the nose or ear (Perheentupa, Kinnunen, Grénman, et al., 2010).

Open fractures cause communication between the skull and the scalp or the mucosa of the upper respiratory tract. Open fractures increase the risk of CNS infection when the fracture creates an opening in the paranasal sinuses or middle ear that causes CSF leakage. They may have a skin laceration overlying the bone fracture called a *compound fracture.* Antibiotics are recommended to prevent osteomyelitis.

Growing fractures are skull fractures associated with an underlying dural tear that may be caused by a leptomeningeal cyst, dilated ventricles, or a herniated brain. Ninety percent of all growing fractures occur before the age of 3 years (Vignes, Jeelani, Jeelani, et al., 2007). Physical examination reveals a pulsatile mass or sunken skull defect; symptoms include headaches, seizures, or both.

Complications

The major complications of trauma to the head are hemorrhage, infection, edema, and herniation through the brainstem. Infection is always a hazard in open injuries, and edema is related to tissue trauma. Vascular rupture may occur even in minor head injuries, causing hemorrhage between the skull and cerebral surfaces. Compression of the underlying brain produces effects that can be rapidly fatal or insidiously progressive.

Epidural Hemorrhage. An epidural hemorrhage is bleeding between the dura and the skull to form a hematoma. This bleeding causes the dura to be stripped from bone, forcing the underlying brain contents downward and inward as the brain expands (Fig. 45-6, *A*). Because bleeding is generally arterial, brain compression occurs rapidly. Most often the expanding hematoma is located in the parietal and temporal regions, although it can occur in the frontal or occipital posterior fossa (Case, 2008). The lower incidence of epidural hematoma in childhood has been attributed to the fact that the middle meningeal artery is not embedded in the bone surface of the skull until approximately 2 years of age. Therefore a fracture of the temporal bone is less likely to lacerate the artery. Second, the dura closely adheres to the inner table of the skull, especially at the level of the sutures, making separation from bleeding less likely. However, a child's skull can be indented with sufficient force to tear the middle meningeal artery and rebound intact without causing a fracture. Hemorrhage can also derive from dural veins or the dural sinuses, especially in infants and small children in whom fracture is less likely to occur. In 20% to 40% of children a skull fracture is not detectable. The classic clinical picture of epidural hemorrhage (momentary unconsciousness followed by a normal period and then lethargy or coma) can be less evident in children (see Box 45-3 for

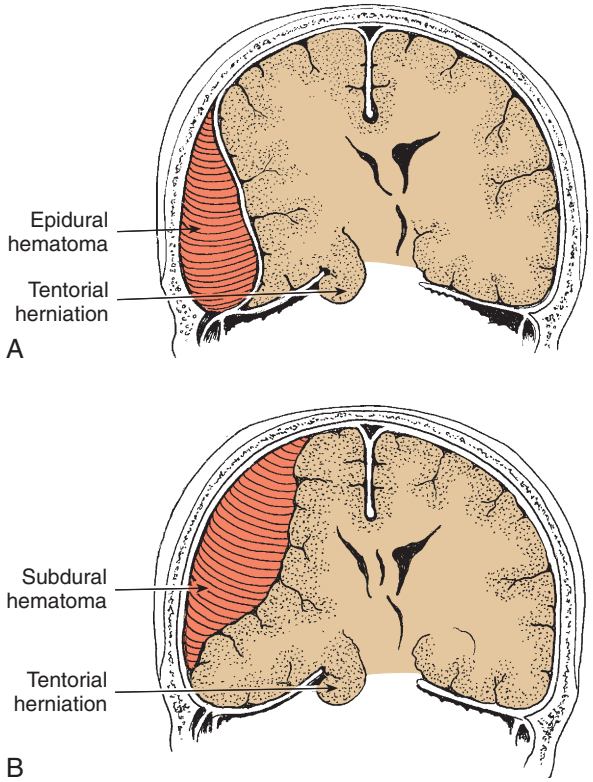

FIG 45-6 **A,** Epidural (extradural) hematoma and compression of temporal lobe through tentorial hiatus. **B,** Subdural hematoma.

BOX 45-3 CLINICAL MANIFESTATIONS OF ACUTE HEAD INJURY

Minor Injury
- May or may not lose consciousness
- Transient period of confusion
- Somnolence
- Listlessness
- Irritability
- Pallor
- Vomiting (one or more episodes)

Signs of Progression
- Altered mental status (e.g., difficulty arousing child)
- Mounting agitation
- Development of focal lateral neurologic signs
- Marked changes in vital signs

Severe Injury
- Signs of increased intracranial pressure (see Box 45-1)
- Bulging fontanel (infant)
- Retinal hemorrhages
- Extraocular palsies (especially cranial nerve III)
- Hemiparesis
- Quadriplegia
- Elevated temperature
- Unsteady gait
- Papilledema

Associated Signs
- Scalp trauma
- Other injuries (e.g., to extremities)

clinical manifestations). Frequently the period of impaired consciousness is lacking; and the symptom-free period is atypical because of nonspecific symptoms such as irritability, headache, and vomiting. Physical findings can include pallor with anemia and cephalhematoma, with infants exhibiting hypotonia and a bulging fontanel. If the severity of the child's signs and symptoms is not recognized, herniation and death will occur.

Subdural Hemorrhage. A subdural hemorrhage is bleeding between the dura and the arachnoid membrane, usually as a result of rupture of cortical veins that bridge the subdural space (see Fig. 45-6, *B*). Subdural hematomas are more common than epidural hematomas, occurring most often in infancy.

Unlike epidural hemorrhage, which develops inwardly against the less resistant brain tissue, subdural hemorrhage tends to develop more slowly and spreads thinly and widely until it is limited by the dural barriers (i.e., the falx and tentorium). Subdural hematomas are fairly common in infants, frequently as a result of birth trauma, falls, assaults, or violent shaking. Presenting signs can include irritability, vomiting, increased head circumference, bulging fontanels in infants, lethargy, or seizures. The small subdural space and dura firmly attached to the skull in this area are highly vulnerable to increased ICP. Hemiparesis, hemiplegia, and unequal pupils are signs of brainstem compression and increased ICP.

! NURSING ALERT

Children with a subdural hematoma and retinal hemorrhages should be evaluated for the possibility of child abuse, especially shaken baby syndrome.

Subdural taps often provide relief in the infant, as revealed by follow-up CT scans, improved neurologic status, and a flat anterior fontanel. The need for surgical evacuation of the hematoma depends on the physical examination, size of the hematoma, and CT scan abnormalities.

Cerebral Edema. Some degree of brain edema is expected, especially 24 to 72 hours after craniocerebral trauma. Cerebral edema associated with **traumatic brain injury** may be caused by direct cellular injury leading to intracellular swelling or vascular injury leading to increased intracellular fluid. Either mechanism can result in increased ICP as a result of the increased intracranial volume and changes in CBF.

Diagnostic Evaluation

A detailed health history, both past and present, is essential in evaluating the child with a craniocerebral trauma. Certain disorders such as drug allergies, hemophilia, diabetes mellitus, or epilepsy may produce similar symptoms. Even minor traumatic injury can aggravate a preexisting disease process, thereby producing neurologic signs out of proportion to the injury. It must be determined whether the infant or child exhibited alterations in consciousness, and any other signs and behaviors exhibited by the child must be noted. Because head injuries are frequently accompanied by injuries in other areas, the examination is performed with care to avoid further damage.

! NURSING ALERT

Stabilize a child's spine after head injury until a spinal cord injury is ruled out.

Initial Assessment. Priorities in the initial stabilization phase of a child with a head injury include assessment of the ABCs (airway, breathing, circulation); evaluation for shock; a neurologic examination focusing on mental status, pupillary responses, and motor responses; and assessment for spinal cord injury. The assessment is carried out quickly in relation to vital signs (see Emergency box).

! NURSING ALERT

Deep, rapid, periodic, or intermittent and gasping respirations; wide fluctuations or noticeable slowing of the pulse; and widening pulse pressure or extreme fluctuations in blood pressure are signs of brainstem involvement. Note that marked hypotension may represent internal injuries.

EMERGENCY

Head Injury

1. Assess child:
   - **A**—Airway
   - **B**—Bleeding
   - **C**—Circulation
   - Neurologic and thermoregulatory status
2. Stabilize neck and spine immediately. Use jaw thrust, not chin lift, to open airway.
3. Clean any abrasions with soap and water.
   - Apply clean dressing.
   - If bleeding, apply pressure and then ice to relieve pain and swelling.
4. Keep NPO until instructed otherwise.
5. Assess pain but do not give analgesics or sedatives.
6. Check pupil reaction every 4 hours (including twice during night) for 48 hours.
7. Awaken twice during the night to check LOC.
8. Seek medical attention if any of the following apply:
   - Injury sustained:
     - At high speed (e.g., automobile)
     - From fall from a significant distance (e.g., height greater than that of the child)
     - From great force (e.g., baseball bat)
     - Under suspicious circumstances
   - Loss of consciousness
   - Amnesia
   - Discomfort (crying) more than 10 minutes after injury
   - Headache that is severe, worsening, interferes with sleep, or lasts more than 24 hours
   - Fluid leak from ears or nose; blackened eyes
   - Vomiting 3 or more times, beginning after injury, or continuing 4 to 6 hours after injury
   - Swelling in front of or above earlobe or swelling that increases in size
   - Confusion or abnormal behaving
   - Difficulty arousing child from sleep
   - Difficulty speaking
   - Blurred vision or diplopia
   - Unsteady gait
   - Difficulty using extremities, weakness, or incoordination
   - Neck pain or stiffness
   - Pupils dilated, unequal, or fixed
   - Infant with bulging fontanel
   - Seizures

LOC, Level of consciousness; *NPO,* nothing by mouth.

Ocular signs such as fixed, dilated, and unequal pupils; fixed and constricted pupils; and pupils that are poorly reactive or nonreactive to light and accommodation indicate increased ICP or brainstem involvement. It is important to remain with the child who demonstrates fixed and dilated pupils because these are ominous signs with a high probability of respiratory arrest. Dilated, nonpulsating blood vessels indicate increased ICP before the appearance of papilledema. Retinal hemorrhages are seen in acute head injuries, including shaken baby syndrome.

! NURSING ALERT

Observation of asymmetric pupils or one dilated, nonreactive pupil in a comatose child is a neurologic emergency.

Less urgent but important additional assessments include examination of the scalp for lacerations and palpation for other abnormalities. A significant amount of blood loss can occur from scalp lacerations. An underlying skull fracture should be ruled out by CT scan.

! NURSING ALERT

Bleeding from the nose or ears needs further evaluation, and a watery discharge from the nose (rhinorrhea) that is positive for glucose (as tested with Dextrostix) suggests leaking of CSF from a skull fracture.

An accurate assessment of clinical signs provides baseline information. Serial evaluations, preferably by a single observer, help to detect changes in the neurologic status. Alterations in mental status, evidenced by increased difficulty in rousing the child, mounting agitation, development of focal lateral neurologic signs, or marked changes in vital signs, usually indicate extension or progression of the basic pathologic process.

Special Tests. After a thorough clinical examination a variety of diagnostic tests are helpful in providing a more definitive diagnosis of the type and extent of the trauma. The severity of a head injury may not be apparent on clinical examination of a child but is detectable on a CT scan. Whenever the child has a history consistent with a serious head injury (unrestrained occupant in a severe motor vehicle accident or a fall from a significant height), it is important to perform a diagnostic scan even if the child initially appears alert and oriented. All children with head injuries who have any alteration of consciousness, headache, vomiting, skull fracture, seizure, or a predisposing medical condition should undergo CT scanning.

After early head injury MRI may be useful in evaluating cerebral edema or structural brain abnormalities, and neurobehavioral assessment can document any cognitive impairments. Skull radiographs are of little benefit in diagnosing skull fractures. EEG is not helpful for diagnosis of head injury but is useful for defining seizure activity. Lumbar puncture is rarely used in craniocerebral trauma and is contraindicated in the presence of increased ICP because of the possibility of herniation.

Posttraumatic Syndromes. Posttraumatic syndromes include postconcussion syndrome, posttraumatic seizures, and structural complications after a head injury.

Postconcussion syndrome is a common sequela to brain injury with or without loss of consciousness. Symptoms can develop within hours to days after a mild head injury but can also occur after moderate-to-severe head injury. The manifestations vary with the child's age and include nausea, dizziness, headache, diplopia, disorientation, and other mental status changes. The duration of manifestations can vary from several days to several months. Death from concussion is preventable unless overwhelming secondary brain injury has occurred (Blinman, Houseknecht, Snyder, et al., 2009).

Posttraumatic seizures occur in a number of children who survive a head injury and are more common in children than in adults (Boran, Boran, Barut, et al., 2006). Seizures are more likely to occur within the first few days after a severe head injury.

Structural complications (e.g., hydrocephalus) may occur as a result of head injuries. Clinical sequelae include cognitive deterioration, motor deficits, optic atrophy, cranial nerve palsies, or aphasia. The type of residual effect depends on the location and nature of the trauma.

FAMILY-CENTERED CARE

Maintaining Contact

Maintaining contact with parents for continued observation and reevaluation of the child, when indicated, facilitates early diagnosis and treatment of possible complications from head injury such as hematoma, hydrocephalus, and posttraumatic seizures. Children are generally hospitalized for 24 to 48 hours of observation if their family lives far from medical facilities or lacks transportation or a telephone that would provide access to immediate help. Other circumstances such as language or other communication barriers or even emotional trauma may hinder learning and make it difficult for families to feel confident in caring for their child at home.

Therapeutic Management

The majority of children with mild traumatic brain injury who have not lost consciousness can be cared for and observed at home after a careful examination reveals no serious intracranial injury. Nurses should provide parents with verbal and written instructions of signs and symptoms that warrant concern and the need for medical reevaluation (see Family-Centered Care box).

Parents are instructed to check the child every 2 hours to determine any changes in responsiveness. The sleeping child should be wakened to see if he or she can be roused normally. Parents are advised to maintain contact with the health care provider, who typically examines the child again in 1 or 2 days. The manifestations of epidural hematoma in children do not generally appear until 24 hours or more after injury.

Children with severe injuries, those who have lost consciousness for more than a few minutes, and those with prolonged and continued seizures or other focal or diffuse neurologic signs must be hospitalized until their condition is stable and their neurologic signs have diminished. The child is maintained on NPO status (nothing by mouth) or restricted to clear liquids until it is determined that vomiting will not occur. IV fluids are indicated in the child who is comatose, displays dulled sensorium, or is vomiting persistently. Fluid balance is monitored closely by daily weights; accurate intake and output measurements; and serum osmolality to detect early signs of water retention, excessive dehydration, and states of hypertonicity or hypotonicity.

The volume of IV fluid is monitored carefully to minimize the possibility of overhydration in cases of SIADH and cerebral edema. However, damage to the hypothalamus or pituitary gland may produce DI with its accompanying hypertonicity and dehydration.

MEDICATION ALERT

Sedating drugs are commonly withheld in the acute phase. Headaches are usually controlled with acetaminophen, although opioids may be needed. Antiepileptics are used for seizure control. Antibiotics may be administered if lacerations, penetrating injuries, or CSF leakage is noted. Cerebral edema is managed as described for the unconscious child. Hyperthermia is controlled with tepid sponges or a hypothermia blanket.

Surgical Therapy. Scalp lacerations are sutured after the underlying bone is carefully examined. Depressed fractures require surgical reduction and removal of bone fragments. Torn dura is sutured. Ping-Pong–ball skull fractures in very young infants ordinarily correct themselves within a few weeks; however, some may require surgical intervention.

Prognosis. The outcome of craniocerebral trauma depends on the extent of injury and complications. In general the prognosis is more favorable for children than for adults. More than 90% of children with concussions or simple linear fractures recover without symptoms after the initial period. Outcomes in children with brain injuries are focused increasingly on long-term cognitive, emotional, and mental problems. The vulnerability of young children's developing brains can result in detrimental disruptions after significant brain injury (Bonnier, Marique, Van Hout, et al., 2007).

True coma (not obeying commands, eyes closed, and not speaking) usually does not last more than 2 weeks. A child's eventual outcome can range from brain death to a persistent vegetative state to complete recovery. However, even the best recovery after a coma may be associated with personality changes, including mood lability and loss of confidence, impaired short-term memory, headaches, and subtle cognitive impairments. Many children are left with significant disabilities after head injury that appear months later as learning difficulties, behavioral changes, or emotional disturbances (Bonnier, Marique, Van Hout, et al., 2007).

CARE MANAGEMENT

The hospitalized child requires careful neurologic assessment and evaluation that are repeated at frequent intervals to establish a correct diagnosis, identify signs and symptoms of increased ICP, determine clinical management, and prevent many complications.

The child is placed on bed rest, usually with the head of the bed elevated slightly and the head in midline position. Appropriate safety measures such as side rails kept up and seizure precautions are implemented. Children may be restless and irritable, but often their reaction is to fall asleep when left undisturbed. A quiet environment helps reduce restlessness and irritability. For extremely restless children hard surfaces may need to be padded, and restraint used to prevent the possibility of further injury. Care is individualized according to the child's specific needs. Shining bright lights directly into the child's face is irritating and makes assessment of ocular responses difficult.

Frequent examinations of vital signs, neurologic signs, and LOC are extremely important nursing observations. When possible, they should be performed by a single observer to better detect subtle changes that may indicate worsening neurologic status. Pupils are checked for size, equality, reaction to light, and accommodation. After the initial elevations usually seen after injury, the vital signs generally return to normal unless there is brainstem involvement.

The most important nursing observation is assessment of the child's LOC. Alterations in consciousness appear earlier in the progression of an injury than alterations of vital signs or focal neurologic signs. Some expected responses may be misinterpreted as deviations from the normal. Frequent examinations of alertness are fatiguing to the child; therefore he or she often desires to fall asleep, which may be confused with depressed consciousness. It is common to observe ocular divergence through the partially closed eyelids.

A key nursing role is to provide sedation and analgesia for the child. The conflict between the need to promote comfort and relieve anxiety in the child versus the need to assess for neurologic changes presents a dilemma. Both goals can be achieved with close observation of the child's LOC and response to analgesics, use of a pain assessment record, and effective communication with the practitioner. Decreasing restlessness after administration of an analgesic most likely reflects pain control rather than a declining LOC.

Observations of position and movement provide additional information. Any abnormal posturing and whether it occurs continuously or intermittently are noted. Questions nurses might consider include:

- Are the child's handgrips strong and equal in strength?
- Are there any signs of flexion or extension posturing?
- What is the child's response to stimulation?
- Is movement purposeful, random, or absent?
- Are movement and sensation equal on both sides or restricted to one side only?

The child may complain of headache or other discomfort. A child who is too young to describe a headache may be fussy and resist being handled. A child who has vertigo often assumes a position of comfort and vigorously resists efforts to be moved. Forcible movement causes the child to vomit and display spontaneous **nystagmus.** Seizures are relatively common in children with head trauma and may be of any type. Carefully observe, record, and report in detail any seizure activity. Children in postictal (postseizure) states are lethargic with sluggish pupils.

Document drainage from any orifice. Bleeding from the ear suggests the possibility of a basal skull fracture. Clear nasal drainage suggests an anterior basal skull fracture. The amount and characteristics of the drainage should be observed, recorded, and reported.

NURSING ALERT

Suctioning through the nares is contraindicated because of the risk of the catheter entering the brain parenchyma through a fracture in the skull.

Head trauma is frequently accompanied by other undetected injuries; therefore any bruises, lacerations, or evidence of internal injuries or fractures of the extremities is noted and reported. Associated injuries are evaluated and treated appropriately.

The child with normal LOC is usually allowed clear liquids unless fluid is restricted. If the child has an IV infusion, it is maintained as prescribed. The diet is advanced to that appropriate for the child's age as soon as the condition permits. Intake and output are measured and recorded, and any incontinence of bowel or bladder is noted if the child has been toilet trained.

Observe the child for any unusual behavior, but behavior should be interpreted in relation to the child's normal behavior. For example, urinary incontinence during sleep would be of no consequence in a child who routinely wets the bed but would be highly significant for one who is always dry. Parents are valuable resources in evaluating objective behavior of their child. Information obtained from parents at or shortly after admission is helpful in evaluating

the child's behavior (e.g., the ease with which the child is roused normally, the usual sleeping position and patterns, motor activities [rolling over, sitting up, climbing], hearing and visual acuity, appetite, and manner of eating [spoon, bottle, cup]).

Family Support. The emotional and educational support of the family presents a challenging aspect to nursing care. Witnessing the parents' grief and helplessness on seeing their child in an altered state, connected to monitoring equipment, and in an intensive care unit evokes empathy. The nurse can encourage the family to be involved in the child's care, bring in familiar belongings, or make a tape recording of familiar voices and sounds. Parents may need a demonstration on how to touch or cuddle their child and may want to talk about their grief. The nurse can listen attentively, reinforce what is being done to help the child, and direct parents toward signs and symptoms of recovery to instill hope without promises. Honesty and kindness along with competent care can help families through this difficult time.

When the child is discharged, the parents are advised of probable posttraumatic symptoms that may be expected. They should understand necessary monitoring and how to contact health care providers in case the child develops any unusual signs or symptoms. The importance of follow-up evaluation should be emphasized.

Rehabilitation. Rehabilitation and management of the child with permanent brain injury are essential aspects of care. Rehabilitation begins as soon as feasible and usually involves the family and a rehabilitation team. Careful assessment of the child's capabilities, limitations, and probable potential is made as early as possible; and appropriate interventions are implemented to maximize the residual capacities. The Brain Injury Association of America* provides information and listings of rehabilitation services and support groups throughout the country.

Pediatric trauma rehabilitation is a national concern. Coordinating care and services for early rehabilitation involves identifying the child's and family's response to the traumatic injury and disability, securing available resources, and recognizing the parental role in the process.

Children with disabilities resulting from head trauma require assessment on a physical, cognitive, emotional, and social level. These children have experienced separation, pain, sensory deprivation and overload, changes in circadian cycle, and fear of the unknown. Recovery and transition require new coping strategies at the same time that regressive and acting-out behavior may start. Parents and children need honest communication for decision making. Rehabilitation is advocated when the child has progressed beyond what can be provided in a hospital setting. The Rancho Los Amigos Scale provides a systematic assessment of the possible progress a child may achieve after a severe head injury.

Prevention. Tremendous strides have been taken to prevent cerebral damage after head injury in children. New developments are directed toward the prevention of cellular injury or the primary insult. Nurses can exert a valuable influence on prevention of children's head injuries through education. Preventable head injuries occur because unnecessary risks go unchecked. Inadequate supervision combined with children's natural sense of indestructibility and exploration can lead to lethal results. Nurses are in the unique position of influencing caregivers in terms of growth and development risks. Banning the use of infant walkers is an example. This equipment does not help develop motor skills and places infants at risk for head and neck injuries from falls, especially down steps. Public education coupled with legislative support can prevent childhood injuries.

Submersion Injury

Submersion injury is a major cause of accidental death in children older than 1 year of age. The term **submersion injury** has replaced *near-drowning* to include any person who experiences distress from submersion or immersion in liquid that results either in death (drowning) or survival at least 24 hours after submersion (near-drowning) (Weiss and American Academy of Pediatrics [AAP] Committee on Injury, Violence, and Poison Prevention, 2010). Most cases of submersion are accidental, usually involving children who are helpless in water such as inadequately attended children in or near swimming pools or infants in bathtubs; small children who fall into ponds, streams, and flooded excavations; occupants of pleasure boats who fail to wear life preservers; children who have diving accidents; and children who are able to swim but overestimate their endurance. Accidental drowning occurs more commonly in toddlers, boys, and African-Americans (Nasrullah and Muazzam, 2011). Drowning can take place in any body of liquid, and sites of drowning are important to consider for preventive education. Children younger than 1 year old are most likely to drown in a bathtub, and buckets filled with fluid cause a risk of drowning to top-heavy toddlers who can fall head first into the buckets (Hon and Leung, 2010). Preschoolers are at risk for drowning in swimming pools; and drowning in school-age children and adolescents most commonly occurs in natural bodies of water such as lakes, ponds, and rivers (Shephard and Quan, 2011). The suction created at the outlet of pools, hot tubs, or whirlpool spas is strong enough to trap any child, even larger children, underwater. Drowning as a form of fatal child abuse has also been recognized as a problem.

Pathophysiology

Hypoxia is the primary cause of injury when submersion occurs and can cause damage to the brain, lungs, heart, kidneys, liver, and gastrointestinal system. Cerebral hypoxia is the major component of morbidity and mortality with submersion events. Within minutes of a submersion, a lack of oxygen leads to coma and ultimately cardiac arrest (Shephard and Quan, 2011). Recovery depends on the timeliness and effectiveness of initial resuscitation and subsequent supportive care measures.

Pathophysiologic features in submersion injuries are hypoxia, aspiration, and hypothermia.

Hypoxia is related to the duration of anoxia and asphyxia. Different cells tolerate variable lengths of anoxia, causing variations of cell damage. Neurons, especially cerebral cells, sustain irreversible damage after 4 to 6 minutes of submersion; but the heart and lungs can survive up to 30 minutes. Regardless of the amount of water aspirated, there is arterial hypoxemia (resulting from atelectasis with shunting of blood through the nonventilated alveoli) and a combined respiratory acidosis (resulting from retained carbon dioxide) and metabolic acidosis (caused by buildup of acid metabolites from anaerobic metabolism). Approximately 10% of drowning victims die without aspirating fluid but succumb from acute asphyxia as a result of prolonged reflex laryngospasm.

Aspiration of fluid is quickly absorbed in the pulmonary circulation, resulting in pulmonary edema, atelectasis, and airway spasm, which aggravates the hypoxia. No clinical or physiologic difference, therapy, or outcome has been noted among human survivors in the submersion of salt water versus fresh water (Shephard and Quan, 2011).

Hypothermia is common after submersion; children are at an increased risk of hypothermia because of their large surface area relative to body mass, decreased subcutaneous fat, and limited thermoregulation (Shephard and Quan, 2011). The temperature of the liquid plays an important role in developing hypoxemia. Cold water decreases metabolic demands and activates the diving reflex, which causes blood to be shunted away from the periphery and concentrated to the brain and heart. However, prolonged submersion in cold liquids can impair cognition, coordination, and muscle strength, ultimately resulting in a loss of consciousness, decreased cardiac output, and cardiac arrest (Shephard and Quan, 2011).

Therapeutic Management

The outcome of children after a submersion event depends on the circumstances and duration of the submersion and the speed and effectiveness of resuscitation efforts (Shephard and Quan, 2011). Resuscitative measures should begin at the scene of a drowning, and the victim should be transported to the hospital with maximal ventilatory and circulatory support. In the hospital intensive care is implemented and continued according to the patient's needs.

In general the management of the victims with submersion injuries is based on the degree of cerebral insult. The first priority is to restore oxygen delivery to the cells and prevent further hypoxic damage. A spontaneously breathing child does well in an oxygen-enriched atmosphere; a more severely affected child requires endotracheal intubation and mechanical ventilation. Blood gases and pH are monitored frequently as a guide to oxygen, fluid, and electrolyte therapies.

! NURSING ALERT

All children who have a submersion injury should be hospitalized for observation. Almost half of asymptomatic or minimally symptomatic alert children experience complications (e.g., respiratory compromise, cerebral edema) during the first 24 hours after the incident (Shephard and Quan, 2011).

Aspiration pneumonia is a frequent complication that occurs about 48 to 72 hours after the episode. Bronchospasm, alveolocapillary membrane damage, atelectasis, abscess formation, and acute respiratory distress syndrome are other complications that occur after aspiration of fluid.

Prognosis. The best predictors of a good outcome are length of submersion less than 5 minutes and the presence of sinus rhythm, reactive pupils, and neurologic responsiveness at the scene. The worst prognoses—for death or severe neurologic impairment—are children submerged for more than 10 minutes and not responding to advanced life support within 25 minutes. All children without purposeful movement and normal brainstem function 24 hours after a submersion injury have sustained severe neurologic deficits or death (Shephard and Quan, 2011). (See Guidelines box.)

CARE MANAGEMENT

Nursing care depends on the child's condition. A child who survives may need intensive respiratory nursing care with attention to vital signs, mechanical ventilation, or tracheostomy, blood gas determination, chest physiotherapy, and IV infusion. Frequently a child who has sustained a submersion injury requires the same care as an unconscious child. A difficult aspect in the care of the child victim of submersion injury is helping the parents cope with severe guilt reactions. Given the magnitude of the event, parents need repeated assurance that everything possible is being done to treat the child.

The parents of the child who is saved from death face the anxiety of not knowing the final outcome. The situation generates such intense feelings of loneliness and guilt that it is important for families to know that they are not alone. They should be reminded frequently that people are available to help them during the crisis. Additional sources of support include psychiatric and social work consultants, community services, and religious support. Self-help groups may be beneficial if these are available in the community.

Nurses often have difficulty relating to the parents if obvious neglect has precipitated the accident and subsequent problems; therefore it is important for those who care for these children and their families to assess their own feelings about the situation in addition to assessing the family's coping abilities and resources. Caring for victims of a submersion injury and their families requires nurses to be sensitive to the needs of the child and family and recognize their own reactions and emotions.

Prevention. Most submersion injuries are preventable. The most common cause of submersion injury of infants and young children is inadequate adult supervision, including a momentary lapse of supervision (Weiss and AAP Committee on Injury, Violence, and Poison Prevention, 2010). Close adult supervision of infants and children around any body of water is essential and should include the adult not engaging in any distracting activities. Other strategies include environmental prevention strategies such as pool fencing; pool covers; water-entry alarms; and lifeguard and individual prevention such as swimming and survival skills, cardiopulmonary resuscitation training, and the use of personal flotation devices

GUIDELINES

Establishing Brain Death in Children

1. Coma and apnea must coexist. Child must exhibit complete loss of consciousness, vocalization, and volitional activity.
2. Brainstem function must be absent, as defined by:
   a. Midposition or fully dilated pupils that do not respond to light. Drugs may influence and invalidate pupillary assessment.
   b. Absence of spontaneous eye movements and those induced by oculocephalic and caloric (oculovestibular) testing.
   c. Absence of movement of bulbar musculature, corneal, gag, cough, sucking, and rooting reflexes.
   d. Absence of respiratory movements with standardized methods for testing apnea.
3. Child must not be hypothermic or hypotensive for age.
4. Flaccid tone and absence of spontaneous or induced movements, excluding activity mediated at the spinal cord level.
5. Examination should remain consistent with brain death throughout the observation and testing period.
6. Observation periods according to age:
   Seven days to 2 months—Two separate examinations and two EEGs separated by at least 48 hours
   Two months to 1 year—Two separate examinations and two EEGs separated by at least 24 hours
   Over 1 year—Two separate examinations separated by at least 12 hours

Modified from Ashwal S, Serna-Fonseca T: Brain death in infants and children, *Crit Care Nurse* 26:117–128, 2006.

(Weiss and AAP Committee on Injury, Violence, and Poison Prevention, 2010).

NERVOUS SYSTEM TUMORS

CNS tumors account for approximately 20% of all childhood cancers, with an estimated annual incidence of 3.1 cases per 100,000 children younger than 15 years of age (Howlader, Noone, Krapcho, et al., 2011).

Brain Tumors

Brain tumors are the most common solid tumor in children and the second most common childhood cancer. In children the use of reference terms *benign* or *malignant* is generally avoided because any tumor, despite its nature, can be fatal or associated with significant morbidities in the developing brain of a child.

CNS tumors can arise from any cell within the brain or spinal cord. The cell origin provides a histologic classification. For instance, astrocytes (cells that form the supportive tissue for neurons) may form a common glial tumor called an astrocytoma. A specific type of tumor called *ependymoma* typically arises within or adjacent to the ependymal lining of the ventricular system. CNS tumors in children are typically glial or neuronal in origin, located in the infratentorium, and generally sensitive to radiation and adjuvant chemotherapy (Merchant, Pollack, and Loeffler, 2010). Infratentorial brain tumors occur in the area of the brain below the tentorium cerebelli involving the cerebellum or brainstem. Types of infratentorial tumors include medulloblastoma, ependymoma, cerebellar astrocytoma, and brainstem glioma. Tumors above the tentorium are referred to as supratentorial and may include astrocytoma, primitive neuroectodermal tumor, craniopharyngioma, and optic pathway glioma. The suprasellar and pineal regions of the brain often are the location of germ cell tumors.

Diagnostic Evaluation

The signs and symptoms of brain tumors are directly related to their anatomic location and size and, to some extent, the child's age. Supratentorial tumors can cause symptoms that include seizures, contralateral hemiparesis, memory loss, personality and behavioral changes, decline in school performance, and vision loss. Infratentorial tumors often cause the obstruction of normal CSF flow, resulting in signs and symptoms of increased ICP. Tumors involving the brainstem may cause cranial neuropathies, difficulty in micturition (if the pontine micturition center is affected), weakness, hypertonicity, and changes in respiratory pattern. Cerebellar tumors often cause ataxia, dysmetria, or nystagmus. In infants and very young children whose cranial sutures are still open, initial signs and symptoms of increased ICP (headache, vomiting, and lethargy) may not be evident, and symptoms may include irritability, failure to thrive, and loss of developmental milestones. Brain tumors involving the pineal gland or suprasellar region often present with endocrinopathies, which include growth failure, precocious puberty, DI, and adrenal insufficiency.

Diagnosis of a brain tumor is based subjectively on presenting clinical signs, objectively on neurologic tests, and surgical confirmation of the histologic diagnosis. A number of tests may be used in the neurologic evaluation, but the most common diagnostic procedure is MRI, which determines the location and extent of the tumor. Other tests that may be used include CT, angiography, EEG, and lumbar puncture. CT or MRI is routinely performed before a lumbar puncture procedure to identify intracranial abnormalities that may cause a contraindication to the procedure (Lin and Safdieh, 2010). Lumbar puncture is dangerous in the presence of increased ICP because of the possibility of brainstem herniation after a sudden release of pressure. The definitive diagnosis of a brain tumor is based on brain tissue specimens obtained during surgery.

Therapeutic Management

Treatment may involve the use of surgery, radiotherapy, and chemotherapy or a combination of these treatment modalities. The optimum treatment is complete surgical resection of the primary tumor with preservation of adequate neurologic function. Radiation therapy is an integral part of treatment for many brain tumors but can cause significant neurocognitive side effects and endocrinopathies. Because rapid brain development occurs during the first 3 years of life, radiation therapy, particularly craniospinal radiation, is avoided in children younger than 3 years of age. Chemotherapy may be used as primary treatment or in an effort to delay radiation therapy until patients are older and may experience fewer neurocognitive side effects. One of the challenges in using chemotherapy for CNS tumors is the blood-brain barrier, which is a natural barrier that significantly influences the penetration of substances into the CNS. Commonly used chemotherapy agents for treatment of brain tumors in children include vincristine, cisplatin, carboplatin, cyclophosphamide, etoposide, lomustine, and temozolomide (Blaney, Haas-Kogan, Young Poussaint, et al., 2011).

Prognosis. The prognosis for a child with a brain tumor varies greatly and depends on the type of brain tumor, the size of the tumor, the extent of the disease, age, and surgical resectability. Recent advances in surgical instrumentation allowing aggressive surgical intervention, modifications in radiation, and use of chemotherapy have increased the long-term survival rates for many children with brain tumors. Currently the overall survival rate for CNS tumors in children younger than 15 years of age is approximately 75% (Howlader, Noone, Krapcho, et al., 2011). Despite an improvement in overall survival, children with brain tumors, particularly those who are very young at diagnosis, may have significant physical, cognitive, and endocrinologic sequelae because of their tumor and associated treatment (Shaw, 2009).

CARE MANAGEMENT

If a brain tumor is suspected in a child admitted to the hospital for cerebral dysfunction, establishing baseline data with which to compare preoperative and postoperative changes is an essential step. It also allows the nurse to assess the degree of physical incapacity and the family's emotional reaction to the diagnosis.

Vital signs, including blood pressure and pulse pressure (the difference between systolic and diastolic pressures), are taken routinely and more often when any change is noted. Any sudden variations are reported immediately. Observation for symptoms of Cushing triad (i.e., a hallmark sign of increased ICP, which includes bradycardia, hypertension, and irregular respirations) is a crucial role of the nurse. It is also important to note a change in vital signs during or after diagnostic procedures. A routine neurologic assessment is performed at the same time as vital signs, and head circumference should be measured for infants and very young children. The child is observed for evidence of headache, vomiting, and any seizure activity. The location, severity, and duration of the headache and its relationship to activity, time of day, and any associated factors are noted. Behaviors such as lying flat and facing away from light or refusing to engage in play are clues to discomfort in nonverbal children. The child's gait is observed at least once daily. Head tilt while

talking or performing an activity and other changes in posturing should always be documented.

Prevent Postoperative Complications. Usually the surgeon prescribes specific orders for vital signs, neurologic checks, positioning, fluid regulation, and medication. These vary somewhat, depending on the location of the craniotomy. The following are general principles of care for infratentorial or supratentorial surgery. Additional aspects of care that are discussed elsewhere may include care of the child with seizures and neurologic assessment of the unconscious child.

Vital signs are taken as frequently as every 15 to 30 minutes until the child is stable. Temperature measurement is particularly important because of hyperthermia resulting from surgical intervention in the hypothalamus or brainstem and from some types of general anesthesia. To prepare for this reaction, a cooling blanket is often placed on the bed *before* the child returns to the unit so it is ready for use when needed. The temperature is monitored carefully when any cooling measures are taken because hypothermia can occur suddenly. Recognizing signs of other complications such as increased ICP, meningitis, and respiratory tract infection is imperative.

Neurologic checks are an essential aspect of care and include pupillary reaction to light, LOC, sleep patterns, and response to stimuli. Although children may be less responsive for a few days after surgery, when they regain full consciousness there should be a steady increase in alertness. Regression to a lethargic, irritable state indicates increasing ICP, possibly caused by hemorrhage, cerebral edema, or meningitis.

! NURSING ALERT

Sluggish, dilated, or unequal pupils are reported immediately because they may indicate increased ICP and potential brainstem herniation, a medical emergency.

Observations for function are not instituted until the child regains consciousness. However, as soon as possible the nurse should begin testing reflexes, hand grip, and functioning of the cranial nerves. Muscle strength is usually diminished as a result of general weakness after surgery but should improve daily. Ataxia may be significantly worse with cerebellar intervention but will improve slowly. Edema near the cranial nerves may depress important functions such as the gag, blink, or swallowing reflex.

Dressings are observed for evidence of drainage. If soiled, the dressing is not removed but is reinforced with dry sterile gauze. The approximate amount of drainage is estimated and recorded. A drain may be placed in the operative site.

! NURSING ALERT

To keep an accurate account of drainage, the soiled area is circled with a pen approximately every hour. In this way continuous bleeding is easily recognized. The presence of colorless drainage is reported immediately because it most likely is CSF from the incisional area. A foul odor from the dressing may indicate an infection. This should be reported immediately, and the nurse should anticipate cultures to be taken from the site.

Correct positioning after surgery is critical to prevent pressure against the operative site, reduce ICP, and avoid the danger of aspiration. If a large tumor was removed, the child is not placed on the operative side because the brain may suddenly shift to that cavity, causing trauma to the blood vessels, linings, and the brain itself. The nurse confers with the surgeon to be certain of the correct position, including degree of neck flexion. The first 24 to 48 hours after brain surgery are critical. If the child's position is restricted, notice of this is posted above the head of the bed. When the child is turned, every precaution is used to prevent jarring or malalignment to prevent undue strain on the sutures. Two nurses are needed—one supporting the head and the other supporting the body. The use of a turning sheet may facilitate turning a heavy child.

The child with an infratentorial procedure is usually positioned on either side with the bed flat. When a supratentorial craniotomy is performed, the head of bed is elevated 20 to 30 degrees with the child on either side or on the back. In a supratentorial craniotomy the head elevation facilitates CSF drainage and decreases excessive blood flow to the brain to prevent hemorrhage. Pillows should be placed against the child's back, not head, to maintain the desired position. Ordinarily the head and neck are kept in midline with the body, and the neck should not be flexed to support venous drainage (Christie, 2008).

! NURSING ALERT

The Trendelenburg position is contraindicated in both infratentorial and supratentorial surgeries because it increases ICP and the risk of hemorrhage. If shock is impending, the practitioner is notified immediately before the head is lowered.

With an infratentorial craniotomy the child is kept NPO for at least 24 hours or longer if the gag and swallowing reflexes are depressed or the child is comatose. With a supratentorial operation cranial neuropathy is less likely, and clear fluids may be resumed soon after the child is alert, sometimes within 24 hours. If the child vomits, oral liquids are stopped. Vomiting not only predisposes the child to aspiration but also increases ICP and the potential for incisional rupture.

The child should be fed to conserve energy and minimize movement. If there is any sign of cranial nerve deficits, he or she is fed slowly to prevent choking and aspiration. Thickening agents can be used if the patient experiences dysphagia with thin liquids. Sometimes enteral feeding is necessary when body functions are too depressed to permit safe oral feedings or when the child refuses to eat or drink. IV fluids are continued until oral fluids are well tolerated or a method of enteral feeding is established. Because of the postoperative cerebral edema and danger of increased ICP, fluid status is monitored carefully.

Headache may be severe and is largely a result of cerebral edema. Measures to relieve some of the discomfort include providing a quiet, dimly lit environment; restricting visitors; preventing any sudden jarring movement such as banging into the bed; and preventing an increase in ICP. Avoiding increased ICP is most effectively achieved by proper positioning and prevention of straining such as during coughing, vomiting, or defecating. The use of opioids such as morphine to relieve pain is controversial because it is thought that they may mask signs of altered consciousness or depress respirations. However, opioids can be given safely because naloxone can be used to reverse their effects (e.g., as sedation or respiratory depression). Acetaminophen and codeine are also effective analgesics for mild-to-moderate pain. When giving medication such as acetaminophen for pain, the nurse should be aware that this medication may also mask the presence of a fever, which could indicate postoperative infection. Regardless of the drugs used, adequate dosage and regular

administration are essential to providing optimal pain relief (see also Pain Assessment; Pain Management, Chapter 30). Placing an ice bag on the forehead may also provide some headache relief, especially if facial edema is severe. Constipation is a common postoperative issue because of anesthesia and immobility. It is important to note that the use of narcotics for pain control may further contribute to constipation. Patients should be given a bowel regimen during the postoperative period until normal bowel function returns.

Support the Child and Family. The family's emotional needs are immense when the diagnosis is a brain tumor; feelings are influenced by the extent of surgery, any neurologic deficits, the expected prognosis, and possible additional therapy. Because few definitive answers can be given before surgery, the surgeon's report after surgery is a significant finding that can vary from a low-grade, completely resected neoplasm to a highly malignant, invasive, and only partially removed tumor. Although parents often try to prepare themselves for the worst possible scenario, being given the news that their child has a potentially fatal tumor or may have significant neurologic impairment from the necessary treatment is always devastating.

Parents should be encouraged to verbalize their feelings about the diagnosis. Often they express tremendous guilt for viewing the insidious onset of symptoms such as ataxia, visual difficulty, or headache, as "minor complaints" by the child. In retrospect many parents feel guilt that they did not associate their child's decline in school performance with an actual medical problem. The nurse needs to exercise particular care not to make any comments that insinuate that the parents should have sought medical advice sooner because this only compounds any feelings of guilt that already exist. During this period the nurse should also discuss with the parents what they plan to tell the child. If the child was prepared honestly, the diagnosis can be expressed in a similar age-appropriate manner. During recovery the child needs additional explanation about the treatment and the reason for any residual neurologic effects such as ataxia or blindness. The increasing availability of child life specialists has served as a tremendous resource in explaining diagnoses such as brain tumors to children, helping them cope with hospitalization and necessary treatment, and helping them understand physical sequelae they may experience (Reynolds and Boyd, 2010).

Neuroblastoma

Neuroblastomas are the most common malignant extracranial solid tumors in children, accounting for 8% to 10% of all childhood cancers (Mullassery, Dominici, Jesudason, et al., 2009). They occur in about one per 7000 live births, with a slightly higher incidence in boys (Brodeur, Hogarty, Mosse, et al., 2011). Approximately 95% of children with neuroblastoma manifest the disease before 10 years of age, with the median age of occurrence at 23 months (Park, Eggert, and Caron, 2010). These tumors originate from embryonic neural crest cells that normally give rise to the adrenal medulla and the sympathetic ganglia. Consequently the majority of tumors develop in the abdomen along the adrenal gland or the retroperitoneal sympathetic chain. Other sites may be in the head, neck, chest, or pelvis.

The signs and symptoms of neuroblastoma depend on the location and stage of the disease. Neuroblastoma is a commonly referred to as a "silent" tumor because approximately half of the patients present with localized disease and display few symptoms. However, children with advanced disease are ill appearing with symptoms of periorbital ecchymoses, proptosis, bone pain, and irritability caused by extensive tumor metastasis, usually in the lymph nodes, bone marrow, skeletal system, skin, or liver (Park, Eggert, and Caron, 2010).

Diagnostic Evaluation

The objective of diagnosis is to locate the primary site and areas of metastasis. Skeletal survey; skull, neck, chest, abdominal, and bone CT scans; and bilateral bone marrow aspirations and biopsies are used to locate a tumor mass and metastasis. A metaiodobenzylguanidine (MIBG) scan is used to determine involvement of bone, bone marrow, and soft tissue involvement.

Urinary excretion of catecholamines is detected in approximately 95% of children with adrenal or sympathetic tumors. Analyzing the breakdown products excreted in the urine (i.e., vanillylmandelic acid, homovanillic acid, dopamine, and norepinephrine) permits detection of suspected tumor before and after medical-surgical intervention (Mullassery, Dominici, Jesudason, et al., 2009). Amplification of proto-oncogene, known as the *MYCN gene,* and chromosome abnormalities correlate strongly with advanced-stage disease, rapid tumor progression, and a poor prognosis (Brodeur, Hogarty, Mosse, et al., 2011).

Therapeutic Management

Accurate clinical staging is important for establishing initial treatment. Therefore surgery is used both to remove as much of the tumor as possible and to obtain biopsies. In early stages complete surgical removal of the tumor is the treatment of choice. If the tumor is large, partial resection is attempted, with a course of irradiation after surgery to shrink it in the hope of complete removal at a later date. Surgery is usually limited to biopsy in stages III and IV because of the extensive metastasis, although the use of additional surgery to assess tumor regression or remove a regressed tumor is not unlikely.

Because radiotherapy can cause vertebral damage and growth arrest, it is contraindicated with intraspinal tumors; however, it can be used for emergency management of a massive neuroblastoma that is causing spinal cord compression (Mullassery, Dominici, Jesudason, et al., 2009). Radiotherapy also offers palliation for metastatic lesions in the bones, lung, liver, or brain.

Chemotherapy is the mainstay of therapy for extensive local or disseminated disease. Agents used in various combinations include cyclophosphamide, doxorubicin, cisplatin, etoposide, vincristine, ifosfamide, carboplatin, topotecan, and teniposide. In children with high-risk or recurrent disease, retinoic acid, radiotherapy, and myeloablative chemotherapy with peripheral stem cell rescue may be used to obtain a longer remission even though a poor overall survival rate is seen (Brodeur, Hogarty, Mosse, et al., 2011).

Prognosis. If all stages are grouped together, the 5-year disease-free survival rates range from 95% for children in the low-risk stage to only 30% in children in the high-risk stage (Park, Eggert, and Caron, 2010). Generally the younger the child at diagnosis (especially younger than 1 year of age), the better the survival rate. Neuroblastoma is one of the few tumors demonstrating spontaneous regression (especially stage IV-S), possibly as a result of maturity of the embryonic cell or the development of an active immune system.

CARE MANAGEMENT

Nursing considerations are similar to those discussed for leukemia and brain tumors, including psychologic and physical preparation for diagnostic and operative procedures; prevention of postoperative complications for abdominal, thoracic, or cranial surgery; and explanation of chemotherapy, radiotherapy, and their side effects.

Because this tumor carries a poor prognosis for many children, every consideration must be given to the family in terms of coping with a life-threatening illness (see Chapter 38). Because of the high

degree of metastasis at the time of diagnosis, many parents experience substantial guilt for not having recognized signs earlier. Parents need much support in dealing with these feelings and expressing them to the appropriate people.

INTRACRANIAL INFECTIONS

The nervous system is subject to infection by the same organisms that affect other organs of the body. However, it is limited in the ways in which it responds to injury. Laboratory studies are needed to identify the causative agent. The inflammatory process can affect the meninges (meningitis) or brain (encephalitis).

Meningitis can be caused by a variety of organisms, but the three main types are (1) bacterial, or pyogenic, caused by pus-forming bacteria, especially meningococci, pneumococci, and *Haemophilus* organisms; (2) viral, or aseptic, caused by a wide variety of viral agents; and (3) tuberculous, caused by the tuberculin bacillus. The majority of children with acute febrile intracranial infections have either bacterial meningitis or viral meningitis as the underlying cause. Bacterial meningitis is considered much more serious than viral meningitis. Compared with viral meningitis, which typically is short lived, self-limiting, and followed by complete recovery, complications from bacterial meningitis can be quite severe and include shock, coma, seizures, intellectual deficits, hearing loss, vision loss, and death (Somand and Meurer, 2009).

Bacterial Meningitis

Bacterial meningitis is an acute inflammation of the meninges and CSF. Suspected bacterial meningitis is a medical emergency, and immediate action must be taken to identify the causative organism and to initiate prompt treatment.

The advent of antimicrobial therapy has had a significant effect on the overall clinical course and prognosis of children with bacterial meningitis. However, the introduction of vaccines has made the most significant impact on the incidence of this disease. After the introduction of the *Haemophilus* influenza type b (Hib) vaccine in 1990 and the pneumococcal conjugate vaccines in 2000, the incidence of bacterial meningitis declined in all age-groups except children younger than 2 months of age. The incidence of bacterial meningitis caused by *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Neisseria meningitidis*, group B streptococcus (GBS), and *Listeria monocytogenes* in children from 2 months of age to 17 years decreased from approximately 17 cases per 100,000 in 1998 to approximately eight cases per 100,000 in 2007 (Thigpen, Whitney, Messonnier, et al., 2011).

Although it is encouraging to recognize the dramatic decline in the incidence of bacterial meningitis, this disease still results in death with the fatality rate of approximately 6.9% in children. The incidence is highest for patients younger than 2 months of age, and GBS is the most common causative organism in these patients. In children older than 2 months of age *S. pneumoniae* and *N. meningitidis* are the most common etiologies for bacterial meningitis (Thigpen, Whitney, Messonnier, et al., 2011). Other causative organisms include β-hemolytic streptococci, *Staphylococcus aureus*, and *Escherichia coli*. The leading causes of neonatal meningitis are GBS, *E. coli*, and *L. monocytogenes*. *E. coli* infection is seldom seen beyond infancy. Meningococcal meningitis occurs in epidemic form and is the only type readily transmitted by droplet infection from nasopharyngeal secretions. Although this condition may develop at any age, the risk of meningococcal infection increases with the number of contacts; therefore it occurs predominantly in school-age children and adolescents. College students, especially those living in dormitory residences, are at moderately increased risk for meningococcal disease compared with other people their age. The meningococcal conjugate vaccine should be given to all people ages 11 to 18 years with a booster dose administered 5 years later (Granoff and Gilsdorf, 2011).

There appear to be some seasonal variations with the organisms. Meningitis caused by *H. influenzae* primarily occurs in autumn or early winter. Pneumococcal and meningococcal infections can occur at any time but are more common in later winter and early spring.

Pathophysiology

The most common route of infection is vascular dissemination from a focus of infection elsewhere. For example, organisms from the nasopharynx invade the underlying blood vessels and enter the cerebral blood supply or form local thromboemboli that release septic emboli into the bloodstream. Invasion by direct extension from infections in the paranasal and mastoid sinuses is less common. Organisms also gain entry by direct implantation after penetrating wounds, skull fractures that provide an opening into the skin or sinuses, lumbar puncture or surgical procedures, anatomic abnormalities such as spina bifida, or foreign bodies such as an internal ventricular shunt or an external ventricular device. After implanting, the organisms spread into the CSF, by which the infection spreads throughout the subarachnoid space.

The infective process is similar to that seen in any bacterial infection and includes inflammation, exudation, white blood cell accumulation, and varying degrees of tissue damage. The brain becomes hyperemic and edematous, and the entire surface of the brain is covered by a layer of purulent exudate that varies with the type of organism. For example, meningococcal exudate is most evident over the parietal, occipital, and cerebellar regions; the thick, fibrinous exudate of pneumococcal infection is confined chiefly to the surface of the brain, particularly the anterior lobes; and the exudate of streptococcal infections is similar to that of pneumococcal infections but thinner. As infection extends to the ventricles, thick pus, fibrin, or adhesions may occlude the narrow passages and obstruct the flow of CSF.

Clinical Manifestations

Patients with bacterial meningitis may present with fever and signs of meningeal irritation, including nausea, vomiting, irritability, anorexia, headache, photophobia, confusion, back pain, and nuchal rigidity. A history of an upper respiratory infection often precedes these symptoms. See Box 45-4 for clinical manifestations of bacterial meningitis. Nuchal rigidity is manifested by inability to flex neck and place chin on chest and presence of Kernig and Brudzinski signs. The Kernig sign is present if the patient, in the supine position with the hip and knee flexed at 90 degrees, cannot extend the knee more than 135 degrees and pain is felt in the hamstrings. Flexion of the opposite knee may also occur. The Brudzinski sign is present if the patient, while in the supine position, flexes the lower extremities if passive flexion of the neck is attempted (Feigin and Cutrer, 2009).

! NURSING ALERT

Any child who is ill and develops a purpuric or petechial rash may have (overwhelming) meningococcemia and must receive medical attention immediately.

BOX 45-4 CLINICAL MANIFESTATIONS OF BACTERIAL MENINGITIS

Children and Adolescents

- Usually abrupt onset
- Fever
- Chills
- Headache
- Vomiting
- Alterations in sensorium
- Seizures (often the initial sign)
- Irritability
- Agitation
- May develop:
  - Photophobia
  - Delirium
  - Hallucinations
  - Aggressive behavior
  - Drowsiness
  - Stupor
  - Coma
- Nuchal rigidity; may progress to opisthotonos
- Positive Kernig and Brudzinski signs
- Hyperactivity but variable reflex responses
- Signs and symptoms peculiar to individual organisms:
  - Petechial or purpuric rashes (meningococcal infection), especially when associated with a shocklike state
  - Joint involvement (meningococcal and *Haemophilus influenzae* infection)
  - Chronically draining ear (pneumococcal meningitis)

Infants and Young Children

- Classic presentation in children (above) is rarely seen in children between 3 months and 2 years of age
- Fever
- Poor feeding
- Vomiting
- Marked irritability
- Frequent seizures (often accompanied by a high-pitched cry)
- Bulging fontanel
- Nuchal rigidity possible
- Brudzinski and Kernig signs not helpful in diagnosis
- Difficult to elicit and evaluate in this age-group
- Subdural empyema (*H. influenzae* infection)

Neonates

Specific Signs

- Extremely difficult to diagnose
- Manifestations vague and nonspecific
- Child well at birth but within a few days begins to look and behave poorly
- Refuses feedings
- Poor sucking ability
- Vomiting or diarrhea
- Poor tone
- Lack of movement
- Weak cry
- Full, tense, and bulging fontanel may appear late in course of illness
- Neck usually supple

Nonspecific Signs That May Be Present

- Hypothermia or fever (depending on infant's maturity)
- Jaundice
- Irritability
- Drowsiness
- Seizures
- Respiratory irregularities or apnea
- Cyanosis
- Weight loss

Diagnostic Evaluation

A lumbar puncture is the definitive diagnostic test for meningitis. The fluid pressure is measured; and samples are obtained for culture, Gram stain, blood cell count, and determination of glucose and protein content. These findings are usually diagnostic. Culture and sensitivity testing are needed to identify the causative organism. Spinal fluid pressure is usually elevated, but interpretation is often difficult when the child is crying. Sedation with fentanyl and midazolam can alleviate the child's pain and fear associated with this procedure. If there is evidence or suspicion of increased ICP (papilledema, focal neurologic deficits, bulging fontanel), a CT scan of the head is warranted before the procedure. Lumbar puncture is contraindicated in any patient with imaging to suggest that the procedure is not safe (e.g., midline shift, mass effect, transependymal migration of CSF). However, a "normal" CT does not always mean that a lumbar puncture is safe in the case of bacterial meningitis. It is important to take the clinical status into careful consideration. Clinical signs, including recent seizure, deteriorating LOC, or brainstem signs (posturing, pupillary changes, respiratory pattern changes), are clinical predictors of when a lumbar puncture should be delayed (Joffe, 2007).

The patient with meningitis generally has an elevated white blood cell count, often predominantly polymorphonuclear leukocytes. Typically in bacterial meningitis the CSF glucose level is reduced, generally in proportion to the duration and severity of the infection. It is a common misconception that the CSF glucose is low because of bacterial consumption of glucose. However, CNS infections may alter glucose transport across the blood-CSF barrier, resulting in a low CSF glucose value. The CSF glucose value in viral meningitis is usually normal (Logan and MacMahon, 2008). The protein concentration is usually increased.

A blood culture is advisable for all children suspected of having meningitis and occasionally is positive when CSF culture is negative. Nose and throat cultures may provide helpful information in some cases.

Therapeutic Management

Acute bacterial meningitis is a medical emergency that requires early recognition and immediate institution of therapy to prevent death or residual disabilities. The initial therapeutic management includes the following:

- Isolation precautions
- Initiation of antimicrobial therapy
- Restrict hydration
- Maintenance of ventilation
- Reduction of increased ICP
- Management of systemic shock
- Control of seizures
- Control of temperature
- Treatment of complications

The child is isolated from other children, usually in an intensive care unit for close observation. An IV infusion is started to facilitate the administration of antimicrobial agents, fluids, antiepileptic drugs, and blood, if needed. The child is placed on a cardiac monitor and in respiratory isolation.

Drugs. Until the causative organism is identified, the choice of antibiotic is based on the known sensitivity of the organism most likely to be the infective agent. After identification of the organism, antimicrobial agents are adjusted accordingly.

MEDICATION ALERT

Dexamethasone may play a role in the initial management of increased ICP and cerebral herniation, but its ability to reduce long-term complications of bacterial meningitis remains controversial. Evidence indicates that dexamethasone therapy decreases the risk of neurologic sequelae in children with Hib meningitis, but data regarding the benefits in other types of bacterial meningitis are inconclusive (Prober and Dyner, 2011a). It is not recommended to be used if aseptic or nonbacterial meningitis is suspected (Granoff and Gilsdorf, 2011).

Signs of gastrointestinal hemorrhage or secondary infection may complicate steroid administration. Antibiotic treatment with cephalosporins demonstrates superiority for promptly sterilizing the CSF and reducing the incidence of severe hearing impairment.

Nonspecific Measures. Maintaining hydration is a prime concern, and the type and amount of IV fluids are determined by the patient's condition. Children with bacterial meningitis must be monitored closely for electrolyte and fluid abnormalities. The optimum hydration involves correction of any fluid deficits followed by fluid restriction until normal serum sodium levels and no signs of increased ICP are present. If needed, measures to decrease ICP are implemented (see p. 1425). Long-term fluid restriction is not the standard of care because a lack of adequate fluid volume can reduce blood pressure and cerebral perfusion pressure, causing CNS ischemia (Prober and Dyner, 2011a).

Complications such as aspiration of subdural effusion in infants and disseminated intravascular coagulation syndrome are treated appropriately. Shock is managed by restoration of circulating blood volume and maintenance of electrolyte balance. Seizures can occur during the first few days of treatment. These are controlled with the appropriate antiepileptic drug. Hearing loss is common. The patient should undergo auditory evaluation 6 months after the illness has resolved.

Lumbar puncture is carried out as needed to determine the effectiveness of therapy. The patient is evaluated neurologically during the convalescent period.

Prognosis. Fewer than 10% of cases of bacterial meningitis in children are fatal (Thigpen, Whitney, Messonnier, et al., 2011). The child's age, duration of illness before antibiotic therapy, rapidity of diagnosis after onset, type of organism, and adequacy of therapy are important in the prognosis of bacterial meningitis. Survivors can experience significant physical and neurologic sequelae. The most common sequelae in children include hearing loss, intellectual disability, spasticity or paresis, and seizure disorder. Approximately half of the survivors of pediatric bacterial meningitis will have at least one sequela at a 5-year follow-up time point (Chandran, Herbert, Misurski, et al., 2011).

Clinical features that are associated with an increased risk of developing neurologic complications include young age, infection with *S. pneumoniae*, CSF with more than 10^7 colony-forming units/mL or low CSF glucose content, delay in antimicrobial therapy for longer than 2 days, prolonged or complicated seizures, focal neurologic deficits, and adequacy of response to infection (Chandran, Herbert, Misurski, et al., 2011). The residual deficits in infants are primarily a result of communicating hydrocephalus and the greater effects of cerebritis on the immature brain. In older children they are related to the inflammatory process itself or result from vasculitis associated with the disease.

Prevention. Vaccines are available for types A, C, Y, and W-135 meningococci and Hib. Meningococcal polysaccharide vaccination is given routinely to children 11 years of age or older; however, children ages 2 to 11 years may be given the vaccine if they are at increased risk for meningococcal disease (Granoff and Gilsdorf, 2011). Routine vaccinations for Hib are recommended for all children beginning at 2 months of age. Pneumococcal conjugate vaccine is now recommended for all children beginning at 2 months of age (Prober and Dyner, 2011a) (see Evidence-Based Practice box).

NURSING ALERT

A major priority of nursing care of a child suspected of having meningitis is to administer antibiotics as soon as they are ordered. The child is placed on respiratory isolation for at least 24 hours after initiation of antimicrobial therapy.

CARE MANAGEMENT

The room is kept as quiet as possible, and environmental stimuli are kept to a minimum because most children with meningitis are sensitive to noise, bright lights, and other external stimuli. Most children are more comfortable without a pillow and with the head of the bed slightly elevated. A side-lying position is more often assumed because of nuchal rigidity. The nurse should avoid actions that cause pain or increase discomfort such as lifting the child's head. Evaluating the child for pain and implementing appropriate relief measures are important during the initial 24 to 72 hours. Acetaminophen with codeine is often used. The nurse should be cautious to evaluate if a patient is febrile before giving acetaminophen or ibuprofen because either of these medications may mask a fever, which is an important clinical indication of infection.

The nursing care of the child with meningitis is determined by the child's symptoms and treatment. Observation of vital signs, neurologic signs, LOC, urinary output, and other pertinent data is carried out at frequent intervals. The child who is unconscious is managed as described previously (see p. 1424); and all children are observed carefully for signs of the complications just described, especially increased ICP, shock, or respiratory distress. Frequent assessment of the open fontanels is needed in the infant because subdural effusions and obstructive hydrocephalus can develop as a complication of meningitis.

Fluids and nourishment are determined by the child's status. The child with dulled sensorium is usually kept NPO. Other children are allowed clear liquids initially and, if these are tolerated, progress to a diet suitable for their age. Careful monitoring and recording of intake and output are needed to determine deviations that might indicate impending shock or increasing fluid accumulation such as cerebral edema or subdural effusion.

One of the most difficult problems in the nursing care of children with meningitis is maintaining IV infusion for the length of time needed to provide adequate antimicrobial therapy (usually 10 days). Because continuous IV fluids are usually not necessary, an

EVIDENCE-BASED PRACTICE

Children with Bacterial Meningitis and Preventive Vaccines

Ask the Question

In children and adolescents with bacterial meningitis, has the administration of Hib, pneumococcal, and meningococcal preventive vaccines reduced the incidence and mortality associated with bacterial meningitis?

Search for Evidence

Search Strategies

Search selection criteria included English, publications within past 10 years, research-based articles (level 3 or lower), children and adult populations.

Databases Used

PubMed and Cochrane Collaboration

Critically Analyze the Evidence

- Laval, Pimenta, de Andrade, et al. (2003) conducted a systematic review of studies done in developed and developing countries that compared the effect of the conjugate of the Hib vaccine in the early 1990s with the more recent use of the heptavalent pneumococcal and the serogroup C meningococcal vaccines. The researchers concluded that all the vaccines mentioned have contributed directly to the decline in acute bacterial meningitis.
- Data trends on *Streptococcus pneumoniae* infections from the Bacterial Core Surveillance of the Centers for Disease Control and Prevention were evaluated during 1998 to 2001. After being licensed in early 2000, the pneumococcal conjugate vaccine significantly reduced the number of invasive pneumococcal cases, with the largest decline in young children younger than 2 years of age (Whitney, Farley, Hadler, et al., 2003).
- Haddy, Perry, Chacko, et al. (2005) compared the incidence of *S. pneumoniae* disease before and after the introduction of conjugated pneumococcal vaccine from 1999 to 2002. The trend in the rates of invasive pneumococcal disease cases showed significant declines during the study period for all ages after the introduction of the heptavalent *S. pneumoniae* protein conjugate vaccine.
- Children's Hospital of Pittsburgh reported the occurrence of bacterial meningitis before and after the licensure of the Hib conjugate vaccine. A total of 221 children, ages 1 month to 18 years, diagnosed with bacterial meningitis were identified from 1988 to 1998. *Haemophilus influenzae* was the organism responsible for approximately 58% of cases of bacterial meningitis. The absolute number of cases of bacterial meningitis caused by *H. influenzae* declined to 2.5 cases per year after the introduction of the Hib conjugate vaccine (Neuman and Wald, 2001).
- Watt, Wolfson, O'Brien, et al. (2009) performed a literature review with studies evaluating Hib disease incidence, fatality ratios, and the effect of Hib vaccine. In 2000 there were 173,000 cases of Hib meningitis and 78,300 deaths among children younger than the age of 5 years worldwide. Expanded use of Hib vaccine can reduce the incidence and mortality of Hib-related disease.
- A recent Cochrane review determined the effect, duration of protection, and age-specific effects of polysaccharide SgAV to prevent meningococcal meningitis in children. The vaccine had a 95% protective effect during the first year in children older than 5 years of age, but its efficacy after the first year could not be determined. Children ages 1 to 5 years in low-income countries were also protected, but the exact efficacy could not be determined (Patel and Lee, 2010).

Apply the Evidence: Nursing Implications

There is *good evidence with strong recommendations* (Guyatt, Oxman, Vist, et al., 2008) to suggest that all children should be immunized against the most common organisms responsible for bacterial meningitis (i.e., Hib, *S. pneumoniae*, and *Neisseria meningitidis*) as preventive vaccines to decrease the incidence of bacterial meningitis. The nurse should stress to the parents, children, adolescents, and young adults the importance of adhering to the immunization schedule to protect the child against serious childhood diseases.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe the rationale for using vaccines to prevent bacterial meningitis.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by determining whether a patient needs Hib, pneumococcal, or meningococcal preventive vaccines.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate the strengths and weakness of evidence for preventive vaccination in children.

intermittent infusion device is used. In some cases children who are recovering uneventfully are sent home with the device, and the parents are taught IV drug administration.

Family Support. The sudden nature of the illness makes emotional support of the child and parents extremely important. Parents are upset and concerned about their child's condition and often feel guilty for not having suspected the seriousness of the illness sooner. They need much reassurance that the natural onset of meningitis is sudden and that they acted responsibly in seeking medical assistance when they did. The nurse encourages the parents to openly discuss their feelings to minimize blame and guilt. They also are kept informed of the child's progress and of all procedures, results, and treatments. In the event that the child's condition worsens, they need the same psychologic supportive care as parents who face the possible death of their child (see Chapter 36).

Nonbacterial (Aseptic) Meningitis

Aseptic meningitis is caused by many different viruses, including arbovirus, herpes simplex virus (HSV), cytomegalovirus, adenovirus, and HIV. Enteroviruses are the most common cause of viral meningitis (Prober and Dyner, 2011b). The term *aseptic meningitis* refers to the onset of meningeal symptoms, fever, and pleocytosis without bacterial growth from CSF cultures. Viral meningitis can occur at any age but is most common in very young children. It has many of the same presenting signs and symptoms as bacterial meningitis, including headache, fever, photophobia, and nuchal rigidity. It can also be accompanied by cutaneous and mucosal manifestations of enterovirus, including hand, foot, and mouth syndrome; herpangina; and maculopapular rash. The clinical course of viral meningitis is much shorter and typically without any significant complications (Logan and MacMahon, 2008).

Diagnosis is based on clinical features and CSF findings. Variations in CSF values in bacterial and viral meningitis are listed in Table 45-2. It is important to differentiate this self-limiting disorder from the more serious forms of meningitis.

Treatment is primarily symptomatic such as acetaminophen for headache and muscle pain, maintenance of hydration, and positioning for comfort. Until a definitive diagnosis is made, antimicrobial agents may be administered, and isolation enforced as a precaution against the possibility that the disease might be of bacterial origin.

TABLE 45-2 VARIATION OF CEREBROSPINAL FLUID ANALYSIS IN BACTERIAL AND VIRAL MENINGITIS

MANIFESTATIONS	BACTERIAL*	VIRAL
WBC count	Elevated; increased polys	Slightly elevated; increased lymphs
Protein content	Elevated	Normal or slightly increased
Glucose content	Decreased	Normal
Gram stain; bacteria culture	Positive	Negative
Color	Cloudy	Clear

WBC, White blood cell.
*Results may vary in the neonate.

Nursing care is similar to the care of the child with bacterial meningitis.

Encephalitis

Encephalitis is an inflammatory process of the CNS resulting in inflammation of the brain parenchyma itself and is caused by a variety of organisms, including bacteria, spirochetes, fungi, protozoa, helminths, and viruses. Most infections are associated with viruses, and this discussion is limited to these agents.

Etiology

Encephalitis can occur as a result of (1) direct invasion of the CNS by a virus, or (2) postinfectious involvement of the CNS after a viral disease. Often the specific type of encephalitis may not be identified. The cause of more than half of the cases reported in the United States is unknown. The majority of cases of known etiology are associated with the childhood diseases of measles, mumps, varicella, and rubella and, less often, with the enteroviruses, herpesviruses, and West Nile virus.

Herpes simplex encephalitis is an uncommon disease, but 30% of cases involve children. The initial clinical findings are nonspecific (fever, altered mental status), but most cases evolve to demonstrate focal neurologic signs and symptoms. Children may experience focal seizures. The CSF is abnormal in most cases. Because of a rise in the number of children with HSV encephalitis, suspected cases require prompt attention, especially because the diagnosis can be difficult. CSF polymerase chain reaction testing can confirm the clinical diagnosis rapidly. The early use of IV acyclovir reduces mortality and morbidity. Empiric therapy with acyclovir is given before precise virologic diagnosis has been established. Approximately two thirds of children with HSV encephalitis have residual neurologic deficits (James, Kimberlin, and Whitley, 2009).

The multiplicity of causes of viral encephalitis makes diagnosis difficult. Most are those involved with arthropod vectors (togaviruses and bunyaviruses) and those associated with hemorrhagic fevers (arenaviruses, filoviruses, and Hantaviruses). In the United States the vector reservoir for most agents pathogenic for humans is the mosquito (St. Louis or West Nile encephalitis); therefore most cases of encephalitis appear during the hot summer months and subside during the autumn.

The clinical features of encephalitis are similar regardless of the agent involved. Manifestations can range from a mild benign form that resembles aseptic meningitis, lasts a few days, and is followed by rapid and complete recovery to a fulminating encephalitis with severe CNS involvement. The onset may be sudden or gradual with malaise, fever, headache, dizziness, apathy, nuchal rigidity, nausea and vomiting, ataxia, tremors, hyperactivity, and speech difficulties (Box 45-5). In severe cases the patient has a high fever, stupor, seizures, disorientation, spasticity, and coma that may proceed to death. Ocular palsies and paralysis also may occur.

Diagnostic Evaluation

The diagnosis is made on the basis of clinical findings and, when possible, identification of the specific virus. Early in the course of encephalitis, CT scan results may be normal. Later hemorrhagic areas in the frontotemporal region may be seen. Togaviruses (some of which were formerly labeled arboviruses) are rarely detected in the blood or spinal fluid; but viruses of herpes, mumps, measles, and enteroviruses may be found in the CSF. Serologic testing may be required. The first blood sample should be drawn as soon as possible after onset, with the second sample drawn 2 or 3 weeks later. There are a number of characteristic EEG findings in encephalitis,

BOX 45-5 CLINICAL MANIFESTATIONS OF ENCEPHALITIS

Onset
- Malaise
- Fever
- Headache
- Dizziness
- Apathy

- Hyperactivity
- Speech difficulties—mutism
- Altered mental status
- Spasticity
- Coma (may proceed to death)
- Ocular palsies
- Paralysis

particularly in HSV encephalitis, and an EEG is often part of the diagnostic evaluation (Somand and Meurer, 2009).

Therapeutic Management

Patients suspected of having encephalitis are hospitalized promptly for observation. Only HSV encephalitis has specific treatment available. In other cases treatment is primarily supportive and includes conscientious nursing care, control of cerebral manifestations, and adequate nutrition and hydration, with observation and management as for other cerebral disorders. Viral encephalitis can cause devastating neurologic injury. Cerebral edema, seizures, abnormal fluid and electrolyte balances, aspiration, and cardiac or respiratory arrest occur in severe viral encephalitis; and close monitoring is needed (Prober and Dyner, 2011b).

The prognosis for the child with encephalitis depends on his or her age, the type of organism, and residual neurologic damage. Long-term outcomes of HSV encephalitis in children can be serious; deficits include visual, auditory, motor, and psychiatric (Prober and Dyner, 2011b). Very young children (younger than 2 years of age) may exhibit increased neurologic disabilities, including learning difficulties and seizure disorders. Follow-up care with periodic reevaluation is important because symptoms are often subtle, and rehabilitation is essential for patients who develop residual effects of the disease.

CARE MANAGEMENT

Nursing care of the child with encephalitis is the same as for any unconscious child and for children with meningitis. Additional nursing interventions include observation for deterioration in consciousness. Isolation of the child is not necessary; however, good hand washing technique must be followed. A main focus of nursing management is the control of rapidly rising ICP. Neurologic monitoring, administration of medications, and support of the child and parents are the major aspects of care.

Rabies

Rabies is an acute infection of the nervous system caused by a virus that is almost invariably fatal if left untreated. It is transmitted to humans by the saliva of an infected mammal and is introduced through a bite or skin abrasion. After entry into a new host, the virus multiplies in muscle cells and is spread through neural pathways without stimulating a protective host immune response.

Approximately 92% of rabies cases are transmitted by wild animals, and the remainder from domestic animals (Blanton, Palmer, and Rupprecht, 2010). Wild animals such as skunks, raccoons, foxes, and bats are the animals most often infected with rabies and the cause of most indigenous cases of human rabies in the United States. The likelihood of human exposure to a rabid domestic animal has decreased greatly. In 2009 only four cases of human rabies were reported in the United States (Blanton, Palmer, and Rupprecht, 2010).

The circumstances of a biting incident are important. An unprovoked attack is more likely than a provoked attack to indicate a rabid animal. Bites inflicted on a child attempting to feed or handle an apparently healthy animal can generally be regarded as provoked. Any child bitten by a wild animal is assumed to be exposed to rabies.

Although rabies is common among wildlife species, human rabies is rarely acquired. Modern-day prophylaxis is nearly 100% successful. The highest incidence occurs in children younger than age 15 years. The incubation period usually ranges from 1 to 3 months but may be as short as 5 days or as long as 8 months (Willoughby, 2011). Only 10% to 15% of persons bitten develop the disease; but, when symptoms are present, rabies progresses to a fatal outcome. In the United States human fatalities associated with rabies occur in people who fail to seek medical attention, usually because they are unaware of their exposure.

The disease is characterized by a period of nonspecific symptoms, including general malaise, fever, headache, and weakness, followed by typical symptoms of severe encephalitis, including agitation, changes in LOC, and seizures. Attempts at swallowing may cause such severe spasm of the pharynx, neck, and diaphragm muscles that apnea, cyanosis, and anoxia (i.e., the characteristics from which the term *hydrophobia* was derived) are produced.

Diagnosis is made on the basis of history and clinical features. Hydrophobia is a cardinal sign of a rabies diagnosis.

Therapeutic Management

Treatment is of little avail after symptoms appear, but the long incubation period allows time for the induction of active and passive immunity before the onset of illness. Two types of immunizing products are available for use in humans: (1) the inactivated rabies vaccines, which induce an active immune response, and (2) the globulins, which contain preformed antibodies. The two types of products should be used concurrently for rabies postexposure treatment when prophylaxis is indicated; however, they are contraindicated after rabies symptoms develop (Willoughby, 2011).

The current therapy for a rabid animal bite consists of thoroughly cleansing the wound with soap and water and administering antibiotics as indicated. Suturing the wound should be avoided whenever possible. Passive immunization with human rabies immunoglobulin should be administered as soon as possible after exposure to provide rapid, short-term passive immunity (Manning, Rupprecht, Fishbein, et al., 2008).

Postexposure active immunity is conferred by administration of the human diploid cell rabies vaccine. The first intramuscular injection of the vaccine is given at the same time as the immunoglobulin (day 0) and is followed by injections at 3, 7, 14, and 28 days after the first dose (Manning, Rupprecht, Fishbein, et al., 2008). Before antirabies prophylaxis is initiated, the local or state health department should be consulted.

CARE MANAGEMENT

Parents and children are frightened by the urgency and seriousness of the situation. They need anticipatory guidance for the therapy and support and reassurance regarding the efficacy of the preventive measures for this dreaded disease. The vaccine is well tolerated by children, although they need preparation for the series of injections. Mass immunization is unnecessary and unlikely to be implemented. In areas where rabies is rare, the schedule given is sufficient. However, certain circumstances may warrant preexposure vaccination such as when a child is being taken to an area of the world where rabies in stray dogs is still a problem.

Reye's Syndrome

RS is a disorder defined as acute encephalopathy associated with other characteristic organ involvement. It is characterized by fever, profoundly impaired consciousness, and disordered hepatic function.

The etiology of RS is not well understood, but most cases follow a common viral illness, typically influenza or varicella. It is a condition characterized pathologically by cerebral edema and fatty changes of the liver. The onset is notable for profuse effortless vomiting and varying degrees of neurologic impairment, including personality changes, seizures, and coma, that lead to increased ICP, herniation, and death (Carey and Balistreri, 2011). The cause of RS is abnormal mitochondrial function induced by various viruses, drugs, exogenous toxins, and genetic factors. Elevated serum ammonia levels tend to correlate with the clinical manifestations and prognosis.

Definitive diagnosis is established by liver biopsy. The staging criteria for RS are based on liver dysfunction and neurologic signs that range from lethargy to coma. As a result of improved diagnostic techniques, children who in the past would have been diagnosed with RS are now diagnosed with other illnesses such as viral or metabolic diseases. Cases of unrecognized, drug-induced encephalopathy by antiemetics given to children during viral illnesses have symptoms similar to those of RS.

The potential association between aspirin therapy for the treatment of fever in children with varicella or influenza and the development of RS precludes its use in these patients. However, by the time the Food and Drug Administration required aspirin product labeling in 1986, most of the decline in RS incidence had already occurred.

CARE MANAGEMENT

The most important aspect of successful management of a child with RS is early diagnosis and aggressive supportive therapy. Rapid progression to coma and high peak ammonia concentrations are associated with a more serious prognosis. Cerebral edema with increased ICP represents the most immediate threat to life.

Care and observations are implemented as for any child with an altered state of consciousness (see p. 1424) and increasing ICP. Accurate and frequent monitoring of intake and output is essential for adjusting fluid volumes to prevent both dehydration and cerebral edema. Because of related liver dysfunction, laboratory studies to determine impaired coagulation such as prolonged bleeding time should be monitored.

Parents of children with RS need to be kept informed of the child's progress, have diagnostic procedures and therapeutic management explained, and be given concerned and sympathetic support. Families need to be aware that salicylate, the alleged offending ingredient in aspirin, is contained in other products (e.g., Pepto-Bismol). They should refrain from administering any product for influenza-like symptoms without first checking the label for "hidden" salicylates.

Prognosis. Recovery from RS is rapid and usually without sequelae if the diagnosis is determined early and therapy is initiated promptly. Patients who survive have full liver function recovery; however, approximately one third may have subtle neuropsychologic deficits (Carey and Balistreri, 2011; Pugliese, Beltramo, and Torre, 2008).

SEIZURE DISORDERS

Seizures are the most common pediatric neurologic disorder. Approximately 4% of children will have at least one seizure by the age of 15 years, with half of those episodes being febrile seizures (Friedman and Ghazala, 2006). Seizures are caused by excessive and disorderly neuronal discharges in the brain. The manifestation of seizures depends on the region of the brain in which they originate and may include unconsciousness or altered consciousness; involuntary movements; and changes in perception, behaviors, sensations, and posture.

Seizures are a symptom of an underlying disease process. Causes may be infectious, neurologic, metabolic, traumatic, or related to ingestion of toxins (Friedman and Ghazala, 2006). Epilepsy is a condition characterized by two or more unprovoked seizures and can be caused by a variety of pathologic processes in the brain. A single seizure event should not be classified as epilepsy and is generally not treated with long-term antiepileptic drugs. Some seizures may result from an acute medical or neurologic illness and cease after the illness is treated. In other cases children may have a single seizure without the cause ever being known.

After it is determined that the child has had a seizure, it is important to classify it according to the International Classification of Epileptic Seizures and assign it to the appropriate epilepsy syndrome, according to the International Classification of Epilepsies and Epileptic Syndromes. Optimum treatment and prognosis require an accurate diagnosis and a determination of the cause whenever possible.

Etiology

Seizures in children have many different causes. They are classified not only according to type but also according to etiology. Acute symptomatic seizures are associated with an acute insult such as head trauma or meningitis. Remote symptomatic seizures are those without an immediate cause but with an identifiable prior brain injury such as major head trauma, meningitis or encephalitis, hypoxia, stroke, or a static encephalopathy such as cognitive impairment or cerebral palsy. Cryptogenic seizures are those occurring with no clear cause. Idiopathic seizures are genetic in origin. A partial list of causative factors is presented in Box 45-6.

Pathophysiology

Regardless of the etiologic factor or type of seizure, the basic mechanism is the same. Abnormal electrical discharges (1) may arise from central areas in the brain that affect consciousness; (2) may be restricted to one area of the cerebral cortex, producing manifestations characteristic of that particular anatomic focus; or (3) may begin in a localized area of the cortex and spread to other portions of the brain and, if sufficiently extensive, produce generalized seizure activity.

Seizure activity begins with a group of neurons in the CNS that, because of excessive excitation and loss of inhibition, amplify their

BOX 45-6 ETIOLOGY OF SEIZURES IN CHILDREN

Nonrecurrent (Acute)

- Febrile episodes
- Intracranial infection
- Intracranial hemorrhage
- Space-occupying lesions (cyst, tumor)
- Acute cerebral edema
- Anoxia
- Toxins
- Drugs
- Tetanus
- Lead encephalopathy
- *Shigella* or *Salmonella* organisms
- Metabolic alterations:
  - Hypocalcemia
  - Hypoglycemia
  - Hyponatremia or hypernatremia
  - Hypomagnesemia
  - Alkalosis
  - Disorders of amino acid metabolism
  - Deficiency states
  - Hyperbilirubinemia

Recurrent (Chronic)

- Idiopathic epilepsy
- Epilepsy secondary to:
  - Trauma
  - Hemorrhage
  - Anoxia
  - Infections
  - Toxins
  - Degenerative phenomena
  - Congenital defects
  - Parasitic brain disease
  - Hypoglycemia injury
- Epilepsy—sensory stimulus
- Epilepsy-stimulating states
  - Narcolepsy and catalepsy
  - Psychogenic
  - Tetany from hypocalcemia, alkalosis
- Hypoglycemic states
  - Hyperinsulinism
  - Hypopituitarism
  - Adrenocortical insufficiency
  - Hepatic disorders
- Uremia
- Allergy
- Cardiovascular dysfunction or syncopal episodes
- Migraine

discharge simultaneously. In response to physiologic stimuli such as cellular dehydration, severe hypoglycemia, electrolyte imbalance, sleep deprivation, emotional stress, and endocrine changes, these hyperexcitable cells activate normal cells in surrounding areas and in distant, synaptically related cells. A generalized seizure develops when the neuronal excitation from the epileptogenic focus spreads to the brainstem, particularly the midbrain and reticular formation. These centers within the brainstem, known as the centrencephalic system, are responsible for the spread of the epileptic potentials. The discharges can originate spontaneously in the centrencephalic system or be triggered by a focal area in the cortex. On the basis of these characteristic neuronal discharges (as recorded by the EEG), seizures are designated as partial, generalized, and unclassified epileptic seizures.

Hallmark early systemic clinical changes during a generalized seizure include tachycardia, hypertension, hyperglycemia, and hypoxemia. Brief seizures rarely produce significant durable side effects. In contrast, prolonged seizures can lead to lactic acidosis rhabdomyolysis, hyperkalemia, hyperthermia, and hypoglycemia. All of these changes can cause long-term neurologic damage (Friedman and Ghazala, 2006).

Seizure Classification and Clinical Manifestations

There are many different types of seizures, and each has unique clinical manifestations. Seizures are classified into three major categories:

- Partial seizures, which have a local onset and involve a relatively small location in the brain
- Generalized seizures, which involve both hemispheres of the brain and are without local onset
- Unclassified epileptic seizures

Descriptions of the different types of seizures are found in Box 45-7 and Table 45-3.

Diagnostic Evaluation

Establishing a diagnosis is critical for establishing a prognosis and planning the proper treatment. The process of diagnosis in a child suspected of having epilepsy includes (1) determining whether epilepsy or seizures exist rather than an alternative diagnosis, and (2) defining the underlying cause if possible. The assessment and diagnosis rely heavily on a thorough history, skilled observation, and several diagnostic tests.

It is especially important to differentiate epilepsy from other brief alterations in consciousness or behavior. Clinical entities that mimic seizures include migraine headaches, toxic effects of drugs, syncope (fainting), breath-holding spells in infants and young children, movement disorders (tics, tremor, chorea), prolonged QT syndrome, sleep disturbances (night terrors), psychogenic seizures, rage attacks, and transient ischemic attacks (rare in children) (Friedman and Ghazala, 2006). Cocaine intoxication should be considered in the differential diagnosis of new-onset seizure activity in a newborn infant.

The history of the seizure should be detailed, including the type of seizure or description of the child's behavior during the event, the age at onset, and the time at which the seizure occurs (e.g., early morning, before meals, while awake, or during sleep). Any factors that may have precipitated the seizure are important, including fever, infection, head trauma, anxiety, fatigue, sleep deprivation, menstrual cycle, alcohol, and activity (e.g., hyperventilation or exposure to strong stimuli such as bright flashing light or loud noises). Record any sensory phenomena that the child can describe. The duration and progression of the seizure (if any) and the postictal feelings and behavior (e.g., confusion, inability to speak, amnesia, headache, and sleep) should also be recorded. It is important to determine whether more than one seizure type exists. It is often more informative to ask the parents to mime the seizure rather than relying on their oral description. Miming often reveals features such as head turning that would otherwise go unrecognized. Some seizures are overlooked by parents. For example, some parents may not identify brief head nods or brief single jerks as seizures unless specifically asked whether their child has these symptoms. The family history should include whether other family members have had a seizure, cognitive impairments, cerebral palsy, or other neurologic disorders. A family history can offer clues to paroxysmal disorders such as migraine headaches, breath-holding spells, febrile seizures, or neurologic diseases.

A complete physical and neurologic examination, including developmental assessment of language, learning, behavior, and motor abilities, may provide clues to the cause of the seizures. A number of laboratory and neuroimaging tests may be ordered, depending on the child's age, whether it is a new-onset seizure, characteristics of the seizure, and the history. Laboratory studies that may prove to be of value include a venous lead level if the history warrants or white blood cell count (for signs of infection). Blood glucose measurements may give evidence of hypoglycemic episodes; and serum electrolytes, blood urea nitrogen, calcium, serum amino acids, lactate, ammonia, and urine organic acids may indicate metabolic disturbances. Blood for chromosome analysis may also be tested if a genetic etiology is suspected. A toxic screen should be performed if alcohol or drug ingestion is suspected. Lumbar puncture can confirm a suspected diagnosis of meningitis.

BOX 45-7 CLASSIFICATION AND CLINICAL MANIFESTATIONS OF SEIZURES

Partial Seizures

Simple Partial Seizures with Motor Signs

- Characterized by:
  - Localized motor symptoms
  - Somatosensory, psychic, autonomic symptoms
  - Combination of these
  - Abnormal discharges remaining unilateral
- Manifestations
  - Aversive seizure (most common motor seizure in children)—eye or eyes and head turn away from the side of the focus; awareness of movement or loss of consciousness
  - Rolandic (Sylvan) seizure—tonic-clonic movements involving the face, salivation, arrested speech; most common during sleep
  - Jacksonian march (rare in children)—orderly, sequential progression of clonic movements beginning in a foot, hand, or face and moving, or "marching," to adjacent body parts

Simple Partial Seizures with Sensory Signs

- Uncommon in children younger than 8 years of age
- Characterized by various sensations, including:
  - Numbness, tingling, prickling, paresthesia, or pain originating in one area (e.g., face or extremities) and spreading to other parts of the body
  - Visual sensations or formed images
  - Motor phenomena such as posturing or hypertonia

Complex Partial Seizures (Psychomotor Seizures)

- Observed more often in children from 3 years through adolescence
- Characterized by:
  - Period of altered behavior
  - Amnesia for event (no recollection of behavior)
  - Inability to respond to environment
  - Impaired consciousness during event
  - Drowsiness or sleep usually following seizure
  - Confusion and amnesia possibly prolonged
  - Complex sensory phenomena (aura)—most frequent sensation is strange feeling in the pit of the stomach that rises toward the throat and is often accompanied by odd or unpleasant odors or tastes; complex auditory or visual hallucinations; ill-defined feelings of elation or strangeness (e.g., déjà vu, a feeling of familiarity in a strange environment); strong feelings of fear and anxiety; a distorted sense of time and self; and in small children emission of a cry or attempt to run for help
- Patterns of motor behavior:
  - Stereotypic
  - Similar with each subsequent seizure
  - May suddenly cease activity, appear dazed, stare into space, become confused and apathetic, and become limp or stiff or display some form of posturing
  - May be confused
  - May perform purposeless, complicated activities in a repetitive manner (automatisms) such as walking, running, kicking, laughing, or speaking incoherently, most often followed by postictal confusion or sleep; may exhibit oropharyngeal activities such as smacking, chewing, drooling, swallowing, and nausea or abdominal pain followed by stiffness, a fall, and postictal sleep; rarely manifests actions such as rage or temper tantrums; aggressive acts uncommon during seizure

Generalized Seizures

Tonic-Clonic Seizures (Formerly Known As Grand Mal)

- Most common and dramatic of all seizure manifestations
- Occur without warning
- Tonic phase lasts approximately 10 to 20 seconds
- Manifestations:
  - Eyes roll upward
  - Immediate loss of consciousness
  - If standing, falls to floor or ground
  - Stiffens in generalized, symmetric tonic contraction of entire body musculature
  - Arms usually flexed
  - Legs, head, and neck extended
  - May utter a peculiar piercing cry
  - Apneic, may become cyanotic
  - Increased salivation and loss of swallowing reflex
- Clonic phase: lasts about 30 seconds but can vary from only a few seconds to a half hour or longer
- Manifestations:
  - Violent jerking movements as the trunk and extremities undergo rhythmic contraction and relaxation
  - May foam at the mouth
  - May be incontinent of urine and feces
- As event ends, movements less intense, occurring at longer intervals and then ceasing entirely
- Status epilepticus—series of seizures at intervals too brief to allow the child to regain consciousness between the time one event ends and the next begins
  - Requires emergency intervention
  - Can lead to exhaustion, respiratory failure, and death
- Postictal state:
  - Appears to relax
  - May remain semiconscious and difficult to arouse
  - May awaken in a few minutes
  - Remains confused for several hours
  - Poor coordination
  - Mild impairment of fine motor movements
  - May have visual and speech difficulties
  - May vomit or complain of severe headache
  - When left alone, usually sleeps for several hours
  - On awakening is fully conscious
  - Usually feels tired and complains of sore muscles and headache
  - No recollection of entire event

Absence Seizures (Formerly Called Petit Mal or Lapses)

- Characterized by:
  - Onset usually between 4 and 12 years of age
  - More common in girls than boys
  - Usually cease at puberty
  - Brief loss of consciousness
  - Minimum or no alteration in muscle tone
  - May go unrecognized because of little change in child's behavior
  - Abrupt onset; suddenly develops 20 or more attacks daily
  - Event often mistaken for inattentiveness or daydreaming
  - Events possibly precipitated by hyperventilation, hypoglycemia, stresses (emotional and physiologic), fatigue, or sleeplessness

Continued

BOX 45-7 CLASSIFICATION AND CLINICAL MANIFESTATIONS OF SEIZURES—cont'd

- Manifestations:
  - Brief loss of consciousness
  - Appear without warning or aura
  - Usually last about 5 to 10 seconds
  - Slight loss of muscle tone may cause child to drop objects
  - Ability to maintain postural control; seldom falls
  - Minor movements such as lip smacking, twitching of eyelids or face, or slight hand movements
  - Not accompanied by incontinence
  - Amnesia for episode
  - May need to reorient self to previous activity

Atonic and Akinetic Seizures (Also Known As Drop Attacks)

- Characterized by:
  - Onset usually between 2 and 5 years of age
  - Sudden, momentary loss of muscle tone and postural control
  - Events recurring frequently during the day, particularly in the morning hours and shortly after awakening
- Manifestations:
  - Loss of tone causing child to fall to the floor violently
  - Unable to break fall by putting out hand
  - May incur serious injury to face, head, or shoulder
  - Loss of consciousness only momentary

Myoclonic Seizures

- Variety of seizure episodes
- May be isolated as benign essential myoclonus
- May occur in association with other seizure forms
- Characterized by:
  - Sudden, brief contractures of a muscle or group of muscles
  - Occur singly or repetitively
  - No postictal state
  - May or may not be symmetric
  - May or may not include loss of consciousness

Infantile Spasms

- Also called *infantile myoclonus, massive spasms, hypsarrhythmia, salaam episodes,* or *infantile myoclonic spasms*
- Most commonly occur during the first 6 to 8 months of life
- Twice as common in boys as girls
- Numerous seizures during the day without postictal drowsiness or sleep
- Poor outlook for normal intelligence
- Manifestations:
  - Possible series of sudden, brief, symmetric, muscular contractions
  - Head flexed, arms extended, and legs drawn up
  - Eyes sometimes rolling upward or inward
  - May be preceded or followed by a cry or giggling
  - May or may not include loss of consciousness
  - Sometimes flushing, pallor, or cyanosis
- Infants who are able to sit but not stand:
  - Sudden dropping forward of head and neck with trunk flexed forward and knees drawn up—the *salaam* or *jackknife* seizure
- Less often: alternate clinical forms
  - Extensor spasms rather than flexion of arms, legs, and trunk, and head nodding
  - Lightning events involving a single, momentary, shocklike contraction of the entire body

TABLE 45-3 COMPARISON OF SIMPLE PARTIAL, COMPLEX PARTIAL, AND ABSENCE SEIZURES

CLINICAL MANIFESTATIONS	SIMPLE PARTIAL	COMPLEX PARTIAL	ABSENCE
Age of onset	Any age	Uncommon before age 3 years	Uncommon before age 3 years
Frequency (per day)	Variable	Rarely over one or two times	Multiple
Duration	Usually <30 sec	Usually >60 sec, rarely <10 sec	Usually >10 sec, rarely >30 sec
Aura	May be sole manifestation of seizure	Frequent	Never
Impaired consciousness	Never	Always	Always; brief loss of consciousness
Automatisms	Never	Frequent	Frequent
Clonic movements	Frequent	Occasional	Occasional
Postictal impairment	Rare	Frequent	Never
Mental disorientation	Rare	Common	Unusual

CT may be done to detect a cerebral hemorrhage, infarctions, and gross malformations. MRI provides greater anatomic detail and is used to detect developmental malformations, tumors, and cortical dysplasias.

An EEG is obtained for most children with seizures and is the most useful tool for evaluating a seizure disorder. It confirms the presence of abnormal electrical discharges and provides information on the seizure type and the focus. The EEG is carried out under varying conditions (e.g., with the child asleep, awake, awake with provocative stimulation [flashing lights, noise], and hyperventilation). Stimulation may elicit abnormal electrical activity, which is recorded on the EEG. Various seizure types produce characteristic EEG patterns: high-voltage spike discharges are seen in tonic-clonic seizures, with abnormal patterns in the intervals between seizures; a three-per-second spike and wave pattern is observed in an absence seizure; and absence of electrical activity in an area suggests a large lesion such as an abscess or subdural collection of fluid.

A normal EEG does not rule out seizures because the EEG is only a surface recording. It only represents approximately 1 hour of time

and therefore may show normal interictal activity. If there is concern about whether a child has seizures or the seizure type cannot be determined, a long-term video EEG may be done to record the child during wakefulness and sleep. The full-body image is recorded on video, with selected EEG channels displayed on the same screen for simultaneous recording and viewing. EEG monitoring is also available in digital EEG and digital video imaging, which allows for greater selection of EEG channels and is available in both routine and long-term EEGs. Although the EEG is very valuable, it should not be used alone to determine the type of seizure. Rather the EEG interpretation along with a thorough clinical description of the patient's behavior during the seizure episode guides to the correct classification of the seizure and the appropriate treatment choice.

Therapeutic Management

The goal of treatment of seizure disorders is to control the seizures or reduce their frequency and severity, discover and correct the cause when possible, and help the child live as normal a life as possible. If the seizure activity is a manifestation of an infectious, traumatic, or metabolic process, the seizure therapy is instituted as part of the general therapeutic regimen and may only be necessary for a certain period of time if the underlying cause is corrected. Management of epilepsy has four treatment options: drug therapy, the ketogenic diet, vagus nerve stimulation (VNS), and epilepsy surgery.

Drug Therapy. It is known that people predisposed to epilepsy have seizures when their basal level of neuronal excitability exceeds a critical point; no event occurs if the excitability is maintained below this threshold. The administration of antiepileptic drugs serves to raise this threshold and prevent seizures. Consequently the primary therapy for seizure disorders is the administration of the appropriate antiepileptic drug or combination of drugs in a dosage that provides the desired effect without causing undesirable side effects or toxic reactions. Antiepileptic drugs are believed to exert their effect primarily by reducing the responsiveness of normal neurons to the sudden, high-frequency nerve impulses that arise in the epileptogenic focus. Thus the seizure is effectively suppressed; however, the abnormal brain waves may or may not be altered. Complete control of seizures can be achieved in 70% to 80% of children (Curatolo, Moavero, Lo Castro, et al., 2009; Lozsadi, Von Oertzen, and Cock, 2010).

The initiation of anticonvulsant therapy is based on several factors, including the child's age, type of seizure, risk of recurrence, and other comorbid or predisposing medical issues. For children who develop recurrent seizures or epilepsy, treatment is begun with a single drug known to be effective and have the lowest toxicity (i.e., the safest side effect profile for the child's particular type of seizure). The dosage is gradually increased until the seizures are controlled or the child develops side effects. If the drug is effective but does not control the seizures sufficiently, a second drug is added in gradually increasing doses. When seizures are controlled, the first drug may be tapered to reduce the potential adverse effects and drug interactions of polytherapy. Monotherapy remains the treatment method of choice for epilepsy, but a combination of medications may be a viable alternative for children who cannot attain seizure control with only one medication (Mikati, 2011).

Measurement of blood levels of the drug is important if the seizures continue when the child is on a therapeutic dose of medication, to adjust the dosage, and to help determine which medication may be causing the side effects if the child is on multiple antiepileptic medications. Some possible causes of low serum blood concentrations are noncompliance, poor absorption, and drug interactions. The dosage needs to be increased as the child grows. Blood cell counts, urinalysis, and liver function tests are obtained at frequent intervals in children receiving particular antiepileptic medications that can affect organ function.

If complete seizure control is maintained on an anticonvulsant drug for 2 years, it is safe to discontinue the drug for patients with no risk factors. Risk factors include children older than 12 years of age at onset, history of neonatal seizures, numerous seizures before control is achieved, and the presence of a neurologic dysfunction (e.g., motor or cognitive impairment). Up to 40% of children whose medications are discontinued experience seizure recurrence. Recurrence occurs most frequently within 6 months of discontinuation (Sillanpää and Schmidt, 2006).

When seizure medications are discontinued, the dosage is decreased gradually over several weeks. Sudden withdrawal of a drug is not recommended because it can cause an increase in the number and severity of seizures.

MEDICATION ALERT

Fosphenytoin is often used to treat seizures instead of IV phenytoin because of possible complications and drug interactions associated with IV phenytoin. If IV phenytoin is used, it should be administered via slow IV push at a rate that does not exceed 50 mg/min. Because phenytoin precipitates when mixed with glucose, only normal saline is used to flush the tubing or catheter. Fosphenytoin may be given in saline or glucose solutions at a rate of up to 150 mg phenytoin equivalent (PE)/min, and it may be given intramuscularly if necessary.

Ketogenic Diet. The ketogenic diet is a high-fat, low-carbohydrate, and adequate protein diet (Freeman, Kossoff, and Hartman, 2007). Consumption of such a diet forces the body to shift from using glucose as the primary energy source to using fat, and the individual develops a state of ketosis. The diet is rigorous. All foods and liquids that the child consumes must be carefully weighed and measured. The diet is deficient in vitamins and minerals; therefore vitamin supplements are necessary. Early side effects of the diet are diarrhea, hypoglycemia, dehydration, acidosis, and lethargy; long-term side effects include dyslipidemia, kidney stones, and poor growth (Freeman, Kossoff, and Hartman, 2007).

The ketogenic diet has been shown to be an efficacious and tolerable treatment for medically refractory seizures (Freeman, Kossoff, and Hartman, 2007). Studies have shown that as many as 56% of children on the diet had greater than a 50% reduction in seizure episodes (Hartman and Vining, 2007).

Vagus Nerve Stimulation. VNS uses an implantable device that reduces seizures in individuals who have not had effective control with drug therapy. It is currently indicated as adjunct therapy in patients 12 years and older with partial-onset seizures (with or without secondary generalization) who are refractory to antiepileptic drugs (Elliott, Rodgers, Bassani, et al., 2011). A programmable signal generator is implanted subcutaneously in the chest. Electrodes tunneled underneath the skin deliver electrical impulses to the left vagus nerve (cranial nerve X). The device is programmed noninvasively to deliver a precise pattern of stimulation to the left vagus nerve. The patient or caregiver can activate the device using a magnet at the onset of a seizure. No long-term adverse effects have been reported with VNS; but dysphonia, throat or neck pain, and cough can occur during stimulation. Studies show that

approximately one third to one half of patients have a reduction in seizures after 1 year of therapy (Elliott, Rodgers, Bassani, et al., 2011).

Surgical Therapy. When seizures are determined to be caused by a hematoma, tumor, or other cerebral lesion, surgical removal is the treatment. In children with epilepsy, surgery is reserved for those who have incapacitating, refractory seizures. Refractory seizures are usually defined as the persistence of seizures despite adequate trials of three antiepileptic medications, alone or in combination (Mikati, 2011). An extensive medical (e.g., invasive EEG monitoring), psychosocial, and psychoneurologic evaluation is required before surgery. There are several types of surgical interventions. Focal resection entails removal of the epileptogenic zone, and hemispherectomy involves removing all or most of one hemisphere in patients with catastrophic hemispheric epilepsy (Mikati, 2011). Corpus callosotomy consists of the separation of the connections between the two hemispheres in the brain to prevent seizure activity by blocking epileptic discharges (Spencer and Huh, 2008). Patients undergoing surgical resection can experience a decrease in the frequency and severity of seizures, a decrease in antiepileptic medication requirements, and an improvement in their quality of life (Spencer and Huh, 2008).

Status Epilepticus. Status epilepticus is a continuous seizure that lasts more than 30 minutes or a series of seizures from which the child does not regain a premorbid LOC (Huff and Fountain, 2011). It has been suggested that the term *impending status epilepticus* be used for a continuous seizure or series of seizures lasting between 5 to 30 minutes (Mikati, 2011). The initial treatment is directed toward support and maintenance of vital functions (i.e., the ABCs of life support, administering oxygen, and gaining IV access) immediately followed by IV administration of antiepileptic agents.

MEDICATION ALERT

Buccal midazolam and rectal diazepam are quick, effective, and safe treatments for home or prehospital treatment of status epilepticus (Shorvon, 2011). Cessation of seizure occurred in 8 minutes with buccal midazolam and 15 minutes with rectal diazepam (Shorvon, 2011). Respiratory depression is a potential side effect of both medications, and patients should be monitored closely after administration (Mikati, 2011).

For in-hospital management of status epilepticus, IV diazepam or lorazepam (Ativan) is the first-line drug of choice (Mikati, 2011). Lorazepam is the preferred agent because of its rapid onset (2 to 5 minutes) and long half-life (12 to 24 hours). The child must be monitored closely during administration to detect early alterations in vital signs that may indicate impending respiratory depression. When a benzodiazepine (diazepam or lorazepam) is ineffective, fosphenytoin followed by phenobarbital is given as the next line of treatment. This combination of therapy places the child at high risk for apnea; therefore respiratory support is generally necessary. Children may also receive an antiepileptic medication, IV valproate, which does not cause respiratory compromise (Mikati, 2011). Children who continue to have seizures despite this drug treatment may require general anesthesia with a continuous infusion of midazolam, propofol, or pentobarbital (Shorvon, 2011). In this situation the patient may need to be intubated, and continuous EEG monitoring is typically done to monitor for and treat electrographic seizures (Friedman and Ghazala, 2006).

MEDICATION ALERT

Diazepam is incompatible with many drugs. To give it intravenously, inject it slowly and directly into the vein or through tubing as close as possible to the vein insertion site.

Nursing care of a child with status epilepticus includes, in addition to the ABCs of life support, monitoring blood pressure and body temperature. During the first 30 to 45 minutes of the seizure, the blood pressure may be elevated. Thereafter it typically returns to normal but may be decreased, depending on the medications being administered for seizure control. Hyperthermia requiring treatment may occur as a result of increased motor activity.

Prognosis. Most children who experience a second seizure experience additional seizures, with as many as 72% of children having additional seizures within 5 years after the second seizure (Berg, 2008). Therefore a history of two seizures is sufficient to diagnose epilepsy. Epidemiologic studies using population- or community-based cohorts show that the underlying etiology of the child's epilepsy is the most important factor affecting prognosis (Nei and Bagla, 2007). Children with epilepsy and severe neurologic disorders were 22 times more likely to die than children with epilepsy and a normal neurologic status (Nei and Bagla, 2007). Mortality is also associated with the severity and frequency of the child's seizures. It does not significantly increase in children who are seizure free but can be as high as 46% in patients with status epilepticus (Nei and Bagla, 2007).

CARE MANAGEMENT

An important nursing responsibility is to observe the seizure episode and accurately document the events. Any alterations in behavior preceding the seizure and the characteristics of the episode such as sensory-hallucinatory phenomena (e.g., an aura), motor effects (e.g., eye movements, muscular contractions), alterations in consciousness, and postictal state are noted and recorded (Box 45-8). The nurse should describe only what is observed rather than trying to label a seizure type. Note the duration of the seizure with start and stop times.

Based on a thorough assessment, several nursing diagnoses are identified. The more common diagnoses for the child with a seizure disorder are included in the Nursing Care Plan.

The child must be protected from injury during the seizure. Nursing observations made during the event provide valuable information for diagnosis and management of the disorder (see Emergency box on p. 1453).

It is impossible to halt a seizure after it has begun, and no attempt should be made to do so. The nurse must remain calm, stay with the child, and prevent her or him from sustaining any harm during the seizure. If possible, the child should be isolated from the view of others by closing a door or pulling screens. A seizure can be upsetting to the child, other visitors, and their families. If other people are present, they should be assured that everything is being done for the child. After the seizure they can be given a simple explanation about the event as needed.

If the nurse is able to reach the child in time, a child who is standing or seated in a chair (including a wheelchair) is eased to the floor immediately. During (and sometimes after) the tonic-clonic seizure, the swallowing reflex is lost, salivation increases, and the tongue is hypotonic. Therefore the child is at risk for aspiration and airway occlusion. Placing the child on the side facilitates drainage

BOX 45-8 GENERAL OBSERVATIONS: THE CHILD DURING A SEIZURE

Observations During Seizure

Describe
- Order of events (before, during, and after)
- Duration of seizure
  - Tonic-clonic—from first signs of event until jerking stops
  - Absence—from loss of consciousness until consciousness is regained
  - Complex partial—from first sign of unresponsiveness, motor activity, and automatisms until there are signs of responsiveness to environment

Onset
- Time of onset
- Significant precipitating events—missed medication dosage, illness, stress, sleep deprivation, menses

Behavior
- Change in facial expression
- Cry or other sound
- Stereotypic or automatous movements
- Random activity (wandering)
- Position of eyes, head, body, extremities
- Unilateral or bilateral posturing of one or more extremities

Movement
- Change of position, if any
- Site of commencement—hand, thumb, mouth, generalized
- Tonic phase—length, parts of body involved
- Clonic phase—twitching or jerking movements, parts of body involved, sequence of parts involved, generalized, change in character of movements
- Lack of movement or muscle tone of body part or entire body

Face
- Color change—pallor, cyanosis, flushing
- Perspiration
- Mouth—position, deviating to one side, teeth clenched, tongue bitten, frothing at mouth, flecks of blood or bleeding
- Lack of expression
- Asymmetric expression

Eyes
- Position—straight ahead, deviation upward or outward, conjugate or divergent gaze
- Pupils—change in size, equality, reaction to light

Respiratory Effort
- Presence and length of apnea

Other
- Incontinence

Postictal Observations
- Duration of postictal period
- State of consciousness
- Orientation
- Arousability
- Motor ability
  - Any change in motor function
  - Ability to move all extremities
  - Paresis or weakness
- Speech
- Sensations
  - Complaint of discomfort or pain
  - Any sensory impairment
  - Recollection of preseizure sensations or aura

and helps maintain a patent airway. Suctioning the oral cavity and posterior oropharynx may be necessary. Take vital signs and allow the child to rest if at school or away from home. When feasible he or she is integrated into the environment as soon as possible. Sending a child with a chronic seizure disorder home from school is not necessary unless requested by the parents.

Seizure precautions are required for children who are known to have seizures or who are under observation for them. The extent of these measures depends on the type and frequency of the seizure (Box 45-9).

! NURSING ALERT

Do not move or forcefully restrain the child during a tonic-clonic seizure and do not place a solid object between the teeth.

Long-Term Care. Care of the child with a recurrent seizure disorder involves physical care and instruction regarding the importance of the drug therapy and, probably more significant, the problems related to the emotional aspects of the disorder. Few diseases generate as much anxiety among relatives as epilepsy. Fears and misconceptions about the disease and its treatment are common. For many it represents the archetype of severe hereditary affliction. Nursing care is directed toward educating the child and family about epilepsy and helping them develop strategies to cope with the psychologic and sociologic problems related to it.

BOX 45-9 SEIZURE PRECAUTIONS

- The extent of precautions depends on type, severity, and frequency of seizures. They may include the following:
  - Side rails raised when child is sleeping or resting
  - Side rails and other hard objects padded
  - Waterproof mattress or pad on bed or crib
- Appropriate precautions during potentially hazardous activities may include the following:
  - Swimming with a companion
  - Showers preferred; bathing only with close supervision
  - Use of protective helmet and padding during bicycle riding, skateboarding, in-line skating
  - Supervision during use of hazardous machinery or equipment
- Have child carry or wear medical identification.
- Alert other caregivers to need for any special precautions.
- Child may not drive or operate hazardous machinery or equipment unless seizure free for designated period (varies by state).

Children with epilepsy are prescribed antiepileptic medications. These medications are administered at regular intervals to maintain adequate levels in the blood. The nurse can help the parents plan the administration of the medication at convenient times to avoid disruptions of family routines as much as possible. It is important to impress on the family the necessity of giving the antiepileptic

NURSING CARE PLAN

The Child with Seizures

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALE
Risk for Injury related to CNS dysfunction and inability to control self (motor) secondary to type of seizure **Child's or Family's Defining Characteristics *(Subjective and Objective Data)*** Change in LOC Disorientation Clonic movements Automatisms Aura Postictal impairment (dependent on type of seizure)	Child will not experience physical injury as a result of seizure activity.	Administer AEDs	To prevent seizure activity
		Teach family and child, as appropriate, the purpose of AEDs, expected response and action, potential side effects, timing, dosage, route of administration, and how to monitor effects	To promote understanding of chronic condition To prevent seizure activity and encourage self-care
		Monitor for side effects of AEDs and therapeutic levels according to child's growth, illness factors that affect metabolism, and effects of drug	To prevent secondary effects of AEDs and prevent seizures from occurring because of subtherapeutic drug levels
		Stress importance of adherence to medication regimen even if child has no evidence of seizure activity	To prevent seizure activity
		Teach patient and family to identify and avoid situations that are known to precipitate a seizure (e.g., blinking lights, sleep deprivation, excess activity or exercise, physical factors)	To prevent seizure activity
		Initiate seizure precautions in the hospital: • Pad side rails of bed, crib, or wheelchair • Keep bed relatively free of objects • Set up suction and oxygen in room	To prevent physical harm
		Educate family to initiate seizure precautions at home: • Bathroom safety includes taking showers instead of baths to prevent drowning; use shower seat if falls occur during typical seizure; leave bathroom door unlocked • Kitchen safety includes cooking when someone else is nearby, using back burners of the stove to prevent accidental burns, and using shatterproof containers as much as possible • Sports safety includes wearing protective equipment, having others nearby, not climbing higher than 10 feet without special equipment	To prevent physical harm
		Teach family seizure first aid: • If child is at risk of falling at beginning of episode, ease child to floor • Loosen tight or restrictive clothing • Turn child to side-lying position • Prevent child from hitting head on objects • Time seizure • Allow seizure to end spontaneously • Reassure child when awakening from seizure • Do not put anything in child's mouth • Do not attempt to restrain child or use force • Call EMS (see Emergency box, p. 1453) if seizure persists more than 5 minutes, for repeated seizures, or if child does not wake up after movements have stopped	To prepare family for emergencies
		Counsel women of childbearing age about contraception and birth defects associated with AEDs	To prevent birth defects
Risk for Aspiration and Ineffective Breathing Pattern related to impaired motor activity, LOC, and loss of airway protection (tonic-clonic seizure) **Child's or Family's Defining Characteristics *(Subjective and Objective Data)*** Decreased LOC Depressed cough reflex Apnea Decreased inspiratory pressure	Child's airway will remain patent. Child will have effective ventilation.	In the event of a seizure, place child in side-lying position on flat surface such as floor or bed	To prevent aspiration and choking
		Remain with patient.	To protect airway
		Remove secretions, food, and liquids from mouth when seizure subsides	To prevent aspiration
		In postictal state monitor oxygenation status	To determine need for oxygen
		Administer oxygen as necessary	To prevent hypoxia
		Administer rescue breaths if spontaneous respirations do not resume shortly after seizure subsides.	To prevent hypoxia
		Administer medications intended to stop seizure longer than 5 minutes (rectal diazepam, IV Dilantin, IV lorazepam)	To prevent continued seizure activity

NURSING CARE PLAN

The Child with Seizures—cont'd

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALE
Anxiety/Fear, Parent, related to child having life-threatening and incapacitating seizure activity*	Parent will cope with child's condition and receive adequate support.	Allow parent to remain with child during seizure	To decrease fear of unknown and allow parent to see measures taken to protect child
Child's or Family's Defining Characteristics ***(Subjective and Objective Data)***		Instruct parent on proper protection interventions during child's seizure activity, including positioning, safety, airway maintenance, reassurance techniques, and emergency medication administration	To promote parent participation and foster sense of control over situation
Anguish Fear Feelings of inadequacy and hopelessness		Provide information regarding nature (type) of seizure, therapeutic interventions, and lifestyle modifications	To promote knowledge of condition, parental intervention, and sense of control
Worry, apprehension Report of apprehension Panic Excitement		Encourage family involvement in daily care of child with goal of normalization and promotion of optimum growth and development	To provide hope
		Involve parents in discussion of fears, anxieties, and resources and support options available to family	To promote family functioning and coping

AED, Antiepileptic drug; *CNS,* central nervous system; *EMS,* emergency medical services; *IV,* intravenous; *LOC,* level of consciousness.
*Nursing diagnosis may also apply to child in the postictal phase, depending on the type of seizure and the child's understanding and cognition level.

EMERGENCY

Seizures

Tonic-Clonic Seizure

During the Seizure

- Remain calm.
- Time seizure episode.
- If child is standing or seated, ease child down to floor.
- Place pillow or folded blanket under child's head.
- Loosen restrictive clothing.
- Remove eyeglasses.
- Clear area of any hazards or hard objects.
- Allow seizure to end without interference.
- If vomiting occurs, turn child to one side.
- Do not:
  - Attempt to restrain child or use force.
  - Put anything in child's mouth.
  - Give any food or liquids.

After the Seizure

- Time postictal period.
- Check for breathing. Check position of head and tongue.
- Reposition if head is hyperextended. If child is not breathing, give rescue breathing and call EMS.
- Keep child on side.
- Remain with child.
- Do not give food or liquids until child is fully alert and swallowing reflex has returned.
- Call EMS when necessary.
- Look for medical identification and determine which factors occurred before onset of seizure that may have been triggering factors.
- Check head and body for possible injuries.
- Check inside of mouth to see if tongue or lips have been bitten.

Complex Partial Seizure

During the Seizure

- Do not restrain.
- Remove harmful objects from area.
- Redirect to safe area.
- Do not agitate; instead, talk in calm, reassuring manner.
- Do not expect child to follow instructions.
- Watch to see if seizure generalizes.

After the Seizure

- Stay with child and reassure until fully conscious.

Call Emergency Medical Services If:

- Child stops breathing.
- There is evidence of injury or child has diabetes or is pregnant.
- Seizure lasts for more than 5 minutes (unless duration of seizure is typically longer than 5 minutes) and written medical order is present.
- Status epilepticus occurs.
- Pupils are not equal after seizure.
- Child vomits continuously 30 minutes after seizure has ended (sign of possible acute problem).
- Child cannot be awakened and is unresponsive to pain after seizure has ended.
- Seizure occurs in water.
- This is child's first seizure.

EMS, Emergency medical services.

medication regularly and for as long as required. In general antiepileptic medications are continued until the child has been seizure free for 2 years (Johnston and Smith, 2007). The medication is then slowly tapered over a period of weeks to avoid the possibility of precipitating a seizure. It is sometimes easy to skip doses or omit them for a variety of reasons, especially when the child is free of seizures most of the time. This is particularly so when the child is older and assumes responsibility for his or her medication. The seizure threshold may be lowered during any illness but particularly with fever. Therefore parents should be aware that, if their child has an illness, he or she is at increased risk for seizures. They should contact their health care provider if the child misses medications during an illness because of vomiting.

Rectal preparations of some antiepileptic medications are highly effective when a child is unable to take oral medications because of repeated vomiting, gastrointestinal surgery, or status epilepticus. Parents can learn to administer rectal antiepileptic medication for home treatment. Buccal midazolam or rectal diazepam is a useful adjunctive home treatment for children at risk for prolonged seizures or clusters of seizures and can minimize the need for hospitalization while enhancing parental confidence.

MEDICATION ALERT

Children taking phenobarbital or phenytoin should receive adequate vitamin D and folic acid because deficiencies of both have been associated with these drugs. Phenytoin should not be taken with milk.

Nurses should educate the child and parents about the possible adverse reactions to the medications used to treat seizures. Parents should understand the common side effects and be encouraged to report their observations to their health care provider. They should understand that the child needs periodic physical assessment and laboratory studies. Possible adverse effects on the hematopoietic system, liver, and kidneys may be reflected in symptoms such as fever, sore throat, enlarged lymph nodes, jaundice, and bleeding (e.g., easy bruising, petechiae, ecchymoses, epistaxis). A common factor in status epilepticus is inadequate blood levels of antiepileptic drugs.

Although children with epilepsy are at increased risk for injury, few limitations should be placed on activities. The degree to which activities are restricted is individualized for each child and depends on the type, frequency, and severity of the seizures; the child's response to therapy; and the length of time the seizures have been controlled. To prevent head injuries children should always wear appropriate safety devices such as helmets and avoid activities involving heights. Although bike riding is safe for most children, children with frequent seizures and impairment of consciousness should avoid it. Skating, in-line skating, and skateboarding should be restricted only in children with frequent seizures. Helmets must be worn while participating in these activities.

Children with epilepsy are at higher risk for submersion injury than children without epilepsy. Young children should never be left alone in the bathtub, even for a few seconds. Older children and adolescents should be encouraged to use a shower and reminded not to lock the bathroom door when showering. They should never swim unsupervised.

Because the child is encouraged to attend school, camp, and other normal activities, the school nurse and teachers should be made aware of his or her condition and therapy. They can help ensure regularity of medication administration and provision of any special care the child might need. Teachers, child care providers, camp counselors, youth organization leaders, coaches, and other adults who assume responsibility for children should be instructed regarding care of the child during a seizure so they can act calmly for the child's welfare and influence the attitude of her or his peers.

Triggering Factors. Careful and detailed documentation of seizures over time may indicate a pattern. In the general population as many as 90% of individuals with epilepsy can recognize at least one trigger for their seizures (Haut and Lipton, 2009). When this occurs, the child, nurse, or responsible adult can intervene to make changes in the lifestyle or environment that may prevent seizures or decrease their frequency. Often the necessary changes are simple but can make an enormous difference in the lives of the child and family.

The most common factors that may trigger seizures in children include emotional stress, sleep deprivation, fatigue, and fever, and illness (Nakken, Solaas, Kjeldsen, et al., 2005). Other precipitating factors include flickering lights, menstrual cycle, and alcohol (Haut and Lipton, 2009). Some individuals have pattern- or photo-sensitive epilepsy (i.e., seizures precipitated by changes in dark-light patterns such as those that occur with a flash on a camera, automobile headlights, reflections of light on snow or water, or rotating blades on a fan). Most of these individuals have absence, myoclonic, or generalized tonic-clonic seizures. Some children have seizures while playing video games. Although the actual incidence of video game–induced epilepsy is unknown, it most commonly affects children between the ages of 9 and 15 years (Shoja, Tubbs, Malekian, et al., 2007). These children are sensitive to intermittent photic stimulation, usually more than three flashes per second, that can trigger an epileptic episode (Shoja, Tubbs, Malekian, et al., 2007). The prognosis for pattern- or photo-epilepsy is good. Prevention techniques such as keeping a distance greater than 2 m from the television or computer screen, using a smaller screen, and taking frequent breaks can reduce the incidence (Shoja, Tubbs, Malekian, et al., 2007).

Febrile Seizures

Febrile seizures are one of the most common neurologic conditions of childhood, affecting approximately 2% to 5% of children between the ages of 6 and 60 months (Steering Committee on Quality Improvement and Management, Subcommittee on Febrile Seizures AAP, 2008). They are classified as simple or complex. Simple febrile seizures occur in children between the ages of 6 months and 5 years with no preexisting neurologic abnormality and consist of a general tonic-clonic seizure that occurs with a fever (>38.0°C) and resolves within 15 minutes with a return to alert mental status after the seizure and with no further seizure occurring within a 24-hour period (Hampers and Spina, 2011). On the other hand, complex febrile seizures can occur in children of any age usually with a previous neurologic impairment and consist of a prolonged seizure lasting more than 15 minutes that can recur within 24 hours and result in neurologic deficits after the seizure (Fetveit, 2008). Most febrile seizures occur between 6 months and 5 years of age, with the peak incidence occurring at 18 months of age (Østergaard, 2009).

The cause of febrile seizures is still uncertain. Risk factors for simple febrile seizures include viral infections and a family history of febrile seizures (Fetveit, 2008). Associations with chromosome mutations, premature birth, and developmental delay have been evaluated but have not demonstrated any conclusive evidence (Fetveit, 2008). Most febrile seizures have stopped by the time the child is taken to a medical facility and require no treatment. However, if the seizure continues, treatment consists of controlling it with IV or rectal diazepam and reducing the temperature with acetaminophen or ibuprofen (Hampers and Spina, 2011). Antiepileptic

prophylaxis usually is not indicated. Antipyretic therapy may lower the child's temperature and provide symptomatic relief but will not prevent a seizure (Steering Committee on Quality Improvement and Management, Subcommittee on Febrile Seizures AAP, 2008). Tepid sponge baths are not recommended for several reasons: they are ineffective in significantly lowering the temperature, the shivering effect further increases metabolic output, and cooling causes discomfort to the child. Parental education and emotional support are important interventions, and information may need to be repeated, depending on the parents' anxiety and education level. Parents need reassurance regarding the benign nature of simple febrile seizures. Several large studies show no difference in neurologic deficits, cognitive functioning, or memory impairments in children with simple or complex febrile seizures compared with population control participants (Fetveit, 2008).

Long-term antiepileptic therapy is usually not required for children with simple febrile seizures. These children have only a 1% risk of developing epilepsy, but children with a complex febrile seizure along with a preexisting neurologic abnormality and a family history of afebrile seizure have a 10% risk of developing epilepsy (Hampers and Spina, 2011).

! NURSING ALERT

If a febrile seizure lasts more than 5 minutes, parents should seek medical attention right away. They should call for emergency assistance (911) and not place the child who is actively having a seizure in the car.

CEREBRAL MALFORMATIONS

Cranial Deformities

In a normal newborn the cranial sutures are separated by membranous seams several millimeters wide. Up to 2 days after birth the cranial bones are highly mobile, which allows them to mold and slide over one another, adjusting the circumference of the head to accommodate to the changing shape and character of the birth canal. The principal sutures in the infant's skull are the sagittal, coronal, and lambdoidal sutures; and the major soft areas at the juncture of these sutures are the anterior and posterior fontanels (see Fig. 13-1).

After birth, growth of the skull bones occurs in a direction perpendicular to the line of the suture, and normal closure occurs in a regular and predictable order. Although there are wide variations in the age at which closure takes place in individual children, normally all sutures and fontanels are ossified by the following ages:

Eight weeks—Posterior fontanel closed
Six months—Fibrous union of suture lines and interlocking of serrated edges
Eighteen months—Anterior fontanel closed
After 12 years—Sutures unable to be separated by increased ICP

Solid union of all sutures is not completed until late childhood. **Craniosynostosis** (i.e., closure of a suture before the expected time) inhibits the perpendicular growth. Because normal increase in brain volume requires expansion, the skull is forced to grow in a direction *parallel* to the fused suture. This alteration in skull growth always produces a distortion of the head shape when the underlying brain growth is normal. A small head with a closed and normal shape is a result of deficient brain growth; the suture closure is secondary to this brain growth failure. Failure of brain growth is not secondary to suture closure.

Various types of cranial deformities are encountered in early infancy. These include an enlarged head with frontal protrusion (bossing; characteristic of hydrocephalus), parietal bossing that is seen in chronic subdural hematoma, a small head, and a variety of skull deformities. Some occur during prenatal development; in others head circumference is usually within normal limits at birth, and the deviation from normal development becomes apparent with advancing age.

Prognosis. The majority of infants with craniosynostosis have normal brain development. The exceptions are those with genetic disorders that involve brain pathologic conditions.

CARE MANAGEMENT

Nursing care of families in which there is a child with a cranial defect involves identifying children with deformities and referring them for evaluation. Because no therapy is available for children with microcephaly, nursing care is directed toward helping parents adjust to caring for a child with brain damage (see Chapter 37).

Infants who benefit from surgery require special emphasis on observation for signs of anemia because of the large blood loss during surgery (see Family Centered-Care box). Nursing care includes observation for signs of hemorrhage, infection, pain, and swelling and parental education for suture care and safety. Surgical sutures should remain dry and intact. Parents need to observe for any signs of redness, drainage, or swelling and report any temperature greater than 38.4° C (101° F).

Hydrocephalus

Hydrocephalus is a condition caused by an imbalance in the production and absorption of CSF in the ventricular system. When production is greater than absorption, CSF accumulates within the ventricular system, usually under increased pressure, producing passive dilation of the ventricles.

Pathophysiology

The causes of hydrocephalus are varied, but the result is either (1) impaired absorption of CSF fluid within the subarachnoid space, obliteration of the subarachnoid cisterns, or malfunction of the arachnoid villi (nonobstructive or communicating hydrocephalus); or (2) obstruction to the flow of CSF through the ventricular system (obstructive or noncommunicating hydrocephalus) (Kinsman and Johnston, 2011). Any imbalance of secretion and absorption causes an increased accumulation of CSF in the ventricles, which become dilated (ventriculomegaly) and compress the brain substance against the surrounding rigid bony cranium. When this occurs before fusion of the cranial sutures, it causes enlargement of the skull and dilation of the ventricles (Fig. 45-7). In children younger than 10 to 12 years

FAMILY-CENTERED CARE

Blood Donation

Parents may wish to provide a compatible blood donor for their infant undergoing a planned surgical correction for craniosynostosis. Nurses need to inform and guide parents through the blood bank procedure.

Early surgical management of craniosynostosis in children ages 3 to 9 months allows proper expansion of the brain and the creation of an acceptable appearance (Ursitti, Fadda, Papetti, et al., 2011). Parents require special support and education during this time, especially from the health care team.

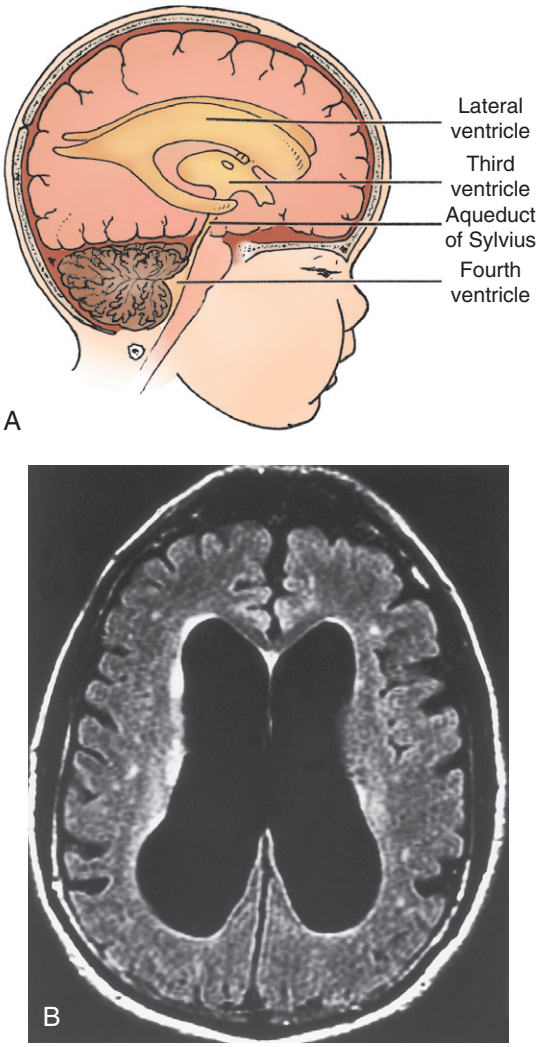

FIG 45-7 Hydrocephalus: a block in flow of cerebrospinal fluid (CSF). **A,** Patent CSF circulation. **B,** Normal-pressure hydrocephalus. (*B* From Grossman RI, Yousem DM: *Neuroradiology*, ed 2, St Louis, 2003.)

of age, partially closed suture lines, especially the sagittal suture, may become diastatic or opened. After 12 years of age the sutures are fused and will not open.

Most cases of noncommunicating hydrocephalus are a result of developmental malformations. Although the defect usually is apparent in early infancy, it may become evident at any time from the prenatal period to late childhood or early adulthood. Other causes include neoplasms, infections, and trauma. An obstruction to the normal flow can occur at any point in the CSF pathway to produce increased pressure and dilation of the pathways proximal to the site of obstruction.

Developmental defects (e.g., Arnold-Chiari malformations, aqueduct stenosis, aqueduct gliosis, and atresia of the foramina of Luschka and Magendie [Dandy-Walker syndrome]) account for most cases of hydrocephalus from birth to 2 years of age. It is so often associated with myelomeningocele that all such infants should be observed for its development. In the remainder of cases there is a history of intrauterine infection, hemorrhage, and neonatal meningoencephalitis. In older children hydrocephalus is most often a result of intracranial masses, intracranial infections, hemorrhage, preexisting developmental defects (e.g., aqueduct stenosis, **Arnold-Chiari malformation**), or trauma.

Clinical Manifestations

The factors that influence the clinical picture in hydrocephalus are the time of onset, acuity of onset, and associated structural malformations. In infancy before closure of the cranial sutures, head enlargement is the predominant sign; but in older infants and children the lesions responsible for hydrocephalus produce other neurologic signs through pressure on adjacent structures before causing CSF obstruction (Box 45-10).

In infants with hydrocephalus the head grows at an abnormal rate; fontanels are bulging and nonpulsatile; scalp veins are dilated, especially when the infant cries; and skull bones are thin with separated sutures, causing a cracked-pot sound (Macewen sign) when palpated. In severe cases infants display frontal protrusion (frontal bossing), eyes depressed and rotated downward (setting-sun sign), and sluggish pupils. The signs and symptoms in early-to-late childhood are caused by increased ICP, and specific manifestations are related to the focal lesion. Most commonly resulting from posterior fossa neoplasms and aqueduct stenosis, the clinical manifestations are primarily those associated with space-occupying lesions (e.g., headaches on awakening with improvement after emesis or being in an upright position, strabismus, ataxia).

Diagnostic Evaluation

Hydrocephalus in infants is based on head circumference that crosses at least one percentile line on the head measurement chart within 2 to 4 weeks. In evaluation of a preterm infant specially adapted head circumference charts are consulted to distinguish abnormal head growth from normal rapid head growth. The primary diagnostic tools to detect hydrocephalus in older infants and children are CT and MRI. Diagnostic evaluation of children who have symptoms of hydrocephalus after infancy is similar to that used in those with suspected intracranial tumor. In neonates echoencephalography is useful in comparing the ratio of lateral ventricle to cortex.

Therapeutic Management

The treatment of hydrocephalus is directed toward relief of the hydrocephalus, treatment of the cause, treatment of associated complications, and management of problems related to the effect of the disorder on psychomotor development. With few exceptions the treatment is surgical. This is accomplished by direct removal of an obstruction (e.g., a tumor) or placement of a shunt that provides primary drainage of the CSF from the ventricles to an extracranial compartment, usually the peritoneum (ventriculoperitoneal [VP] shunt) (Fig. 45-8).

Most shunt systems consist of a ventricular catheter, a flush pump, a unidirectional flow valve, and a distal catheter. In all models the valves are designed to open at a predetermined intraventricular pressure and close when the pressure falls below that level, thus preventing backflow of secretions.

The major complications of VP shunts are malfunction and infection. All shunts are subject to mechanical difficulties such as kinking, plugging, or separation or migration of the tubing. Malfunction is most often caused by mechanical obstruction either within the ventricles from particulate matter (tissue or exudate) or at the distal end from thrombosis or displacement as a result of growth. Revisions are needed when signs of malfunction appear. The child with a shunt obstruction is often first seen in an emergency

BOX 45-10 CLINICAL MANIFESTATIONS OF HYDROCEPHALUS

Infancy (Early)
- Abnormally rapid head growth
- Bulging fontanels (especially anterior) sometimes without head enlargement:
  - Tense
  - Nonpulsatile
- Dilated scalp veins
- Separated sutures
- Macewen sign (cracked-pot sound on percussion)
- Thinning of skull bones

Infancy (Later)
- Frontal enlargement, or bossing
- Depressed eyes
- Setting-sun sign (sclera visible above iris)
- Pupils sluggish with unequal response to light

Infancy (General)
- Irritability
- Lethargy
- Infant cries when picked up or rocked and quiets when allowed to lie still
- Early infantile reflex acts may persist
- Normally expected responses fail to appear
- May display:
  - Change in LOC
  - Opisthotonos (often extreme)
  - Lower-extremity spasticity
  - Vomiting
- Advanced cases:
  - Difficulty in sucking and feeding
  - Shrill, brief, high-pitched cry
  - Cardiopulmonary embarrassment

Childhood
- Headache on awakening; improvement after emesis or upright posture
- Papilledema
- Strabismus
- Extrapyramidal tract signs (e.g., ataxia)
- Irritability
- Lethargy
- Apathy
- Confusion
- Incoherence
- Vomiting

LOC, Level of consciousness.

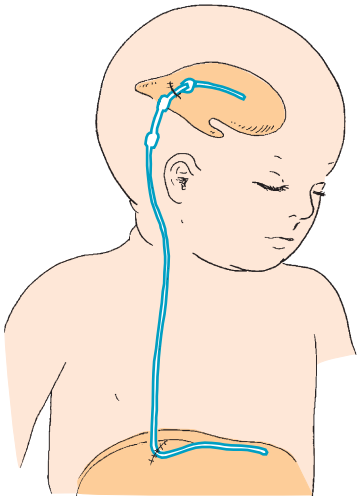

FIG 45-8 Ventriculoperitoneal shunt. The catheter is threaded beneath the skin.

department with clinical manifestations of increased ICP, frequently accompanied by worsening neurologic status.

The most serious complication, shunt infection, can occur at any time, but the period of greatest risk is 1 to 2 months after placement. The infection is generally a result of intercurrent infections at the time of shunt placement. Infections include septicemia, bacterial endocarditis, wound infection, shunt nephritis, meningitis, and ventriculitis. Meningitis and ventriculitis are of greatest concern because any complicating CNS infection is a significant predictor of poor intellectual outcome. Infection is treated with antibiotics administered intravenously or intrathecally for a minimum of 7 to 10 days. A persistent infection requires removal of the shunt until the infection is controlled. External ventricular drainage (EVD) is used until CSF is sterile. The EVD allows for removal of CSF through a tube that is placed in the child's ventricle and flows by gravity into a collection device.

An alternative to shunt placement is the endoscopic third ventriculostomy in children with noncommunicating hydrocephalus. In this procedure a small opening is made in the floor of the third ventricle that allows the CSF to flow freely through the previously blocked ventricle. Complications include CSF leak, intraventricular hemorrhage, meningitis, cranial nerve injury, obstruction, and hypothalamic injury (Hader, Walker, Myles, et al., 2008).

Prognosis. The prognosis for children with treated hydrocephalus depends largely on the rate at which it develops, the duration of increased ICP, the frequency of complications, and the cause of the hydrocephalus. For example, children with malignant tumors may have a high mortality rate regardless of other complicating factors.

Surgically treated hydrocephalus with continued neurosurgical and medical management has a survival rate of about 80%, with the highest incidence of mortality occurring within the first year of treatment (Paulsen, Lundar, and Lindegaard, 2010). Of the surviving children, approximately 60% were reported to have normal intellectual ability, but only 30% had an IQ above 90 (Gupta, Park, Solomon, et al., 2007). Although most children with a history of hydrocephalus are good-natured and friendly, some can have aggressive or delinquent behavior and may be depressed (Gupta, Park, Solomon, et al., 2007; Kinsman and Johnston, 2011).

CARE MANAGEMENT

An infant with diagnosed or suspected hydrocephalus is observed carefully for signs of increasing ventricular size and increasing ICP. In infants the head is measured daily at the largest point, the occipitofrontal circumference (see Head Circumference, Chapter 29, for technique). Fontanels and suture lines are palpated for size, signs of bulging, tenseness, and separation. Irritability, lethargy, or seizure activity and altered vital signs and feeding behavior may indicate an advancing pathologic condition.

In older children the most valuable indicators of increasing ICP are alterations in the child's LOC, headaches, and changes with environmental interactions. Changes are identified by observation and comparison of present behavior with customary behavior, sleep patterns, developmental capabilities, and habits obtained through a detailed history and a baseline assessment. This baseline information serves as a guide for postoperative assessment and evaluation of shunt function.

The nurse is responsible for preparing the child for diagnostic tests such as MRI or CT scan and assisting with procedures such as a ventricular tap, which is often performed to relieve excessive pressure during the preoperative period and for CSF examination. Sedation is required because the child must remain absolutely still during diagnostic testing (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 39).

Postoperative Care. In addition to routine postoperative care and observation, the infant or child is positioned carefully on the unoperated side to prevent pressure on the shunt valve. She or he is kept flat to avoid complications resulting from too-rapid reduction of intracranial fluid. The surgeon indicates the position to be maintained and the extent of activity allowed. Pain management can be achieved with acetaminophen with or without codeine for mild-to-moderate pain and opioids for severe pain (see Pain Management, Chapter 30).

Observation is continued for signs of increased ICP, which indicates obstruction of the shunt. Neurologic assessment includes evaluation of pupillary dilation (pressure causes compression or stretching of the oculomotor nerve, producing dilation on the same side as the pressure) and blood pressure (hypoxia to the brainstem causes variability in these vital signs). If there is increased ICP, the surgeon prescribes elevation of the head of the bed and allows the child to sit up to enhance gravity flow through the shunt.

! NURSING ALERT

Arbitrary pumping of the shunt may cause obstruction or other problems and should not be performed unless indicated by a neurosurgeon.

Because infection is the greatest hazard of the postoperative period, nurses are continually on the alert for the usual manifestations of CSF infection such as elevated temperature, poor feeding, vomiting, decreased responsiveness, and seizure activity. There may be signs of local inflammation at the operative sites and along the shunt tract. The child is also observed for abdominal distention because CSF may cause peritonitis or a postoperative ileus as a complication of distal catheter placement. Antibiotics are administered by the IV route as ordered, and the nurse may also need to assist with intraventricular instillation. The incision site is inspected for leakage, and any suspected drainage is tested for glucose, an indication of CSF.

Family Support. Specific needs and concerns of parents during periods of hospitalization are related to the reason for the child's hospitalization (shunt revision, infection, diagnosis) and the diagnostic and surgical procedures to which the child is subjected. Parents may have little understanding of anatomy; therefore they need further exploration and reinforcement of information that was given to them by the physician and neurosurgeon, including information about what to expect. They are especially frightened of any procedure that involves the brain, and the fear of intellectual disability or brain damage is real and pervasive. Nurses can calm their anxiety with explanations of the rationale underlying the various nursing and medical activities such as positioning or testing and by simply being available and willing to listen to their concerns.

To prepare for the child's discharge and home care, the parents are instructed on how to recognize signs that indicate shunt malfunction or infection. Active children may have injuries such as a fall that can damage the shunt, and the tubing may pull out of the distal insertion site or become disconnected during normal growth. Contact sports should be avoided, and a helmet should be worn when outside play is vigorous.

The management of hydrocephalus in a child is a demanding task for both family and health care providers, and helping a family cope with the child's difficulties is an important nursing responsibility. Children with hydrocephalus have lifelong special health care needs and require evaluation on a regular basis. The overall aim is to establish realistic goals and an appropriate educational program that will help the child to achieve his or her optimal potential.

Families can be referred to community agencies for support and guidance. The National Hydrocephalus Foundation* and the Hydrocephalus Association† provide information on the condition for families and help interested groups establish local organizations.

KEY POINTS

- LOC is the most important indicator of neurologic health; altered levels include full consciousness, confusion, disorientation, lethargy, obtundation, stupor, coma, and a persistent vegetative state.
- Complete neurologic examination includes LOC; posture; motor, sensory, cranial nerve, and reflex testing; and vital signs.
- Nursing care of the unconscious child focuses on ensuring respiratory management; performing neurologic assessment; monitoring ICP; supplying adequate nutrition and hydration; providing drug therapy; promoting elimination, hygienic care, proper positioning, exercise, and stimulation; and providing family support.
- Fractures resulting from head injuries may be classified as linear, depressed, comminuted, basilar, open, and growing.
- Primary head injury involves features that occur at the time of trauma, including fractured skull, contusions, intracranial hematoma, and diffuse injury. Secondary complications include hypoxic brain damage, increased ICP, infection, cerebral edema, and posttraumatic syndromes.
- The young child's response to head injury is different because of the following features: larger head size, expandable skull, larger blood volume to the brain, and small subdural spaces.
- Problems resulting from submersion injury include hypoxia, asphyxiation, aspiration, and hypothermia.
- Nursing care of the child with a brain tumor includes observing for signs and symptoms related to the tumor, preparing the child and family for diagnostic tests and operative procedures,

preventing postoperative complications, planning for discharge, and promoting a return to optimal health.
- Nursing care of the child with meningitis includes administering antibiotics, taking isolation precautions, removing environmental stimuli, ensuring correct positioning, monitoring vital signs, administering IV therapy, promoting adequate fluid and nutritional status, and providing supportive care to the family.
- Routine immunization of infants with Hib and pneumococcal conjugate vaccines has reduced the incidence of bacterial meningitis.
- Encephalitis may result from direct invasion of the CNS by a virus or from involvement of the CNS after viral disease.
- A seizure is a symptom of an underlying pathologic condition and may be manifested by sensory-hallucinatory phenomena, motor effects, sensorimotor effects, or loss of consciousness.
- Partial seizures are categorized as simple (without associated impairment of consciousness) or complex (with impaired consciousness); both types may become generalized.
- Generalized seizures are categorized as tonic, clonic, tonic-clonic, absence, atonic, and myoclonic.
- Long-term care of a child with recurrent seizure disorders includes physical care and education regarding the importance of drug therapy and problems related to emotional aspects of the disorder.
- Febrile seizures are the most common type of childhood seizure.
- Many cranial deformities are amenable to surgical correction.
- Hydrocephalus is a symptom of underlying brain pathologic condition demonstrated by impaired absorption of CSF or obstruction to the flow of CSF within the ventricles.
- Therapy for hydrocephalus involves relief of the hydrocephalus, treatment of the underlying brain disorder if possible, prevention or treatment of complications, and management of problems related to development.

CHAPTER

46

Endocrine Dysfunction

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Differentiate between the disorders caused by hypopituitary and hyperpituitary dysfunction.
- Describe the manifestations of thyroid hypofunction and hyperfunction and the management of children with the disorders.
- Distinguish between the manifestations of adrenal hypofunction and hyperfunction.
- Differentiate among the various categories of diabetes mellitus.
- Discuss the management and nursing care of the child with diabetes mellitus in the acute care setting.
- Distinguish between a hypoglycemic and a hyperglycemic reaction.
- Formulate a teaching plan for instructing the parents of a child with diabetes mellitus.

THE ENDOCRINE SYSTEM

The endocrine system consists of three components: (1) the cells, which send chemical messages by means of hormones; (2) the target cells, or end organs, which receive the chemical messages; and (3) the environment through which the chemicals are transported (blood, lymph, extracellular fluids) from the sites of synthesis to the sites of cellular action. The endocrine system controls or regulates metabolic processes governing energy production, growth, fluid and electrolyte balance, response to stress, and sexual reproduction (Baxter and Ribeiro, 2004). The pathophysiology review in Fig. 46-1 provides a summary of the principal pituitary hormones and their target organs.

Hormones

A hormone is a complex chemical substance produced and secreted into body fluids by a cell or group of cells that exerts a physiologic controlling effect on other cells (Kliegman, Stanton, St. Geme, et al., 2011). These effects may be local or distant and may affect either most cells of the body or specific "target" tissues. Hormones are released by the endocrine glands into the bloodstream, and production is regulated by a feedback mechanism. The master gland of the endocrine system is the anterior pituitary, which is in turn controlled by the hypothalamus. Some hormones, such as insulin, are regulated by other mechanisms.

DISORDERS OF PITUITARY FUNCTION

The pituitary gland is divided into two lobes—the anterior and the posterior lobe. Each lobe is responsible for different hormones. Disorders of the anterior pituitary hormones may be attributable to organic defects or have an idiopathic etiology and may occur as a single hormonal problem or in combination with other hormonal disorders. The clinical manifestations depend on the hormones involved and the age of onset. Panhypopituitarism is often defined clinically as the loss of all anterior pituitary hormones, leaving only posterior function intact (Toogood and Stewart, 2008).

! NURSING ALERT

Children with panhypopituitarism should wear medical identification, such as a bracelet.

Hypopituitarism

Hypopituitarism is diminished or deficient secretion of pituitary hormones. The consequences of the condition depend on the degree of dysfunction and can lead to gonadotropin deficiency with absence or regression of secondary sex characteristics; growth hormone (GH) deficiency, in which children display slowed somatic growth;

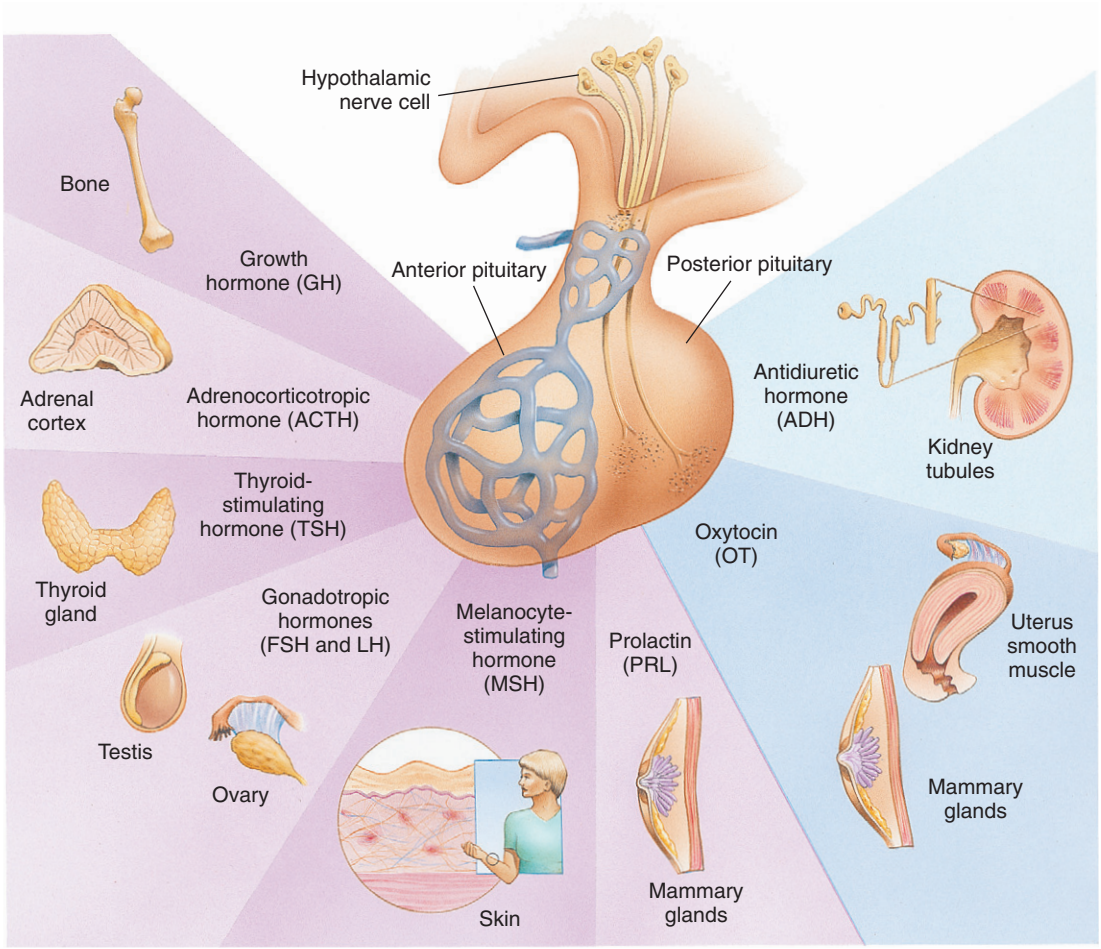

FIG 46-1 Principal anterior and posterior pituitary hormones and their target organs. *FSH,* Follicle-stimulating hormone; *LH,* luteinizing hormone. (From Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

thyroid-stimulating hormone (TSH) deficiency, which produces hypothyroidism; and corticotropin deficiency, which results in manifestations of adrenal hypofunction. Hypopituitarism can result from any of the conditions listed in Box 46-1. The most common organic cause of pituitary undersecretion is tumors in the pituitary or hypothalamic region, especially the craniopharyngiomas. Congenital hypopituitarism can be seen in newborn infants, often as a result of birth trauma. Symptoms of hypoglycemia and seizure activity often manifest within the first 24 hours after birth (Toogood and Stewart, 2008).

Idiopathic hypopituitarism, or idiopathic pituitary growth failure, is usually related to GH deficiency, which inhibits somatic growth in all cells of the body (Miller and Zimmerman, 2004). Growth failure is defined as an absolute height of less than −2 standard deviation (SD) for age or a linear growth velocity consistently less than −1 SD for age. When this occurs without the presence of hypothyroidism, systemic disease, or malnutrition, an abnormality of the GH–insulin-like growth factor (IGF-I) axis should be considered (Richmond and Rogol, 2008). Not all children with short stature have GH deficiency. In most instances, the cause is either familial short stature or constitutional growth delay. Familial short stature refers to otherwise healthy children who have ancestors with adult height in the lower percentiles. Constitutional growth delay refers to individuals (usually boys) with delayed linear growth, generally beginning as a toddler, and skeletal and sexual maturation that is behind that of age mates (Halac and Zimmerman, 2004; Miller and Zimmerman, 2004). Typically, these children will reach normal adult height. Often there is a history of a similar pattern of growth in one of the child's parents or other family members. The untreated child will proceed through normal changes as expected on the basis of bone age. Although treatment with GH is not usually indicated, its use has become controversial, especially in relation to parental and child requests for treatment to accelerate growth.

Clinical Manifestations

Children with hypopituitarism generally grow normally during the first year and then follow a slowed growth curve that is below the third percentile. Skeletal proportions and weight are normal for the age, but these children may appear younger than their chronologic age. Dentition is delayed, and teeth may be overcrowded and malpositioned because of the undeveloped jaw. Sexual development is usually delayed but is otherwise normal unless the gonadotropin hormones are deficient. Growth may extend into the third or fourth decade of life, but permanent height is usually diminished if the disorder is left untreated. Symptoms such as headache and vision changes may indicate the presence of a tumor. Clinical manifestations of panhypopituitarism are listed in Box 46-1.

BOX 46-1 CLINICAL MANIFESTATIONS OF PANHYPOPITUITARISM

Growth Hormone
- Short stature but proportional height and weight
- Delayed epiphyseal closure
- Delayed bone age proportional to height
- Premature aging common in later life
- Increased insulin sensitivity

Thyroid-Stimulating Hormone
- Short stature with infantile proportions
- Dry, coarse skin; yellow discoloration, pallor
- Cold intolerance
- Constipation
- Somnolence
- Bradycardia
- Dyspnea on exertion
- Delayed dentition, loss of teeth

Gonadotropins
- Absence of sexual maturation or loss of secondary sexual characteristics
- Atrophy of genitalia, prostate gland, breasts
- Amenorrhea without menopausal symptoms
- Decreased spermatogenesis

Adrenocorticotropic Hormone
- Severe anorexia, weight loss
- Hypoglycemia
- Hypotension
- Hyponatremia, hyperkalemia
- Adrenal apoplexy, especially in response to stress
- Circulatory collapse

Antidiuretic Hormone
- Polyuria
- Polydipsia
- Dehydration

Melanocyte-Stimulating Hormone
- Decreased pigmentation

BOX 46-2 EVALUATING THE GROWTH CURVE

Ensure reliability of measurements. Accurately obtain and plot height and weight measurements.

Determine absolute height. The child's absolute height bears some relationship to the likelihood of a pathologic condition. However, the majority of children who have a height below the lowest percentile (either the third or fifth percentile on the height curve) do not have a pathologic growth problem.

Assess height velocity. The most important aspect of a growth evaluation is the observation of a child's height over time, or height velocity. Accurate determination of height velocity requires at least 4 and preferably 6 months of observation. A substantial deceleration in height velocity (crossing several percentiles) between 3 and 12 or 13 years of age indicates a pathologic condition until proven otherwise.

Determine weight-to-height relationship. Determination of the weight-to-height ratio has some diagnostic value in ascertaining the cause of growth delay in a short child.

Project target height. The height of a child can be judged inappropriately short only in the context of his or her genetic potential. Determine the target height of the child with the formula:

$$[\text{Father's height (cm)} + \text{Mother's height (cm)}] + 13\tfrac{1}{2} \text{ for boys}$$

or

$$[\text{Father's height (cm)} + \text{Mother's height (cm)}] - 13\tfrac{1}{2} \text{ for girls}$$

Most children achieve an adult stature within approximately 10 cm (4 inches) of the target height.

Adapted from Vogiatzi MG, Copeland KC: The short child, *Pediatr Rev* 19(3):92–99, 1998.

BOX 46-3 BONE AGE FOR EVALUATING GROWTH DISORDERS

Bone age refers to a method of assessing skeletal maturity by comparing the appearance of representative epiphyseal centers obtained on x-ray examination with age-appropriate published standards.

Most conditions that cause poor linear growth also cause a delay in skeletal maturation and a delayed bone age. Observation of even a profoundly delayed bone age is never diagnostic or even indicative of a specific diagnosis. A delayed bone age merely indicates that the associated short stature is to some extent "partially reversible" because linear growth will continue until epiphyseal fusion is complete. In comparison, a bone age that is not delayed in a short child is of much greater concern and may, in fact, be of some diagnostic value under certain circumstances.

Adapted from Vogiatzi MG, Copeland KC: The short child, *Pediatr Rev* 19(3):92–99, 1998.

Diagnostic Evaluation

Only a small number of children with delayed growth or short stature have hypopituitary dwarfism. In the majority of instances, the cause is constitutional delay. Diagnostic evaluation is aimed at isolating organic causes, which, in addition to GH deficiency, may include hypothyroidism, oversecretion of cortisol, gonadal aplasia, chronic illness, nutritional inadequacy, Russell-Silver dwarfism, or hypochondroplasia.

A complete diagnostic evaluation should include a family history, a history of the child's growth patterns and previous health status, physical examination, psychosocial evaluation, radiographic surveys, and endocrine studies. Accurate measurement of height (using a calibrated stadiometer) and weight and comparison with standard growth charts are essential. Multiple height measures reflect a more accurate assessment of abnormal growth patterns (Box 46-2) (Hall, 2000). Parental height and familial patterns of growth are important clues to diagnosis.

A skeletal survey in children younger than 3 years and radiographic examination of the hand-wrist for centers of ossification (bone age) (Box 46-3) in older children are important in evaluating growth.

Definitive diagnosis is based on absent or subnormal reserves of pituitary GH. Because GH levels are variable in children, GH stimulation testing is usually required for diagnosis. Initial assessment of the serum IGF-I and IGF binding protein 3 (IGFBP3) indicates a need for further evaluation of GH dysfunction if levels are less than −1 SD below the mean for age. It is recommended that GH

stimulation tests be reserved for children with low serum IGF-I and IGFBP3 levels and poor growth who do not have other causes for short stature (Richmond and Rogol, 2008). GH stimulation testing involves the use of pharmacologic agents such as levodopa, clonidine, arginine, insulin, propranolol, or glucagon to provoke the release of GH (Kliegman, Stanton, St. Geme, et al., 2011). Children with poor linear growth, delayed bone age, and abnormal GH stimulation tests are considered GH deficient.

Therapeutic Management

Treatment of GH deficiency caused by organic lesions is directed toward correction of the underlying disease process (e.g., surgical removal or irradiation of a tumor). The definitive treatment of GH deficiency is replacement of GH, which is successful in 80% of affected children. Biosynthetic GH is administered subcutaneously on a daily basis. Growth velocity increases in the first year and then declines in subsequent years. Final height is likely to remain less than normal (Bryant, Baxter, Cave, et al., 2007), and early diagnosis and intervention are essential (Leschek, Rose, Yanovski, et al., 2004).

The decision to stop GH therapy is made jointly by the child, family, and health care team. Growth rates of less than 1 inch per year and a bone age of more than 14 years in girls and more than 16 years in boys are often used as criteria to stop GH therapy (Kliegman, Stanton, St. Geme, et al., 2011). Children with other hormone deficiencies require replacement therapy to correct the specific disorders.

CARE MANAGEMENT

The principal nursing consideration is identifying children with growth problems. Even though the majority of growth problems are not a result of organic causes, any delay in normal growth and sexual development poses special emotional adjustments for these children.

The nurse may be a key person in helping establish a diagnosis. For example, if serial height and weight records are not available, the nurse can question parents about the child's growth compared with that of siblings, peers, or relatives. Preparation of the child and family for diagnostic testing is especially important if a number of tests are being performed, and the child requires particular attention during provocative testing. Blood samples are usually taken every 30 minutes for a 3-hour period. Children also have difficulty overcoming hypoglycemia generated by tests with insulin so they must be observed carefully for signs of hypoglycemia, but those receiving glucagon are at risk for nausea and vomiting. Clonidine may cause hypotension, requiring administration of intravenous (IV) fluids.

Child and Family Support. Children undergoing hormone replacement require additional support. The nurse should provide education for patient self-management during the school-age years. Nursing functions include family education concerning medication preparation and storage, injection sites, injection technique, and syringe disposal (see Chapter 39). Administration of GH is facilitated by family routines that include a specific time of day for the injection. Younger children may enjoy using a calendar and colorful stickers to designate received injections.

! NURSING ALERT

Optimum dosing is often achieved when GH is administered at bedtime. Physiologic release is more normally stimulated as a result of pituitary release of GH during the first 45 to 90 minutes after the onset of sleep.

Even when hormone replacement is successful, these children attain their eventual adult height at a slower rate than their peers; therefore they need assistance in setting realistic expectations regarding improvement. Because these children appear younger than their chronologic age, others frequently relate to them in infantile or childish ways. Parents and teachers benefit from guidance directed toward setting realistic expectations for the child based on age and abilities. For example, in the home, such children should have the same age-appropriate responsibilities as their siblings. As they approach adolescence, they should be encouraged to participate in group activities with peers. If abilities and strengths are emphasized rather than physical size, such children are more likely to develop a positive self-image.

Professionals and families can find resources for research, education, support, and advocacy from the Human Growth Foundation.* The treatment is expensive, but the cost is often partially covered by insurance if the child has a documented deficiency. Children with panhypopituitarism should be advised to wear medical identification at all times.

Pituitary Hyperfunction

Excess GH before closure of the epiphyseal shafts results in proportional overgrowth of the long bones until the individual reaches a height of 2.4 m (8 ft) or more. Vertical growth is accompanied by rapid and increased development of muscles and viscera. Weight is increased but is usually in proportion to height. Proportional enlargement of head circumference also occurs and may result in delayed closure of the fontanels in young children. Children with a pituitary-secreting tumor may also demonstrate signs of increasing intracranial pressure, especially headache.

If oversecretion of GH occurs after epiphyseal closure, growth is in the transverse direction, producing a condition known as acromegaly. Typical facial features include overgrowth of the head, lips, nose, tongue, jaw, and paranasal and mastoid sinuses; separation and malocclusion of the teeth in the enlarged jaw; disproportion of the face to the cerebral division of the skull; increased facial hair; thickened, deeply creased skin; and an increased tendency toward hyperglycemia and diabetes mellitus (DM). Acromegaly can develop slowly, leading to delays in diagnosis and treatment.

Diagnostic Evaluation

Diagnosis is based on a history of excessive growth during childhood and evidence of increased levels of GH. Radiographic studies may reveal a tumor in an enlarged sella turcica, normal bone age, enlargement of bones (e.g., the paranasal sinuses), and evidence of joint changes. Endocrine studies to confirm excess of other hormones, specifically thyroid, cortisol, and sex hormones, should also be included in the differential diagnosis.

Therapeutic Management

If a lesion is present, surgery is performed to remove the tumor when feasible. Other therapies aimed at destroying pituitary tissue include external irradiation and radioactive implants. New pharmacologic agents have evolved and may be used in combination with other therapies (Natchtigall, Delgado, Swearingen, et al., 2008). Depending on the extent of surgical extirpation and degree of pituitary insufficiency, hormone replacement with thyroid extract, cortisone, and sex hormones may be necessary.

*997 Glen Cove Ave., Suite 5, Glen Head, NY 11545; 800-451-6434; e-mail: hgf1@hgfound.org; www.hgfound.org.

CARE MANAGEMENT

The primary nursing consideration is early identification of children with excessive growth rates. Although medical management cannot reduce growth already attained, further growth can be delayed. The earlier the treatment, the more control there is in predetermining a normal adult height. Nurses should also observe for signs of a tumor, especially headache, and evidence of concurrent hormonal excesses, particularly the gonadotropins, which cause sexual precocity. Children with excessive growth rates require as much emotional support as those with short stature.

Precocious Puberty

Manifestations of sexual development before age 9 years in boys or age 8 years in girls have traditionally been considered precocious development, and these children were recommended for further evaluation (Kempers and Otten, 2002; Midyett, Moore, and Jacobson, 2003). Recent examination of the age limit for defining when puberty is precocious reveals that the onset of puberty in girls is occurring earlier than previous studies have documented (Biro, Huang, Crawford, et al., 2006; Slyper, 2006). The mean onset of puberty is 10.2 years in Caucasian girls and 9.6 years in African-American girls. Based on these findings, precocious puberty evaluation for a pathologic cause should be performed for Caucasian girls younger than 7 years or for African-American girls younger than 6 years. No change in the guidelines for evaluation of precocious puberty in boys is recommended. However, recent data suggest that boys may be beginning maturation earlier as well (Herman-Giddens, 2006; Slyper, 2006).

Normally, the hypothalamic-releasing factors stimulate secretion of the **gonadotropic hormones** from the anterior pituitary at the time of puberty. In boys, interstitial cell–stimulating hormone stimulates Leydig cells of the testes to secrete testosterone; in girls, follicle-stimulating hormone (FSH) and luteinizing hormone (LH) stimulate the ovarian follicles to secrete estrogens (Nebesio and Eugster, 2007). This sequence of events is known as the hypothalamic-pituitary-gonadal axis. If for some reason the cycle undergoes premature activation, the child will display evidence of advanced or precocious puberty. Causes of precocious puberty are found in Box 46-4.

Isosexual precocious puberty is more common among girls than boys. Approximately 80% of children with precocious puberty have central precocious puberty (CPP), in which pubertal development is activated by the hypothalamic gonadotropin-releasing hormone (GnRH) (Greiner and Kerrigan, 2006). This produces early maturation and development of the gonads with secretion of sex hormones, development of secondary sex characteristics, and sometimes production of mature sperm and ova (Lee, Houk, Ahmed, et al., 2006; Root, 2000). CPP may be the result of congenital anomalies; infectious, neoplastic, or traumatic insults to the central nervous system (CNS); or treatment of longstanding sex hormone exposure (Trivin, Couto-Silva, Sainte-Rose, et al., 2006). CPP occurs more frequently in girls and is usually idiopathic, with 95% demonstrating no causative factor (Greiner and Kerrigan, 2006; Nebesio and Eugster, 2007; Root, 2000). A CNS insult or structural abnormality is found in more than 90% of boys with CPP (Root, 2000).

Peripheral precocious puberty (PPP) includes early puberty resulting from hormone stimulation other than the hypothalamic GnRH–stimulated pituitary gonadotropin release. Isolated manifestations that are usually associated with puberty may be seen as variations in normal sexual development (Greiner and Kerrigan, 2006). They appear without other signs of pubescence and are caused by excess secretion of sex hormones through the gonads or adrenal glands and may be isosexual or contrasexual. Included are premature thelarche (development of breasts in prepubertal girls), premature pubarche (premature adrenarche, early development of sexual hair), and premature menarche (isolated menses without other evidence of sexual development).

BOX 46-4 CAUSES OF PRECOCIOUS PUBERTY

Central Precocious Puberty
- Idiopathic, with or without hypothalamic hamartoma
- Secondary:
  - Congenital anomalies
  - Postinflammatory—Encephalitis, meningitis, abscess, granulomatous disease
  - Radiotherapy
  - Trauma
  - Neoplasms
- After effective treatment of longstanding pseudosexual precocity

Peripheral Precocious Puberty
- Familial male-limited precocious puberty
- Albright syndrome
- Gonadal or extragonadal tumors
- Adrenal:
  - Congenital adrenal hyperplasia
  - Adenoma, carcinoma
  - Glucocorticoid resistance
- Exogenous sex hormones
- Primary hypothyroidism

Incomplete Precocious Puberty
- Premature thelarche
- Premature menarche
- Premature pubarche or adrenarche

Adapted from Root AW: Precocious puberty, *Pediatr Rev* 21(1):10–19, 2000.

Therapeutic Management

Treatment of precocious puberty is directed toward the specific cause when known. In 50% of cases, precocious pubertal development regresses or stops advancing without any treatment (Carel and Leger, 2008). If needed, precocious puberty of central (hypothalamic-pituitary) origin is managed with monthly injections of a synthetic analog of luteinizing hormone–releasing hormone, which regulates pituitary secretions (Greiner and Kerrigan, 2006; Muir, 2006). The available preparation, leuprolide acetate (Lupron Depot), is given in a dosage of 0.2 to 0.3 mg/kg intramuscularly once every 4 weeks. Longer-acting formulations have recently been developed as well. Breast development regresses or does not advance, and growth returns to normal rates, enhancing predicted height. Studies suggest that not all patients attain adult targeted heights, and the addition of GH therapy may be warranted (Carel and Leger, 2008). Treatment is discontinued at a chronologically appropriate time, allowing pubertal changes to resume. Psychologic management of the patient and family is an important aspect of care. Both parents and the affected child should be taught the injection procedure.

CARE MANAGEMENT

Psychologic support and guidance of the child and family are the most important aspects of management. Parents need anticipatory guidance, support and information resources, and reassurance of the benign nature of the condition (Greiner and Kerrigan, 2006; O'Sullivan and O'Sullivan, 2002). Dress and activities for the physically precocious child should be appropriate to the chronologic age. Sexual interest is not usually advanced beyond the child's chronologic age, and parents need to understand that the child's mental age is congruent with the chronologic age.

Diabetes Insipidus

The principal disorder of posterior pituitary hypofunction is diabetes insipidus (DI), also known as neurogenic DI, resulting from undersecretion of antidiuretic hormone (ADH), or vasopressin (Pitressin), and producing a state of uncontrolled diuresis (Makaryus and McFarlane, 2006). This disorder is not to be confused with nephrogenic DI, a rare hereditary disorder affecting primarily males and caused by unresponsiveness of the renal tubules to the hormone.

Neurogenic DI may result from a number of different causes. Primary causes are familial or idiopathic; of the total cases, approximately 45% to 50% are idiopathic. Secondary causes include trauma (accidental or surgical), tumors, granulomatous disease, infections (meningitis or encephalitis), and vascular anomalies (aneurysm). Certain drugs, such as alcohol and phenytoin (diphenylhydantoin), can cause a transient polyuria. DI may be an early sign of an evolving cerebral process (De Buyst, Massa, Christophe, et al., 2007).

The cardinal signs of DI are polyuria and polydipsia. In older children, signs such as excessive urination accompanied by a compensatory insatiable thirst may be so intense that the child does little more than go to the toilet and drink fluids (Cheetham and Baylis, 2002). Frequently, the first sign is enuresis. In infants, the initial symptom is irritability that is relieved with feedings of water but not milk. These infants are also prone to dehydration, electrolyte imbalance, hyperthermia, azotemia, and potential circulatory collapse.

Dehydration is usually not a serious problem in older children, who are able to drink larger quantities of water. However, any period of unconsciousness, such as after trauma or anesthesia, may be life threatening because the voluntary demand for fluid is absent. During such instances, careful monitoring of urine volumes, blood concentration, and IV fluid replacement is essential to prevent dehydration.

! NURSING ALERT

Children with DI complicated by congenital absence of the thirst center must be encouraged to drink sufficient quantities of liquid to prevent electrolyte imbalance.

Diagnostic Evaluation

The simplest test used to diagnose this condition is restriction of oral fluids and observation of consequent changes in urine volume and concentration. Normally, reducing fluids results in concentrated urine and diminished volume. In DI, fluid restriction has little or no effect on urine formation but causes weight loss from dehydration. Accurate results from this procedure require strict monitoring of fluid intake and urinary output, measurement of urine concentration (specific gravity or osmolality), and frequent weight checks. A weight loss between 3% and 5% indicates significant dehydration and requires termination of the fluid restriction.

! NURSING ALERT

Small children require close observation during fluid deprivation to prevent them from drinking, even from toilet bowls, flower vases, and other unlikely sources of fluid.

If this test result is positive, the child should be given a test dose of injected aqueous vasopressin, which should alleviate the polyuria and polydipsia. Unresponsiveness to exogenous vasopressin usually indicates nephrogenic DI. An important diagnostic consideration is to differentiate DI from other causes of polyuria and polydipsia, especially DM. DI may be the early sign of an evolving cerebral process (De Buyst, Massa, Christophe, et al., 2007).

Therapeutic Management

The usual treatment is hormone replacement, either with an intramuscular or subcutaneous injection of vasopressin tannate in peanut oil or with a nasal spray of aqueous lysine vasopressin (Makaryus and McFarlane, 2006; Verbalis, 2003). The injectable form has the advantage of lasting 48 to 72 hours, which affords the child a full night's sleep. However, it has the disadvantage of requiring frequent injections and proper preparation of the drug.

! NURSING ALERT

To be effective, vasopressin must be thoroughly resuspended in the oil by being held under warm running water for 10 to 15 minutes and shaken vigorously before being drawn into the syringe. If this is not done, the oil may be injected minus the ADH. Small brown particles, which indicate drug dispersion, must be seen in the suspension.

CARE MANAGEMENT

The initial objective is identification of the disorder. Because an early sign may be sudden enuresis in a child who is toilet trained, excessive thirst with bedwetting is an indication for further investigation. Another clue is persistent irritability and crying in an infant that is relieved only by bottle feedings of water. After head trauma or certain neurosurgical procedures, the development of DI can be anticipated; therefore these patients must be closely monitored.

Assessment includes measurement of body weight, serum electrolytes, blood urea nitrogen (BUN), hematocrit, and urine specific gravity. Fluid intake and output should be carefully measured and recorded. Alert patients are able to adjust intake to urine losses, but unconscious or very young patients require closer fluid observation. In children who are not toilet trained, collection of urine specimens may require application of a urine-collecting device.

After confirmation of the diagnosis, parents need a thorough explanation regarding the condition with specific clarification that DI is a different condition from DM. They must realize that treatment is lifelong. Caregivers should be taught the correct procedure for preparation and administration of the injectable form of the drug. When children are old enough, they should be encouraged to assume full responsibility for their care.

For emergency purposes, these children should wear medical alert identification. Older children should carry the nasal spray with them for temporary relief of symptoms. School personnel need to

be aware of the problem so they can grant children unrestricted use of the lavatory.

Syndrome of Inappropriate Antidiuretic Hormone

The disorder that results from hypersecretion of ADH from the posterior pituitary hormone is known as *syndrome of inappropriate ADH secretion (SIADH)*. It is observed with increased frequency in a variety of conditions, especially those involving infections, tumors, or other CNS disease or trauma, and is the most common cause of hyponatremia in the pediatric population (Lin, Liu, and Lim, 2005, Rivkees, 2008).

The manifestations are directly related to fluid retention and hypotonicity. Excess ADH causes most of the filtered water to be reabsorbed from the kidneys back into central circulation. Serum osmolality is low, and urine osmolality is inappropriately elevated. When serum sodium levels are diminished to 120 mEq/L, affected children may display anorexia, nausea (and sometimes vomiting), stomach cramps, irritability, and personality changes. With progressive reduction in sodium, other neurologic signs, stupor, and convulsions may be evident. The symptoms usually disappear when the underlying disorder is corrected.

The immediate management consists of restricting fluids. Subsequent management depends on the cause and severity. Fluids continue to be restricted to one-fourth to one-half maintenance. When there are no fluid abnormalities but SIADH can be anticipated, fluids are often restricted expectantly at two-thirds to three-fourths maintenance.

CARE MANAGEMENT

The first goal of nursing management is recognizing the presence of SIADH from symptoms described in patients at risk.

! NURSING ALERT

Nausea, vomiting, and malaise may precede the onset of more severe stages such as disorientation, confusion, coma, and seizures (Majzoub and Muglia, 2003).

Accurately measuring intake and output, noting daily weight, and observing for signs of fluid overload are primary nursing functions, especially in children receiving IV fluids. Seizure precautions are implemented, and the child and family need education regarding the rationale for fluid restrictions. The rare child with chronic SIADH will be placed on long-term ADH-antagonizing medication, and the child and family will require instructions for its administration.

DISORDERS OF THYROID FUNCTION

The thyroid gland secretes two types of hormones: thyroid hormone (TH), which consists of the hormones thyroxine (T_4) and triiodothyronine (T_3), and calcitonin. The secretion of THs is controlled by TSH from the anterior pituitary, which in turn is regulated by thyrotropin-releasing factor (TRF) from the hypothalamus as a negative feedback response. Consequently, hypothyroidism or hyperthyroidism may result from a defect in the target gland or from a disturbance in the secretion of TSH or TRF. Because the functions of T_3 and T_4 are qualitatively the same, the term *thyroid hormone* is used throughout the discussion.

The synthesis of TH depends on available sources of dietary iodine and tyrosine. The thyroid is the only endocrine gland capable of storing excess amounts of hormones for release as needed. During circulation in the bloodstream, T_4 and T_3 are bound to carrier proteins (thyroxine-binding globulin). They must be unbound before they are able to exert their metabolic effect.

The main physiologic action of TH is to regulate the basal metabolic rate and thereby control the processes of growth and tissue differentiation. Unlike GH, TH is involved in many more diverse activities that influence the growth and development of body tissues. Therefore a deficiency of TH exerts a more profound effect on growth than that seen in hypopituitarism.

Calcitonin helps maintain blood calcium levels by decreasing the calcium concentration. Its effect is the opposite of parathyroid hormone (PTH) in that it inhibits skeletal demineralization and promotes calcium deposition in the bone.

Juvenile Hypothyroidism

Hypothyroidism is one of the most common endocrine problems of childhood. It may be either congenital or acquired and represents a deficiency in secretion of TH (Foley, 2001).

Beyond infancy, primary hypothyroidism may be caused by a number of defects. For example, a congenital hypoplastic thyroid gland may provide sufficient amounts of TH during the first year or two but be inadequate when rapid body growth increases demands on the gland. A partial or complete thyroidectomy for cancer or thyrotoxicosis can leave insufficient thyroid tissue to furnish hormones for body requirements. Radiotherapy for Hodgkin disease or other malignancies may lead to hypothyroidism (Pizzo and Poplack, 2010). Infectious processes may cause hypothyroidism. It can also occur when dietary iodine is deficient, although it is now rare in the United States because iodized salt is a readily available source of the nutrient.

Clinical manifestations depend on the extent of dysfunction and the child's age at onset. Primary congenital hypothyroidism is characterized by low levels of circulating THs and raised levels of TSH at birth (Macchia, 2000). If left untreated, congenital hypothyroidism causes decreased mental capacity. Improvements in newborn screening have led to earlier detection and prevention of complications (American Academy of Pediatrics [AAP], 2006). The GnRH test and baseline measurement of gonadotropin and sex hormone serum concentrations at 3 months of age are promising options for assessment of hypothalamic-pituitary-gonadal function in infants with congenital hypothyroidism (van Tijn, Schroor, Delemarre-van de Waal, et al., 2007). The presenting symptoms are decelerated growth from chronic deprivation of TH or thyromegaly. Impaired growth and development are less severe when hypothyroidism is acquired at a later age, and because brain growth is nearly complete by 2 to 3 years of age, intellectual disability and neurologic sequelae are not associated with juvenile hypothyroidism. Other manifestations are myxedematous skin changes (dry skin, puffiness around the eyes, sparse hair), constipation, lethargy, and mental decline (Box 46-5).

Therapy is TH replacement, the same as for hypothyroidism in infants, although the prompt treatment needed in infants is not required in children. L-thyroxine is administered over a period of 4 to 8 weeks to avoid symptoms of hyperthyroidism. Researchers have found that children treated early continue to have mild delays in reading, comprehension, and arithmetic but catch up by grade six (Rovet and Ehrlich, 2000). However, adolescents may demonstrate problems with memory, attention, and visuospatial processing.

BOX 46-5 CLINICAL MANIFESTATIONS OF JUVENILE HYPOTHYROIDISM

- Decelerated growth:
  - Less when acquired at later age
- Myxedematous skin changes:
  - Dry skin
  - Puffiness around eyes
  - Sparse hair
  - Constipation
  - Sleepiness
  - Mental decline

BOX 46-6 CLINICAL MANIFESTATIONS OF LYMPHOCYTIC THYROIDITIS

Enlarged Thyroid Gland
- Usually symmetric
- Firm
- Freely movable
- Nontender

Hyperthyroidism (Possible)
- Nervousness
- Irritability
- Increased sweating
- Hyperactivity

Tracheal Compression
- Sense of fullness
- Hoarseness
- Dysphagia

CARE MANAGEMENT

Growth cessation in a child whose growth has previously been normal should alert the health care provider to the possibility of hypothyroidism. After diagnosis and implementation of thyroxine therapy, the importance of compliance and periodic monitoring of response to therapy should be stressed to parents. Children should learn to take responsibility for their own health as soon as they are old enough, at about 9 or 10 years of age.

Goiter

A goiter is an enlargement or hypertrophy of the thyroid gland. It may occur with deficient (hypothyroid), excessive (hyperthyroid), or normal (euthyroid) TH secretion. It can be congenital or acquired. Congenital disease occurs as a result of maternal administration of antithyroid drugs or iodides during pregnancy or as an inborn error of TH production. Acquired disease can result from increased secretion of pituitary TSH in response to decreased circulating levels of TH or from infiltrative neoplastic or inflammatory processes. In most children, goiter is caused by chronic autoimmune thyroiditis (de Vries, Bulvik, and Phillip, 2009). In areas where dietary iodine (essential for TH production) is deficient, goiter can be endemic.

Enlargement of the thyroid gland may be mild and noticeable only when there is an increased demand for TH (e.g., during periods of rapid growth). Enlargement of the thyroid at birth can be sufficient to cause severe respiratory distress. Colloid goiters are diffuse and benign and occur more frequently in adolescent girls. Thyroid function is normal, and the gland will gradually decrease over several years without treatment. TH replacement may be necessary to treat the hypothyroidism and reverse the TSH effect on the gland.

CARE MANAGEMENT

Large goiters are identified by their obvious appearance. In older children, each lobe of the thyroid should be approximately the same as the terminal phalanx of the child's thumb (de Vries, Bulvik, and Phillip, 2009). Smaller nodules may be evident only on palpation. Benign enlargement of the thyroid gland may occur during adolescence and should not be confused with pathologic states. Nodules rarely are caused by a cancerous tumor but always require evaluation. Questions regarding exposure to radiation should be included in the assessment.

Immediate surgery to remove part of the gland may be lifesaving in infants born with a goiter. When thyroid replacement is necessary, parents have the same needs regarding its administration as discussed for the parents of children who have hypothyroidism.

Lymphocytic Thyroiditis

Lymphocytic thyroiditis (Hashimoto disease, chronic autoimmune thyroiditis) is the most common cause of thyroid disease in children and adolescents and accounts for the largest percentage of juvenile hypothyroidism (Szymborska and Staroszczyk, 2000). It accounts for many of the enlarged thyroid glands formerly designated *thyroid hyperplasia of adolescence* or *adolescent goiter*. Although it can occur during the first 3 years of life, it occurs more frequently after age 6 years. It reaches a peak incidence during adolescence, and there is evidence that the disease is self-limiting. The presence of a goiter and elevated thyroglobulin antibody with progressive increase in both thyroid peroxidase antibody and TSH may be predictive factors for future development of hypothyroidism (Radetti, Gottardi, Bona, et al., 2006).

The presence of the enlarged thyroid gland is usually detected during a routine examination, although it may be noted by parents when the child swallows. In most children, the entire gland is enlarged symmetrically (although it may be asymmetric) and is firm, freely movable, and nontender. There may be manifestations of moderate tracheal compression (sense of fullness, hoarseness, and dysphagia), but it is extremely rare for a nontoxic diffuse goiter to enlarge to the extent that it causes mechanical obstruction. Most children are euthyroid, but some display symptoms of hypothyroidism, including delayed growth and puberty and declining school performance. Other signs suggestive of thyroiditis are found in Box 46-6.

Diagnostic Evaluation

Thyroid function test results are usually normal, although TSH levels may be slightly or moderately elevated. With progressive disease, the T_4 decreases followed by a decrease in T_3 levels and an increase in TSH. The majority of children have antithyroid antibody titers. However, levels in children are lower than in adults; therefore repeated measurements may be needed in doubtful cases because titers may increase later in the disease.

Therapeutic Management

In many cases, the goiter is transient and asymptomatic and regresses spontaneously within a year or two. Therapy of a nontoxic diffuse goiter is usually simple, uncomplicated, and effective. Oral administration of TH decreases the size of the gland significantly and provides the feedback needed to suppress TSH stimulation, and the hyperplastic thyroid gland gradually regresses in size. TSH levels

should be monitored, with the goal of restoring normal growth and development. Surgery is contraindicated in this disorder. Untreated patients should be evaluated periodically.

CARE MANAGEMENT

Nursing care consists of identifying the child with thyroid enlargement, reassuring the child that the condition is probably only temporary, and reinforcing instructions for thyroid therapy.

Hyperthyroidism

The largest percentage of hyperthyroidism in childhood is caused by Graves disease, which is usually associated with an enlarged thyroid gland and exophthalmos (Ma, Xie, Kuang, et al., 2006; Streetman and Khanderia, 2004; Thompson, 2002). Most cases of Graves disease in children occur between ages 6 and 15 years, with a peak incidence at 12 to 14 years of age, but the disease may be present at birth in children of thyrotoxic mothers. The incidence is 5 times higher in girls than in boys.

The hyperthyroidism of Graves disease is apparently caused by an autoimmune response to TSH receptors, but no specific etiology has been identified. There is definitive evidence for familial association, with a high concordance incidence in twins. Patients with Graves disease possess the histocompatibility antigens *A1, B8,* and *DR3* (Dallas and Foley, 2003; Simmonds, Howson, Heward, et al., 2005). There may be an association with other autoimmune diseases such as rheumatoid arthritis and lupus.

The development of manifestations is highly variable. Signs and symptoms develop gradually, with an interval between onset and diagnosis of approximately 6 to 12 months. The principal clinical features are excessive motion, including irritability, hyperactivity, short attention span, tremors, insomnia, and emotional lability. Clinical manifestations are presented in Box 46-7.

Exophthalmos (protruding eyeballs), which is observed in many children, is accompanied by a wide-eyed staring expression, increased blinking, eyelid lag, lack of convergence, and absence of wrinkling of the forehead when looking upward. As protrusion of the eyeball increases, the child may not be able to completely cover the cornea with the eyelid. Visual disturbances may include blurred vision and loss of visual acuity. Ophthalmopathy can develop long before or after the onset of hyperthyroidism. A consistent pathogenic link between them has not been identified. It is now thought that Graves ophthalmopathy is a disorder of autoimmune origin caused by a complex interplay of endogenous and environmental factors (Bartalena, Tanda, Piantanida, et al., 2003).

Diagnostic Evaluation

The presence of a thyroid mass in a child requires a thorough history, including inquiry into prior irradiation to the head and neck and exposure to a goitrogen. The diagnosis is established on the basis of increased levels of T_4 and T_3. TSH is suppressed to unmeasurable levels (Ma, Xie, Kuang, et al., 2006). Graves disease is confirmed by measurement of thyroid-stimulating immunoglobulin.

Therapeutic Management

Therapy for hyperthyroidism is controversial, but all methods are directed toward slowing the rate of hormone secretion. The three acceptable modes available are antithyroid drugs (methimazole), which interferes with the biosynthesis of TH; subtotal thyroidectomy; and ablation with radioiodine (^{131}I iodide) (Rivkees and Cornelius, 2003; Streetman and Khanderia, 2004). Each is effective, but each has advantages and disadvantages. Pharmacologic therapy may induce a remission, and treatment may be discontinued. However, relapse may occur. Radioactive iodine ablation is usually effective but response may be slower, and there have been concerns about a possible link to thyroid cancer in younger children. Surgery is often used when other treatments are not effective. These children require lifelong monitoring.

When affected children exhibit signs and symptoms of hyperthyroidism (e.g., increased weight loss, pulse, pulse pressure, and blood pressure), their activity should be limited to classwork only. Vigorous exercise is restricted until thyroid levels are decreased to normal or near-normal values.

Thyrotoxicosis (thyroid "crisis" or thyroid "storm") may occur from sudden release of the hormone. Although thyrotoxicosis is unusual in children, a crisis can be life threatening. These "storms" are evidenced by the acute onset of severe irritability and restlessness, vomiting, diarrhea, hyperthermia, hypertension, severe tachycardia, and prostration. There may be rapid progression to delirium, coma, and even death. A crisis may be precipitated by acute infection, surgical emergencies, or discontinuation of antithyroid therapy. Treatment, in addition to antithyroid drugs, is administration of β-adrenergic blocking agents (propranolol), which provide relief

BOX 46-7 CLINICAL MANIFESTATIONS OF HYPERTHYROIDISM (GRAVES DISEASE)

Cardinal Signs

- Emotional lability
- Physical restlessness, characteristically at rest
- Decelerated school performance
- Voracious appetite with weight loss in 50% of cases
- Fatigue

Physical Signs

- Tachycardia
- Widened pulse pressure
- Dyspnea on exertion
- Exophthalmos (protruding eyeballs)
- Wide-eyed, staring expression with eyelid lag
- Tremor
- Goiter (hypertrophy and hyperplasia)
- Warm, moist skin
- Accelerated linear growth
- Heat intolerance (may be severe)
- Hair fine and unable to hold a curl
- Systolic murmurs

Thyroid Storm

- Acute onset:
  - Severe irritability and restlessness
  - Vomiting
  - Diarrhea
  - Hyperthermia
  - Hypertension
  - Severe tachycardia
  - Prostration
- May progress rapidly to:
  - Delirium
  - Coma
  - Death

from the adrenergic hyperresponsiveness that produces the disturbing side effects of the reaction. Therapy is usually required for 2 to 3 weeks.

The American Thyroid Association* has an extensive website with information related to prevention, treatment, and cure of thyroid disease.

CARE MANAGEMENT

The initial nursing objective is identification of children with hyperthyroidism. Because the clinical manifestations often appear gradually, the goiter and ophthalmic changes may not be noticed and the excessive activity may be attributed to behavioral problems. Nurses in ambulatory settings, particularly schools, need to be alert to signs that suggest this disorder, especially weight loss despite an excellent appetite, academic difficulties resulting from a short attention span and inability to sit still, unexplained fatigue and sleeplessness, and difficulty with fine motor skills such as writing. Exophthalmos may develop long before the onset of signs and symptoms of hyperthyroidism and may be the only presenting sign (Thompson, 2002). Exophthalmos is less common in adults than in children (Jospe, 2001).

Much of these children's care is related to treating physical symptoms before a response to drug therapy is achieved. A regular routine is beneficial in providing frequent rest periods, minimizing the stress of coping with unexpected demands, and meeting the children's needs promptly. Physical activity is restricted. Mood swings and irritability can disrupt interpersonal relationships, creating difficulties within and outside the home. The child and parents should be encouraged to express feelings about the behavior and its effect on others. Heat intolerance may be minimized by the use of light cotton clothing, good ventilation, air conditioning or fans, frequent baths, and adequate hydration. Dietary requirements should be adjusted to meet the child's increased metabolic rate. Rather than three large meals, the child's appetite may be better satisfied by five or six moderate meals throughout the day.

! NURSING ALERT

Children being treated with methimazole must be carefully monitored for side effects of the drug. Because sore throat and fever accompany the grave complication of leukopenia, these children should be seen by a health care practitioner if such symptoms occur. Parents and children should be taught to recognize and report symptoms immediately.

! NURSING ALERT

The earliest indication of hypoparathyroidism may be anxiety and mental depression followed by paresthesia and evidence of heightened neuromuscular excitability, such as:

- **Chvostek sign**—facial muscle spasm elicited by tapping the facial nerve in the region of the parotid gland
- **Trousseau sign**—carpal spasm elicited by pressure applied to nerves of the upper arm
- **Tetany**—Carpopedal spasm (sharp flexion of wrist and ankle joints), muscle twitching, cramps, seizures, and stridor

*6066 Leesburg Pike, Suite 550, Falls Church, VA 22041; 800-THYROID; e-mail: thyroid@thyroid.org; www.thyroid.org.

DISORDERS OF PARATHYROID FUNCTION

The parathyroid glands secrete PTH, the main function of which, along with vitamin D and calcitonin, is homeostasis of serum calcium concentration (Perheentupa, 2003). The effect of PTH on calcium is opposite that of calcitonin. The net result of the integrated action of PTH and vitamin D is maintenance of serum calcium levels within a narrow normal range and the mineralization of bone. Secretion of PTH is controlled by a negative feedback system involving the serum calcium ion concentration. Low ionized calcium levels stimulate PTH secretion, causing absorption of calcium by the target tissues; high ionized calcium concentrations suppress PTH.

Hypoparathyroidism

Hypoparathyroidism is a spectrum of disorders that result in deficient PTH. Congenital hypoparathyroidism may be caused by a specific defect in the synthesis or cellular processing of PTH or by aplasia or hypoplasia of the gland (Perheentupa, 2003).

Hypoparathyroidism can also occur secondary to other causes, including infection and autoimmune syndromes. Postoperative hypoparathyroidism may follow thyroidectomy with acute or gradual onset and be transient or permanent. Two forms of transient hypoparathyroidism may be present in newborns, both of which are the result of a relative PTH deficiency. One type is caused by maternal hyperparathyroidism or maternal DM. A more common, later form appears almost exclusively in infants fed a milk formula with a high phosphate-to-calcium ratio.

Pseudohypoparathyroidism occurs when there is a genetic defect in the cellular receptors to PTH. The result is normal parathyroid gland and elevated PTH levels. Abnormal calcium and phosphorus levels are not affected by administration of PTH. These children typically have a short, stocky build; a round face; and abnormally shaped hands and fingers. Other endocrine dysfunction may be found concurrently (Shoback, 2008).

Clinical signs of hypoparathyroidism are found in Box 46-8. Muscle cramps are an early symptom, progressing to numbness, stiffness, and tingling in the hands and feet. A positive Chvostek or Trousseau sign or laryngeal spasms may be present. Convulsions with loss of consciousness may occur. These episodes may be preceded by abdominal discomfort, tonic rigidity, head retraction, and cyanosis. Headaches and vomiting with increased intracranial pressure and papilledema may occur and may suggest a brain tumor (Kliegman, Stanton, St. Geme, et al., 2011).

Diagnostic Evaluation

The diagnosis of hypoparathyroidism is made on the basis of clinical manifestations associated with decreased serum calcium and increased serum phosphorus. Levels of plasma PTH are low in idiopathic hypoparathyroidism but high in pseudohypoparathyroidism. End-organ responsiveness is tested by the administration of PTH with measurement of urinary cyclic adenosine monophosphate (cAMP). Kidney function tests are included in the differential diagnosis to rule out renal insufficiency. Magnesium levels should also be tested. Although bone radiograph findings are usually normal, they may demonstrate increased bone density and suppressed growth.

Therapeutic Management

The objective of treatment is to maintain normal serum calcium and phosphate levels with minimal complications. Acute or severe tetany is corrected immediately by IV and oral administration of calcium

BOX 46-8 CLINICAL MANIFESTATIONS OF HYPOPARATHYROIDISM

Pseudohypoparathyroidism
- Short stature
- Round face
- Short, thick neck
- Short, stubby fingers and toes
- Dimpling of skin over knuckles
- Subcutaneous soft tissue calcifications
- Intellectual disability a prominent feature

Idiopathic Hypoparathyroidism
- None of the above physical characteristics observed
- May include papilledema
- May have intellectual disability

Both Types
- Dry, scaly, coarse skin with eruptions
- Hair often brittle
- Nails thin and brittle with characteristic transverse grooves
- Dental and enamel hypoplasia
- Muscle contractions:
  - Tetany
  - Carpopedal spasm
  - Laryngospasm (laryngeal stridor)
  - Muscle cramps and twitching
  - Positive Chvostek sign or Trousseau sign (see Nursing Alert on p. 1470)
- Neurologic:
  - Headache
  - Seizures (generalized, absence, or focal)
  - Swings of emotion
  - Loss of memory
  - Depression
  - Confusion possible
  - Paresthesias, tingling
- Gastrointestinal:
  - Muscle cramps
  - Diarrhea
  - Vomiting
- Delayed skeletal growth

gluconate and follow-up daily doses to achieve normal levels. Twice-daily serum calcium measurements are taken to monitor the efficacy of therapy and prevent hypercalcemia. When diagnosis is confirmed, vitamin D therapy is begun. Vitamin D therapy is somewhat difficult to regulate because the drug has a prolonged onset and a long half-life. Some authorities advocate beginning with a lower dose with stepwise increases and careful monitoring of serum calcium until stable levels are achieved. Others prefer rapid induction with higher doses and rapid reduction to lower maintenance levels (Cooper and Gittoes, 2008; Kliegman, Stanton, St. Geme, et al., 2011).

Long-term management usually consists of vitamin D and oral calcium supplementation. Blood calcium and phosphorus are monitored frequently until the levels have stabilized and then routinely thereafter. Renal function, blood pressure, and serum vitamin D levels are measured every 6 months. Serum magnesium levels are measured to permit detection of hypomagnesemia, which may raise the requirement for vitamin D.

BOX 46-9 CLINICAL MANIFESTATIONS OF HYPERPARATHYROIDISM

Gastrointestinal
- Nausea
- Vomiting
- Abdominal discomfort
- Constipation

Central Nervous System
- Delusions
- Confusion
- Hallucinations
- Impaired memory
- Lack of interest and initiative
- Depression
- Varying levels of consciousness

Neuromuscular
- Weakness
- Easy fatigability
- Muscle atrophy (especially proximal muscles of lower limbs)
- Tongue twitching
- Paresthesias in extremities

Skeletal
- Vague bone pain
- Subperiosteal resorption of phalanges
- Spontaneous fractures
- Absence of lamina dura around teeth

Renal
- Polyuria
- Polydipsia
- Renal colic
- Hypertension

CARE MANAGEMENT

The initial objective is recognition of hypocalcemia. Unexplained convulsions, irritability (especially to external stimuli), gastrointestinal symptoms (diarrhea, vomiting, cramping), and positive signs of tetany should lead the nurse to suspect this disorder. Much of the initial nursing care is related to the physical manifestations and includes institution of seizure and safety precautions; reduction of environmental stimuli; and observation for signs of laryngospasm such as stridor, hoarseness, and a feeling of tightness in the throat. A tracheostomy set and injectable calcium gluconate should be available for emergency use. The administration of calcium gluconate requires precautions against extravasation of the drug and tissue destruction.

After initiating treatment, the nurse discusses with the parents the need for continuous daily administration of calcium salts and vitamin D. Because vitamin D toxicity can be a serious consequence of therapy, parents are advised to watch for signs that include weakness, fatigue, lassitude, headache, nausea, vomiting, and diarrhea. Early renal impairment is manifested by polyuria, polydipsia, and nocturia.

Hyperparathyroidism

Hyperparathyroidism is rare in childhood but can be primary or secondary. The most common cause of primary hyperparathyroidism is adenoma of the gland (Kliegman, Stanton, St. Geme, et al., 2011). The most common causes of secondary hyperparathyroidism are chronic renal disease, renal osteodystrophy, and congenital anomalies of the urinary tract. The common factor is hypercalcemia. The clinical signs of hyperparathyroidism are listed in Box 46-9.

Diagnostic Evaluation

Blood studies to identify elevated calcium and decreased phosphorus levels are routinely performed. Measurement of PTH, as well as several tests to isolate the cause of the hypercalcemia, such as renal function studies, should be included. Other procedures used to sub-

stantiate the physiologic consequences of the disorder include electrocardiography and radiographic bone surveys.

Therapeutic Management

Treatment depends on the cause of hyperparathyroidism. The treatment of primary hyperparathyroidism is surgical removal of the tumor or hyperplastic tissue. Treatment of secondary hyperparathyroidism is directed at the underlying contributing cause, which subsequently restores the serum calcium balance. However, in some instances, such as in chronic renal failure, the underlying disorder is irreversible. In this case, treatment is aimed at raising serum calcium levels to inhibit the stimulatory effect of low levels on the parathyroids. This includes oral administration of calcium salts, high doses of vitamin D to enhance calcium absorption, a low-phosphorus diet, and administration of a phosphorus-mobilizing aluminum hydroxide to reduce phosphate absorption.

CARE MANAGEMENT

The initial nursing objective is recognition of the disorder. Because secondary hyperparathyroidism is a consequence of chronic renal failure, the nurse is always alert to signs that suggest this complication, especially bone pain and fractures. Because urinary symptoms are the earliest indication, assessment of other body systems for evidence of high calcium levels is indicated when polyuria and polydipsia coexist. Clues to the possibility of hyperparathyroidism include change in behavior, especially inactivity; unexplained gastrointestinal symptoms; and cardiac irregularities.

DISORDERS OF ADRENAL FUNCTION

The adrenal cortex secretes three main groups of hormones collectively called steroids and classified according to their biologic activity: (1) glucocorticoids (cortisol, corticosterone); (2) mineralocorticoids (aldosterone); and (3) sex steroids (androgens, estrogens, and progestins). Alterations in the levels of these hormones produce significant dysfunction in a variety of body tissues and organs. Because the adrenocortical cells are capable of producing any of the steroids, pathologic conditions may result in a deficiency or an excess of more than one type of hormone. However, most are rare in children.

The adrenal medulla secretes the catecholamines epinephrine and norepinephrine. Both hormones have essentially the same effects on various organs as those caused by direct sympathetic stimulation except that the hormonal effects last several times longer. Catecholamine-secreting tumors are the primary cause of adrenal medullary hyperfunction.

Acute Adrenocortical Insufficiency

The acute form of adrenocortical insufficiency (adrenal crisis) may have a number of causes during childhood. Although a rare disorder, some of the more common etiologic factors include hemorrhage into the gland from trauma, which may be caused by a prolonged, difficult labor; fulminating infections, such as meningococcemia, which result in hemorrhage and necrosis (Waterhouse-Friderichsen syndrome); abrupt withdrawal of exogenous sources of cortisone or failure to increase exogenous supplies during stress; or congenital adrenogenital hyperplasia of the salt-losing type.

Early symptoms of adrenocortical insufficiency include increased irritability, headache, diffuse abdominal pain, weakness, nausea and vomiting, and diarrhea. Other clinical signs are found in Box 46-10. In newborns, adrenal crisis is accompanied by extreme hyperpyrexia (high temperature), tachypnea, cyanosis, and seizures. Usually there is no evidence of infection or purpura. However, hemorrhage into the adrenal gland may be evident as a palpable retroperitoneal mass.

BOX 46-10 CLINICAL MANIFESTATIONS OF ACUTE ADRENOCORTICAL INSUFFICIENCY

Early Symptoms
- Increased irritability
- Headache
- Diffuse abdominal pain
- Weakness
- Nausea and vomiting
- Diarrhea

Generalized Hemorrhagic Manifestations (Waterhouse-Friderichsen Syndrome)
- Fever (increases as condition worsens)
- Central nervous system signs:
  - Nuchal rigidity
  - Seizures
  - Stupor
  - Coma

Shocklike State
- Weak, rapid pulse
- Decreased blood pressure
- Shallow respirations
- Cold, clammy skin
- Cyanosis
- Circulatory collapse (terminal event)

Newborn
- Hyperpyrexia
- Tachypnea
- Cyanosis
- Seizures
- Gland evident as palpable retroperitoneal mass (hemorrhagic)

Diagnostic Evaluation

There is no rapid, definitive test for confirmation of acute adrenocortical insufficiency. Routine procedures such as measurement of plasma cortisol levels are too time consuming to be practical. Therefore diagnosis is usually made based on clinical presentation, especially when a fulminating sepsis is accompanied by hemorrhagic manifestations and signs of circulatory collapse despite adequate antibiotic therapy. Because there is no real danger in administering a cortisol preparation for a short period, treatment should be instituted immediately. Improvement with cortisol therapy confirms the diagnosis.

Therapeutic Management

Treatment involves replacement of cortisol, replacement of body fluids to combat dehydration and hypovolemia, administration of glucose solutions to correct hypoglycemia, and specific antibiotic therapy in the presence of infection. Initially, IV hydrocortisone (Solu-Cortef) is administered. Normal saline containing 5% glucose is given parenterally to replace lost fluid, electrolytes, and glucose. If hemorrhage has been severe, whole blood may be replaced. In the event that these measures do not reverse the circulatory collapse, vasopressors are used for immediate vasoconstriction and elevation of blood pressure.

After the child's condition has been stabilized, oral doses of cortisone, fluids, and salt are given, similar to the regimen used for chronic adrenal insufficiency. To maintain sodium retention, aldosterone is replaced by synthetic salt-retaining steroids.

CARE MANAGEMENT

Because of the abrupt onset and potentially fatal outcome of this condition, prompt recognition is essential. Vital signs, including

blood pressure, are taken every 15 minutes to monitor the hyperpyrexia and shocklike state. Seizure precautions are instituted because convulsions from the elevated temperature are not uncommon. As soon as therapy is instituted, the nurse should monitor the child's response to fluid and cortisol replacement. Whereas too rapid administration of fluids can precipitate cardiac failure, overdosage with cortisol produces hypotension and a sudden fall in temperature.

When the acute phase is over and the hypovolemia has been corrected, the child is given oral fluids, such as small quantities of ginger ale, fruit juice, or salted broth. Too rapid ingestion of oral fluids may induce vomiting, which increases dehydration. Therefore the nurse should plan a gradual schedule for reintroducing liquids.

! NURSING ALERT

Monitor serum electrolyte levels and observe for signs of hypokalemia or hyperkalemia (e.g., weakness, poor muscle control, paralysis, cardiac dysrhythmias, and apnea). The condition is rapidly corrected with IV or oral potassium replacement.

! NURSING ALERT

When an oral potassium preparation is given, it should be mixed with a small amount of strongly flavored fruit juice to disguise its bitter taste.

The sudden, severe nature of this disorder necessitates a great deal of emotional support for the child and family. The child may be placed in an intensive care unit where the surroundings are strange and frightening. Despite the need for emergency intervention, the nurse must be sensitive to the family's psychologic needs and prepare them for each procedure even if this is a brief statement such as "The IV infusion is necessary to replace fluid that your child is losing." Because recovery within 24 hours is often dramatic, the nurse should keep the parents apprised of the child's condition, emphasizing signs of improvement such as a lowered temperature and improved blood pressure.

Chronic Adrenocortical Insufficiency (Addison Disease)

Chronic adrenocortical insufficiency is rare in children. Causes include infections, destructive lesion of the adrenal gland or neoplasms, autoimmune processes, or idiopathic. Formerly, generalized tuberculosis was the leading cause of adrenal gland destruction.

Evidence of this disorder is usually gradual in onset because 90% of adrenal tissue must be nonfunctional before signs of insufficiency are manifested. However, during periods of stress, when demands for additional cortisol are increased, symptoms of acute insufficiency may appear in a previously well child (Box 46-11).

Definitive diagnosis is based on measurements of functional cortisol reserve. The fasting serum cortisol and urinary 17-hydroxycorticosteroid levels are low and fail to rise, and plasma adrenocorticotropic hormone (ACTH) levels are elevated with corticotropin (ACTH) stimulation, the definitive test for the disease.

Therapeutic Management

Treatment involves replacement of glucocorticoids (cortisol) and mineralocorticoids (aldosterone). Some children are able to be maintained solely on oral supplements of cortisol (cortisone or hydrocortisone preparations) with a liberal intake of salt. During stressful situations, such as fever, infection, emotional upset, or surgery, the dosage must be tripled to accommodate the body's increased need for glucocorticoids. Failure to meet this requirement will precipitate an acute crisis. Overdosage produces appearance of cushingoid signs.

Children with more severe states of chronic adrenal insufficiency require mineralocorticoid replacement to maintain fluid and electrolyte balance. Other forms of therapy include monthly injections of desoxycorticosterone acetate or implantation of desoxycorticosterone acetate pellets subcutaneously every 9 to 12 months.

BOX 46-11 CLINICAL MANIFESTATIONS OF CHRONIC ADRENOCORTICAL INSUFFICIENCY

Neurologic Symptoms
- Muscular weakness
- Mental fatigue
- Irritability, apathy, and negativism
- Increased sleeping, listlessness

Pigmentary Changes
- Previous scars
- Palmar creases
- Mucous membranes
- Hair
- Hyperpigmentation over pressure points (elbows, knees, or waist)
- Less frequently, vitiligo (loss of pigmentation)

Gastrointestinal Symptoms
- Dehydration
- Anorexia
- Weight loss

Circulatory Symptoms
- Hypotension
- Small heart size
- Dizziness
- Syncopal (fainting) attacks

Hypoglycemia
- Headache
- Hunger
- Weakness
- Trembling
- Sweating

Other Signs (Seen in Some Children)
- Recurrent, unexplained seizures
- Intense craving for salt
- Acute abdominal pain
- Electrolyte imbalances

CARE MANAGEMENT

After the disorder is diagnosed, parents need guidance concerning drug therapy. They must be aware of the continuous need for cortisol replacement. Sudden termination of the drug because of inadequate supplies or inability to ingest the oral form because of vomiting places the child in danger of an acute adrenal crisis. Therefore parents should always have a spare supply of the medication in the home. Ideally, they will have a prefilled syringe of hydrocortisone and be instructed in proper technique for intramuscular administration of the drug in case of crisis. Unnecessary administration of cortisone will not harm the child, but if it is needed, it may be lifesaving. Any evidence of acute insufficiency should be reported to the health care practitioner immediately.

Parents also need to be aware of side effects of the drugs. Undesirable side effects of cortisone include gastric irritation, which is minimized by ingestion with food or the use of an antacid; increased excitability and sleeplessness; weight gain, which may require dietary management to prevent obesity; and, rarely, behavioral changes,

BOX 46-12 ETIOLOGY OF CUSHING SYNDROME

- **Pituitary**—Cushing syndrome with adrenal hyperplasia, usually attributed to an excess of ACTH
- **Adrenal**—Cushing syndrome with hypersecretion of glucocorticoids, generally a result of adrenocortical neoplasms
- **Ectopic**—Cushing syndrome with autonomous secretion of ACTH, most often caused by extrapituitary neoplasms
- **Iatrogenic**—Cushing syndrome frequently a result of administration of large amounts of exogenous corticosteroids
- **Food dependent**—Inappropriate sensitivity of adrenal glands to normal postprandial increases in secretion of gastric inhibitory polypeptide

Adapted from Magiakou MA, Mastorakos G, Oldfield EH, et al: Cushing's syndrome in children and adolescents: presentation, diagnosis, and therapy, *N Engl J Med* 331(10):629–636, 1994.
ACTH, Adrenocorticotropic hormone.

including depression or euphoria. Parents should be aware of signs of overdose and report these to the health care practitioner. In addition, the drug has a bitter taste, which creates a challenge for nurses and parents in its administration.

Because the body cannot supply endogenous sources of cortical hormones during times of stress, the home environment should be stable and relatively free of stress. Parents need to be aware that during periods of emotional or physical crisis, the child requires additional hormone replacement. The child should wear medical identification, such as a bracelet, to permit medical personnel to adjust requirements during emergency care.

Cushing Syndrome

Cushing syndrome is a characteristic group of manifestations caused by excessive circulating free cortisol. It can result from a variety of causes, which generally fall into one of five categories (Box 46-12). Cushing syndrome in young children may be caused by an adrenal tumor (Moshang, 2003).

Cushing syndrome is uncommon in children. When seen, it is often caused by excessive or prolonged steroid therapy that produces a cushingoid appearance (Fig. 46-2). This condition is reversible after the steroids are gradually discontinued. Abrupt withdrawal will precipitate acute adrenal insufficiency. Gradual withdrawal of exogenous supplies is necessary to allow the anterior pituitary an opportunity to secrete increasing amounts of ACTH to stimulate the adrenals to produce cortisol.

Clinical Manifestations

Because the actions of cortisol are widespread, clinical manifestations are equally profound and diverse. The symptoms that produce changes in physical appearance occur early in the disorder and are of considerable concern to school-age and older children. The physiologic disturbances, such as hyperglycemia, susceptibility to infection, hypertension, and hypokalemia, may have life-threatening consequences unless recognized early and treated successfully. Children with short stature may be responding to increased cortisol levels, resulting in Cushing syndrome. Cortisol inhibits the action of GH.

Diagnostic Evaluation

Several tests are helpful in confirming excess Cushing syndrome. Serum cortisol levels should be measured at midnight and in the morning along with corticotropin hormone, urinary free cortisol,

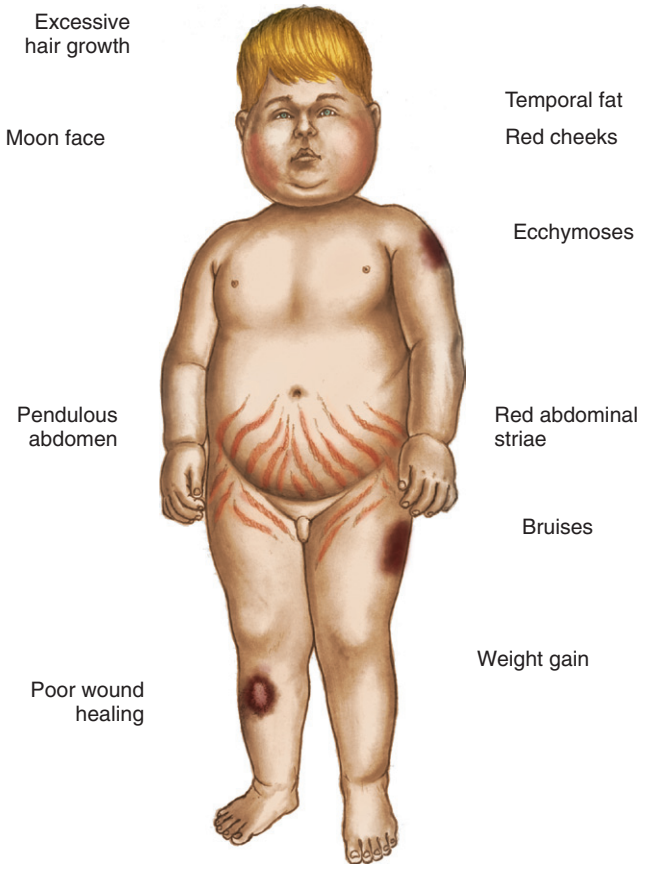

FIG 46-2 Characteristics of Cushing syndrome.

fasting blood glucose levels for hyperglycemia, serum electrolyte levels for hypokalemia and alkalosis, and 24-hour urinary levels of elevated 17-hydroxycorticoids and 17-ketosteroids. Imaging of the pituitary and adrenal glands to assess for tumors, bone density studies for evidence of osteoporosis, and skull radiographs to determine enlargement of the sella turcica may also aid in the diagnosis. Another procedure used to establish a more definitive diagnosis is the dexamethasone (cortisone) suppression test (Nieman and Ilias, 2005). Administration of an exogenous supply of cortisone normally suppresses ACTH production. However, in individuals with Cushing syndrome, cortisol levels remain elevated. This test is helpful in differentiating between children who are obese and those who appear to have cushingoid features.

Therapeutic Management

Treatment depends on the cause. In most cases, surgical intervention involves bilateral adrenalectomy and postoperative replacement of the cortical hormones (the therapy for this is the same as that outlined for chronic adrenal insufficiency). If a pituitary tumor is found, surgical extirpation or irradiation may be chosen. In either of these instances, treatment of panhypopituitarism with replacement of GH, thyroid extract, ADH, gonadotropins, and steroids may be necessary for an indefinite period (Nieman and Ilias, 2005).

CARE MANAGEMENT

Nursing care also depends on the cause. When cushingoid features are caused by steroid therapy, the effects may be lessened with administration of the drug early in the morning and on an

alternate-day basis. Giving the drug early in the day maintains the normal diurnal pattern of cortisol secretion. If given during the evening, it is more likely to produce symptoms because endogenous cortisol levels are already low and the additional supply exerts more pronounced effects. An alternate-day schedule allows the anterior pituitary an opportunity to maintain more normal hypothalamic-pituitary-adrenal control mechanisms.

If an organic cause is found, nursing care is related to the treatment regimen. Although a bilateral adrenalectomy permanently solves one condition, it reciprocally produces another syndrome. Before surgery, parents need to be adequately informed of the operative benefits and disadvantages. Postoperative teaching regarding drug replacement is the same as discussed in the previous section.

! NURSING ALERT

Postoperative complications of adrenalectomy are related to the sudden withdrawal of cortisol. Observe for shocklike symptoms (e.g., hypotension, hyperpyrexia).

Anorexia and nausea and vomiting are common and may be improved with the use of nasogastric decompression. Muscle and joint pain may be severe, requiring use of analgesics. The psychologic depression can be profound and may not improve for months. Parents should be aware of the physiologic reasons behind these symptoms in order to be supportive of the child.

Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is a family of disorders caused by decreased enzyme activity required for cortisol production in the adrenal cortex. The adrenal gland produces excessive amounts of cortisol precursors and androgens to compensate. The most common defect is 21-hydroxylase deficiency, which constitutes more than 90% of all cases of CAH (AAP, 2000). This deficiency is an autosomal recessive disorder that results in improper steroid hormone synthesis. It occurs in approximately 1 in 12,000 to 15,000 births and can be life threatening in its most severe form (Glatt, Garzon, and Popovic, 2005).

Excessive androgens cause masculinization of the urogenital system at approximately the tenth week of fetal development. The most pronounced abnormalities occur in girls, who are born with varying degrees of ambiguous genitalia. Masculinization of external genitalia causes the clitoris to enlarge so that it appears as a small phallus. Fusion of the labia produces a saclike structure resembling the scrotum without testes. However, no abnormal changes occur in the internal sexual organs, although the vaginal orifice is usually closed by the fused labia. The label *ambiguous genitalia* should be applied to any infant with hypospadias or micropenis and no palpable gonads, and a diagnostic evaluation for CAH should be contemplated. Males do not display genital abnormalities at birth (New and Ghizzoni, 2003).

Increased pigmentation of skin creases and genitalia caused by increased ACTH may be a subtle sign of adrenal insufficiency. A salt-wasting crisis frequently occurs, usually within the first few weeks of life (Kliegman, Stanton, St. Geme, et al., 2011). Infants fail to gain weight, and hyponatremia and hyperkalemia may be significant. Cardiac arrest can occur.

Untreated CAH results in early sexual maturation, with enlargement of the external sexual organs; development of axillary, pubic, and facial hair; deepening of the voice; acne; and a marked increase in musculature with changes toward an adult male physique. However, in contrast to precocious puberty, breasts do not develop in girls and they remain amenorrheic and infertile. In boys, the testes remain small and spermatogenesis does not occur. In both sexes, linear growth is accelerated and epiphyseal closure is premature, resulting in short stature by the end of puberty.

Diagnostic Evaluation

Clinical diagnosis is initially based on congenital abnormalities that lead to difficulty in assigning sex to the newborn and on signs and symptoms of adrenal insufficiency. Newborn screening is currently done in all 50 U.S. states by measurement of the cortisol precursor *17-hydroxyprogesterone.* Definitive diagnosis is confirmed by evidence of increased 17-ketosteroid levels in most types of CAH (AAP, 2000). In complete 21-hydroxylase deficiency, blood electrolytes demonstrate loss of sodium and chloride and elevation of potassium. In older children, bone age is advanced and linear growth is increased. DNA analysis for positive sex determination and to rule out any other genetic abnormality (e.g., Turner syndrome) is always done in any case of ambiguous genitalia.

Another test that can be used to visualize the presence of pelvic structures is ultrasonography, a noninvasive, painless imaging technique that does not require anesthesia or sedation. It is especially useful in CAH because it readily identifies the absence or presence of female reproductive organs or male testes in a newborn or child with ambiguous genitalia. Because ultrasonography yields immediate results, it has the advantage of determining the child's sex long before the more complex laboratory results for chromosome analysis or steroid levels are available.

Therapeutic Management

After diagnosis is confirmed, medical management includes administration of glucocorticoids to suppress the abnormally high secretions of ACTH and adrenal androgens (Glatt, Garzon, and Popovic, 2005). If cortisone is begun early enough, it is very effective. Cortisone depresses the secretion of ACTH by the adenohypophysis, which in turn inhibits the secretion of adrenocorticosteroids, which stems the progressive virilization. The signs and symptoms of masculinization in girls gradually disappear, and excessive early linear growth is slowed. Puberty occurs normally at the appropriate age.

The recommended oral dosage is divided to simulate the normal diurnal pattern of ACTH secretion. Because these children are unable to produce cortisol in response to stress, it is necessary to increase the dosage during episodes of infection, fever, surgery, or other stresses. Acute emergencies require immediate IV or intramuscular administration. Children with the salt-losing type of CAH require aldosterone replacement, as outlined in the discussion of chronic adrenal insufficiency, and supplementary dietary salt. Frequent laboratory tests are conducted to assess the effects on electrolytes, hormonal profiles, and renin levels. The frequency of testing is individualized to the child.

Gender assignment and surgical intervention in the newborn with ambiguous genitalia is complex and controversial. It is a significant stress for families, who need support from a multidisciplinary team of experienced specialists. Factors that influence gender assignment include genetic diagnosis, genitalia appearance, surgical options, fertility, and family and cultural preferences. Generally, genetically female (46,XX) infants should be raised as girls. Early reconstructive surgery should be considered only in the case of severe virilization (Lee, Houk, Ahmed, et al., 2006). Emphasis is on functional rather than cosmetic outcomes, and surgery can often be delayed. Reports concerning sexual satisfaction after partial clitoridectomy indicate that the capacity for orgasm and sexual

gratification is not necessarily impaired. Male infants may require phallic reconstruction by an experienced surgeon.

Unfortunately, not all children with CAH are diagnosed at birth and raised in accordance with their **genetic sex.** Particularly in the case of affected females, masculinization of the external genitalia may have led to gender assignment as a male. In males, diagnosis is usually delayed until early childhood, when signs of virilism appear. In these situations, it is advisable to continue rearing the child as a male in accordance with assigned gender and phenotype. Hormone replacement may be required to permit linear growth and to initiate male pubertal changes. Surgery is usually indicated to remove the female organs and reconstruct the phallus for satisfactory sexual relations. These individuals are not fertile.

CARE MANAGEMENT

Of major importance is recognition of ambiguous genitalia and diagnostic confirmation in newborns. Parents need assistance in understanding and accepting the condition and time to grieve for the loss of perfection in their newborn child. As soon as the gender is determined, parents should be informed of the findings and encouraged to choose an appropriate name, and the child should be identified as a male or female with no reference to ambiguous gender.

In general, rearing a genetically female child as a girl is preferred because of the success of surgical intervention and the satisfactory results with hormones in reversing virilism and providing a prospect of normal puberty and the ability to conceive. This is in contrast to the choice of rearing the child as a boy, in which case the child is sterile and may never be able to function satisfactorily in heterosexual relationships. If the parents persist in their decision to assign a male gender to a genetically female child, a psychologic consultation should be requested to explore their motivations and ensure their understanding of the future consequences for the child.

Nursing care management regarding cortisol and aldosterone replacement are the same as those discussed for chronic adrenocortical insufficiency. Because infants are especially prone to dehydration and salt-losing crises, parents need to be aware of signs of dehydration and the urgency of immediate medical intervention to stabilize the child's condition. Parents should have injectable hydrocortisone available and know how to prepare and administer the intramuscular injection (see Chapter 39).

In the unfortunate situation in which the gender is erroneously assigned and the correct gender determined later, parents need a great deal of help in understanding the reason for the incorrect gender identification and the options for gender reassignment or medical-surgical intervention.

Parents should be referred for genetic counseling before they conceive another child because CAH is an autosomal recessive disorder. Prenatal diagnosis and treatment are available.

! NURSING ALERT

The parents should be advised that there is no physical harm in treating for suspected adrenal insufficiency that is not present, but the consequence of not treating acute adrenal insufficiency can be fatal.

Pheochromocytoma

Pheochromocytoma is a rare tumor characterized by secretion of catecholamines. The tumor most commonly arises from the chromaffin cells of the adrenal medulla but may occur wherever these cells are found, such as along the paraganglia of the aorta or thoracolumbar sympathetic chain (Pacak, Eisenhofer, Ahlman, et al., 2007). Approximately 10% of these tumors are located in extraadrenal sites. In children, they are frequently bilateral or multiple and are generally benign. Often there is a familial transmission of the condition as an autosomal dominant trait (Kliegman, Stanton, St. Geme, et al., 2011).

The clinical manifestations of pheochromocytoma are caused by an increased production of catecholamines, producing hypertension, tachycardia, headache, decreased gastrointestinal activity with resultant constipation, increased metabolism with anorexia, weight loss, hyperglycemia, polyuria, polydipsia, hyperventilation, nervousness, heat intolerance, and diaphoresis. In severe cases, signs of congestive heart failure are evident.

Diagnostic Evaluation

The clinical manifestations mimic those of other disorders, such as hyperthyroidism or DM. Usually the tumor is identified by computed tomography (CT) scan or magnetic resonance imaging (MRI). Definitive tests include 24-hour measurement of urinary levels of the catecholamine metabolites, histamine stimulation, and α-adrenergic blocking agents.

Therapeutic Management

Definitive treatment consists of surgical removal of the tumor. In children, the tumors may be bilateral, requiring a bilateral adrenalectomy and lifelong glucocorticoid and mineralocorticoid therapy. The major complications that can occur during surgery are severe hypertension, tachydysrhythmias, and hypotension. The first two are caused by excessive release of catecholamines during manipulation of the tumor, and the latter results from catecholamine withdrawal and hypovolemic shock.

Preoperative medication to inhibit the effects of catecholamines is begun 1 to 3 weeks before surgery to prevent these complications. The major group of drugs used is the α-adrenergic blocking agents with or without β-adrenergic blocking agents. The most commonly used β-adrenergic blocker is phenoxybenzamine (Dibenzyline), a long-acting medication given orally every 12 hours. The shorter-acting phentolamine (Regitine) is equally effective but less satisfactory for long-term use, although it is useful for acute hypertension. The importance of meticulous preoperative conditioning with alpha-blockers cannot be overemphasized. This intervention is largely responsible for the improvement in outcomes. In select cases, beta-blockers (medications that slow the heart rate) may be added after adequate alpha-blockade has been established.

Success of therapy is judged by lowering of blood pressure to normal, absence of hypertensive attacks (flushing or blanching, fainting, headache, palpitations, tachycardia, nausea and vomiting, profuse sweating), heat tolerance, a decrease in perspiration, and disappearance of hyperglycemia. A disadvantage of these drugs is their inability to block the effects of catecholamines on beta receptors.

CARE MANAGEMENT

An initial nursing objective is identification of children with this disorder. Outstanding clues are hypertension and hypertensive attacks. Because of behavioral changes (nervousness, excitability, overactivity, and even psychosis), increased cardiac and respiratory activity may appear to be related to an acute anxiety attack. Therefore a careful history of the onset of symptoms and association with

stressful events is helpful in distinguishing between an organic and a psychologic cause for the symptoms.

Preoperative nursing care involves frequent monitoring of vital signs and observation for evidence of hypertensive attacks and congestive heart failure. Therapeutic effects are evidenced by normal vital signs and absence of glycosuria. Daily blood glucose levels, urine acetone, and any signs of hyperglycemia are noted and reported immediately.

! NURSING ALERT

Do not palpate the mass. Preoperative palpation of the mass releases catecholamines, which can stimulate severe hypertension and tachydysrhythmias.

The environment is made conducive to rest and free of emotional stress. This requires adequate preparation during hospital admission and before surgery. Parents are encouraged to room-in with their child and to participate in care. Play activities need to be tailored to the child's energy level without being overly strenuous or challenging because these can increase metabolic rate and promote frustration and anxiety.

After surgery, the child is observed for signs of shock from removal of excess catecholamines. If a bilateral adrenalectomy was performed, the nursing interventions are those discussed for chronic adrenocortical insufficiency.

DISORDERS OF PANCREATIC HORMONE SECRETION

Diabetes Mellitus

Diabetes mellitus is a chronic disorder of metabolism characterized by a partial or complete deficiency of the hormone insulin. It is the most common metabolic disease, resulting in metabolic adjustment or physiologic change in almost all areas of the body. In the United States, approximately 215,000 individuals younger than 20 years have either type 1 or type 2 diabetes (Centers for Disease Control and Prevention [CDC], 2012). The odds are higher for African-American and Hispanic children—nearly 50% of them will develop diabetes (Urrutia-Rojas and Menchaca, 2006). DM in children can occur at any age but has a peak incidence between ages 10 and 15 years, with 75% diagnosed before 18 years of age. The incidence in boys is slightly higher than in girls (1:1 to 1.2:1).

Traditionally, DM had been classified according to the type of treatment needed. The former categories were insulin-dependent diabetes mellitus (IDDM), or type I, and non–insulin-dependent diabetes mellitus (NIDDM), or type II. In 1997, these terms were eliminated because treatment can vary (some people with NIDDM require insulin) and because the terms do not indicate the underlying problem. The new terms are *type 1* and *type 2,* using Arabic symbols to avoid confusion (e.g., *type II* could be read as *type eleven*) (American Diabetes Association, 2001). The characteristics of type 1 DM and type 2 DM are outlined in Table 46-1.

In the age-group younger than 10 years, most diabetes cases are type 1 and occur most frequently in non-Hispanic whites. In the age-group 10 to 19 years, type 1 diabetes is more prominent in non-Hispanic whites followed by African-Americans and then Hispanics; the lowest prevalence is among Native Americans. In type 2 diabetes, Native Americans have the highest incidence followed by African-Americans, Asian Pacific individuals, and Hispanics; the lowest prevalence is in non-Hispanic whites (CDC, 2011). The Pima Indian Tribe reports a greater than 51% incidence of type 2 DM.

TABLE 46-1 CHARACTERISTICS OF TYPE 1 AND TYPE 2 DIABETES MELLITUS

CHARACTERISTIC	TYPE 1	TYPE 2
Age at onset	<20 years	Increasingly occurring in younger children
Type of onset	Abrupt	Gradual
Sex ratio	Affects males slightly more than females	Females outnumber males
Percentage of diabetic population	5%-8%	85%-90%
Heredity:		
Family history	Sometimes	Frequently
Human leukocyte antigen	Associations	No association
Twin concordance	25%-50%	90%-100%
Ethnic distribution	Primarily Caucasians	Increased incidence in Native Americans, Hispanics, African-Americans
Presenting symptoms	3 P's common: *p*olyuria, *p*olydipsia, *p*olyphagia	May be related to long-term complications
Nutritional status	Underweight	Overweight
Insulin (natural):		
Pancreatic content	Usually none	>50% normal
Serum insulin	Low to absent	High or low
Primary resistance	Minimum	Marked
Islet cell antibodies	80%-85%	<5%
Therapy:		
Insulin	Always	20%-30% of patients
Oral agents	Ineffective	Often effective
Diet only	Ineffective	Often effective
Chronic complications	>80%	Variable
Ketoacidosis	Common	Infrequent

Type 1 diabetes is characterized by destruction of the pancreatic β cells, which produce insulin; this usually leads to absolute insulin deficiency. Type 1 diabetes has two forms. Immune-mediated DM results from an autoimmune destruction of the β cells; it typically starts in children or young adults who are slim, but it can arise in adults of any age. Idiopathic type 1 refers to rare forms of the disease that have no known cause.

Type 2 diabetes usually arises because of insulin resistance in which the body fails to use insulin properly combined with relative (rather than absolute) insulin deficiency. People with type 2 can range from predominantly insulin resistant with relative insulin deficiency to predominantly deficient in insulin secretion with some insulin resistance. It typically occurs in those who are older that 45

BOX 46-13 CLINICAL MANIFESTATIONS OF TYPE 1 DIABETES MELLITUS

- Polyphagia
- Polyuria
- Polydipsia
- Weight loss
- Enuresis or nocturia
- Irritability; "not himself" or "herself"
- Shortened attention span
- Lowered frustration tolerance
- Dry skin
- Blurred vision
- Poor wound healing
- Fatigue
- Flushed skin
- Headache
- Frequent infections
- Hyperglycemia:
  - Elevated blood glucose levels
  - Glucosuria
- Diabetic ketosis:
  - Ketones and glucose in urine
  - Dehydration in some cases
- Diabetic ketoacidosis:
  - Dehydration
  - Electrolyte imbalance
  - Acidosis
  - Deep, rapid breathing (Kussmaul respirations)

years, are overweight and sedentary, and have a family history of diabetes.

The symptomatology of diabetes is more readily recognizable in children than in adults, so it is surprising that the diagnosis may sometimes be missed or delayed. Diabetes is a great imitator; influenza, gastroenteritis, and appendicitis are the conditions most often diagnosed when it turns out that the disease is really diabetes (Box 46-13).

Pathophysiology

Insulin is needed to support the metabolism of carbohydrates, fats, and proteins, primarily by facilitating the entry of these substances into the cells. Insulin is needed for the entry of glucose into the muscle and fat cells, prevention of mobilization of fats from fat cells, and storage of glucose as glycogen in the cells of liver and muscle. Insulin is not needed for the entry of glucose into nerve cells or vascular tissue. The chemical composition and molecular structure of insulin are such that it fits into receptor sites on the cell membrane. Here it initiates a sequence of poorly defined chemical reactions that alter the cell membrane to facilitate the entry of glucose into the cell and stimulate enzymatic systems outside the cell that metabolize the glucose for energy production.

With a deficiency of insulin, glucose is unable to enter the cells and its concentration in the bloodstream increases. The increased concentration of glucose (hyperglycemia) produces an osmotic gradient that causes the movement of body fluid from the intracellular space to the interstitial space and then to the extracellular space and into the glomerular filtrate to "dilute" the hyperosmolar filtrate. Normally, the renal tubular capacity to transport glucose is adequate to reabsorb all the glucose in the glomerular filtrate. When the glucose concentration in the glomerular filtrate exceeds the renal threshold (≤180 mg/dL), glucose spills into the urine (glycosuria) along with an osmotic diversion of water (polyuria), a cardinal sign of diabetes. The urinary fluid losses cause the excessive thirst (polydipsia) observed in diabetes. This water "washout" results in a depletion of other essential chemicals, especially potassium.

Protein is also wasted during insulin deficiency. Because glucose is unable to enter the cells, protein is broken down and converted to glucose by the liver (glucogenesis); this glucose then contributes to the hyperglycemia. These mechanisms are similar to those seen in starvation when substrate (glucose) is absent. The body is actually in a state of starvation during insulin deficiency. Without the use of carbohydrates for energy, fat and protein stores are depleted as the body attempts to meet its energy needs. The hunger mechanism is triggered, but increased food intake (polyphagia) enhances the problem by further elevating blood glucose.

Ketoacidosis. When insulin is absent or insulin sensitivity is altered, glucose is unavailable for cellular metabolism and the body chooses alternate sources of energy, principally fat. Consequently, fats break down into fatty acids and glycerol in the fat cells is converted by the liver to ketone bodies (β-hydroxybutyric acid, acetoacetic acid, acetone). Any excess is eliminated in the urine (ketonuria) or the lungs (acetone breath). The ketone bodies in the blood (ketonemia) are strong acids that lower serum pH, producing ketoacidosis.

Ketones are organic acids that readily produce excessive quantities of free hydrogen ions, causing a fall in plasma pH. Then chemical buffers in the plasma, principally bicarbonate, combine with the hydrogen ions to form carbonic acid, which readily dissociates into water and carbon dioxide. The respiratory system attempts to eliminate the excess carbon dioxide by increased depth and rate (**Kussmaul respirations,** or the hyperventilation characteristic of metabolic acidosis). The ketones are buffered by sodium and potassium in the plasma. The kidneys attempt to compensate for the increased pH by increasing tubular secretion of hydrogen and ammonium ions in exchange for fixed base, thus depleting the base buffer concentration.

With cellular death, potassium is released from the cells **(intracellular fluid)** into the bloodstream (extracellular fluid) and excreted by the kidneys, where the loss is accelerated by osmotic diuresis. The total body potassium is then decreased even though the serum potassium level may be elevated as a result of the decreased fluid volume in which it circulates. Alteration in serum and tissue potassium can lead to cardiac arrest.

If these conditions are not reversed by insulin therapy in combination with correction of the fluid deficiency and electrolyte imbalance, progressive deterioration occurs, with dehydration, electrolyte imbalance, acidosis, coma, and death. Diabetic ketoacidosis (DKA) should be diagnosed promptly in a seriously ill patient and therapy instituted in an intensive care unit.

Long-Term Complications. Long-term complications of diabetes involve both the microvasculature and the macrovasculature. The principal microvascular complications are nephropathy, retinopathy, and neuropathy. Microvascular disease develops during the first 30 years of diabetes, beginning in the first 10 to 15 years after puberty, with renal involvement evidenced by proteinuria and clinically apparent retinopathy. Macrovascular disease develops after 25 years of diabetes and creates the predominant problems in patients with type 2 DM. The process appears to be one of glycosylation, wherein proteins from the blood become deposited in the walls of small vessels (e.g., glomeruli), where they become trapped by "sticky" glucose compounds (glycosyl radicals). The buildup of these substances over time causes narrowing of the vessels, with subsequent interference with microcirculation to the affected areas (Rosenson and Herman, 2008).

With poor diabetic control, vascular changes can appear as early as 2½ to 3 years after diagnosis; however, with good to excellent control, changes can be postponed for 20 or more years. Intensive insulin therapy appears to delay the onset and slow the progression of retinopathy, nephropathy, and neuropathy. Hypertension and atherosclerotic cardiovascular disease are also major causes of

morbidity and mortality in patients with DM (Karnik, Fields, and Shannon, 2007).

Other complications have been observed in children with type 1 DM. Hyperglycemia appears to influence thyroid function, and altered function is frequently observed at the time of diagnosis and in poorly controlled diabetes. Limited mobility of small joints of the hand occurs in 30% of 7- to 18-year-old children with type 1 DM and appears to be related to changes in the skin and soft tissues surrounding the joint as a result of glycosylation.

! NURSING ALERT

Recurrent vaginal and urinary tract infections, especially with *Candida albicans,* are often an early sign of type 2 DM, especially in adolescents.

Diagnostic Evaluation

Three groups of children who should be considered as candidates for diabetes are (1) children who have glycosuria, polyuria, and a history of weight loss or failure to gain despite a voracious appetite; (2) those with transient or persistent glycosuria; and (3) those who display manifestations of metabolic acidosis, with or without stupor or coma. In every case, diabetes must be considered if there is glycosuria, with or without ketonuria, and unexplained hyperglycemia.

Glycosuria by itself is not diagnostic of diabetes. Other sugars, such as galactose, can produce a positive result with certain test strips, and a mild degree of glycosuria can be caused by other conditions, such as infection, trauma, emotional or physical stress, hyperalimentation, and some renal or endocrine diseases.

An 8-hour fasting blood glucose level of 126 mg/dL or more, a random blood glucose value of 200 mg/dL or more accompanied by classic signs of diabetes, or an oral glucose tolerance test (OGTT) finding of 200 mg/dL or more in the 2-hour sample is almost certain to indicate diabetes (Silverstein, Klingensmith, Copeland, et al., 2005). Postprandial blood glucose determinations and the traditional OGTTs have yielded low detection rates in children and are not usually necessary for establishing a diagnosis. Serum insulin levels may be normal or moderately elevated at the onset of diabetes; delayed insulin response to glucose indicates impaired glucose tolerance.

Ketoacidosis must be differentiated from other causes of acidosis or coma, including hypoglycemia, uremia, gastroenteritis with metabolic acidosis, salicylate intoxication encephalitis, and other intracranial lesions. DKA is a state of relative insulin insufficiency and may include the presence of hyperglycemia (blood glucose level ≥200 mg/dL), ketonemia (strongly positive), acidosis (pH <7.30 and bicarbonate <15 mmol/L), glycosuria, and ketonuria (Wolsdorf, Craig, Daneman, et al., 2009). Tests used to determine glycosuria and ketonuria are the glucose oxidase tapes (Keto-Diastix).

Therapeutic Management

The management of the child with type 1 DM consists of a multidisciplinary approach involving the family; the child (when appropriate); and professionals, including a pediatric endocrinologist, diabetes nurse educator, nutritionist, and exercise physiologist. Often psychologic support from a mental health professional is also needed. Communication among the team members is essential and extends to other individuals in the child's life, such as teachers, school nurse, school guidance counselor, and coach.

The definitive treatment is replacement of insulin that the child is unable to produce. However, insulin needs are also affected by emotions, nutritional intake, activity, and other life events such as illnesses and puberty. The complexity of the disease and its management require that the child and family incorporate diabetes needs into their lifestyle. Medical and nutritional guidance are primary, but management also includes continuing diabetes education, family guidance, and emotional support.

Insulin Therapy. Insulin replacement is the cornerstone of management of type 1 DM. Insulin dosage is tailored to each child based on home blood glucose monitoring. The goal of insulin therapy is maintaining near-normal blood glucose values while avoiding too frequent episodes of hypoglycemia. The goals of treatment are to maintain near-normal glucose levels of less than 126 mg/dL and glycosylated hemoglobin (hemoglobin A_{1c}) of 7% or less (Hannon, Gungor, and Arslanian, 2006). Glycemic control decreases the likelihood of long-term complications in patients with DM (Petitti, Imperatore, Palla, et al., 2007). Insulin is administered as two or more injections per day or as continuous subcutaneous infusion using a portable insulin pump.

Healthy pancreatic cells secrete insulin at a low but steady basal rate with superimposed bursts of increased secretion that coincide with intake of nutrients. Consequently, insulin levels in the blood increase and decrease coincidentally with rises and falls in blood glucose levels. In addition, insulin is secreted directly into the portal circulation; therefore the liver, which is the major site of glucose disposal, receives the largest concentration of insulin. No matter which method of insulin replacement is used, this normal pattern cannot be duplicated. Subcutaneous injection results in absorption of the drug into the general circulation, thus reducing the concentrations of insulin to which the liver is exposed.

Insulin Preparations. Insulin is available in highly purified pork preparations and in human insulin biosynthesized by and extracted from bacterial or yeast cultures. Most clinicians suggest human insulin as the treatment of choice. Insulin is available in rapid-, intermediate-, and long-acting preparations, and all are packaged in the strength of 100 units/mL. Some insulins are available as premixed insulins, such as 70/30 and 50/50 ratios, the first number indicating the percentage of intermediate-acting insulin and the second number the percentage of rapid-acting insulin. The different types of insulin are found in Box 46-14.

! NURSING ALERT

The human insulins from various manufacturers may be interchangeable, but human insulin and pork insulin or pure pork insulin should never be substituted for one another.

Dosage. Conventional management has consisted of a twice-daily insulin regimen of a combination of rapid-acting and intermediate-acting insulin drawn up into the same syringe and injected before breakfast and before the evening meal. The amount of morning regular insulin is determined by patterns in the late morning and lunchtime blood glucose values. The morning intermediate-acting dosage is determined by patterns in the late afternoon and supper blood glucose values. Fasting blood glucose patterns at breakfast help determine the evening dose of intermediate-acting insulin, and the blood glucose patterns at bedtime help determine the evening dose of rapid-acting (regular) insulin. For some children, better morning glucose control is achieved by a later (bedtime) injection of intermediate-acting insulin.

Regular insulin is best administered at least 30 minutes before meals. This allows sufficient time for absorption and results in a

significantly greater reduction in the postprandial rise in blood glucose than if the meal were eaten immediately after the insulin injection. Intensive therapy consists of multiple injections throughout the day with a once- or twice-daily dose of long-acting (Ultralente) insulin to simulate the basal insulin secretion and injections of rapid-acting insulin before each meal. A multiple daily injection program reduces microvascular complications of diabetes in young, healthy patients who have type 1 DM.

The precise dose of insulin needed cannot be predicted. Therefore the total dosage and percentage of regular- to intermediate-acting insulin should be determined empirically for each child. Usually 60% to 75% of the total daily dose is given before breakfast and the remainder is given before the evening meal. Furthermore, insulin requirements do not remain constant but change continuously during growth and development; the need varies according to the child's activity level and pubertal status. For example, less insulin is required during spring and summer months when children are more active. Illness also alters insulin requirements. Some children require more frequent insulin administration. This includes children with difficult-to-control diabetes and children during the adolescent growth spurt.

BOX 46-14 TYPES OF INSULIN

- There are four types of insulin, based on the following criteria:
  - How soon the insulin starts working (onset)
  - When the insulin works the hardest (peak time)
  - How long the insulin lasts in the body (duration)
- However, each person responds to insulin in his or her own way. That is why onset, peak time, and duration are given as ranges.

  Rapid-acting insulin (e.g., NovoLog) reaches the blood within 15 minutes after injection. The insulin peaks 30 to 90 minutes later and may last as long as 5 hours.

  Short-acting (regular) insulin (e.g., Novolin R) usually reaches the blood within 30 minutes after injection. The insulin peaks 2 to 4 hours later and stays in the blood for about 4 to 8 hours.

  Intermediate-acting insulins (e.g., Novolin N) reach the blood 2 to 6 hours after injection. The insulins peak 4 to 14 hours later and stay in the blood for about 14 to 20 hours.

  Long-acting insulin (e.g., Lantus) takes 6 to 14 hours to start working. It has no peak or a very small peak 10 to 16 hours after injection. The insulin stays in the blood between 20 and 24 hours.
- Some insulins come mixed together (e.g., Novolin 70/30). For example, you can buy regular insulin and NPH insulins already mixed in one bottle, which makes it easier to inject two kinds of insulin at the same time. However, you cannot adjust the amount of one insulin without also changing how much you get of the other insulin.

NPH, Neutral protamine Hagedorn.

Methods of Administration. Daily insulin is administered subcutaneously by twice-daily injections, by multiple-dose injections, or by means of an insulin infusion pump. The insulin pump is an electromechanical device designed to deliver fixed amounts of regular or lispro insulin continuously (basal rate), thereby more closely imitating the release of the hormone by the islet cells (Phillip, Battelino, Rodriguez, et al., 2007). Although the pump delivers a programmed amount of basal insulin, the child or parent must program a dose for the pump to deliver before each meal.

The system consists of a syringe to hold the insulin, a plunger, and a computerized mechanism to drive the plunger. The insulin flows from the syringe through a catheter to a needle inserted into subcutaneous tissue (the abdomen or thigh), and the lightweight device is worn on a belt or a shoulder holster. The needle and catheter are changed every 48 to 72 hours by the child or parent using aseptic technique and then taped in place.

Although the pump provides more consistent insulin delivery, it has certain disadvantages. Pump therapy is expensive and requires commitment from the parent and child. A certain level of math skills is required to calculate infusion rates. It should also not be removed for more than 1 hour at a time, which may limit some activities. Skin infections are common, and as with any other mechanical device, it is subject to malfunction. However, the pumps are equipped with alarms that signal problems, such as a depleted battery, an occluded needle or tubing, or a microprocessor malfunction.

Monitoring. Daily monitoring of blood glucose levels is an essential aspect of appropriate DM management. Plasma blood glucose and hemoglobin A_{1c} goal ranges are found in Table 46-2.

Blood Glucose. Self-monitoring of blood glucose (SMBG) has improved diabetes management and is used successfully by children from the onset of their diabetes. By testing their own blood, children are able to change their insulin regimen to maintain their glucose level in the euglycemic (normal) range of 80 to 120 mg/dL. Diabetes

TABLE 46-2 PLASMA BLOOD GLUCOSE AND HEMOGLOBIN A_{1C} GOALS FOR TYPE 1 DIABETES MELLITUS BY AGE-GROUP

AGE	VALUE* BEFORE MEALS (mg/dL)	VALUE* AT BEDTIME/ OVERNIGHT (mg/dL)	HEMOGLOBIN A_{1C} (%)	IMPLICATIONS
Toddlers and preschoolers (<6 years)	100-180	110-200	≤8.5% (but ≥7.5%)	High risk and vulnerability to hypoglycemia
School age (6-12 years)	90-180	100-180	<8%	Risks for hypoglycemia and relatively low risk for complications before puberty
Adolescents (>12 years) and young adults	90-130	90-150	<7.5%	Risk for hypoglycemia Developmental and psychologic issues

*Plasma blood glucose goal range.

management depends to a great extent on SMBG. In general, children tolerate the testing well.

Glycosylated Hemoglobin. The measurement of glycosylated hemoglobin (hemoglobin A_{1c}) levels is a satisfactory method for assessing control of the diabetes. As red blood cells circulate in the bloodstream, glucose molecules gradually attach to the hemoglobin A molecules and remain there for the lifetime of the red blood cell, approximately 120 days. The attachment is not reversible; therefore this glycosylated hemoglobin reflects the average blood glucose levels over the previous 2 to 3 months. The test is a satisfactory method for assessing control, detecting incorrect testing, monitoring the effectiveness of changes in treatment, defining patients' goals, and detecting nonadherence. Nondiabetic hemoglobin A_{1c} values are generally between 4% and 6% but can vary by laboratory. Diabetes control for children depends on age, with hemoglobin A_{1c} levels of 6.5% to 8% indicating a slightly elevated but acceptable range (Silverstein, Klingensmith, Copeland, et al., 2005). Hemoglobin A_{1c} levels of less than 7% are a well-established goal at most care centers.

Urine. Urine testing for glucose is no longer used for diabetes management; there is poor correlation between simultaneous glycosuria and blood glucose concentrations. However, urine testing can be carried out to detect evidence of ketonuria.

! NURSING ALERT

It is recommended that urine be tested for ketones every 3 hours during an illness or whenever the blood glucose level is over 240 mg/dL when illness is not present.

Nutrition. Essentially, the nutritional needs of children with diabetes are no different from those of healthy children. Children with diabetes need no special foods or supplements. They need sufficient calories to balance daily expenditure for energy and to satisfy the requirement for growth and development. Unlike children without diabetes, whose insulin is secreted in response to food intake, insulin injected subcutaneously has a relatively predictable time of onset, peak effect, duration of action, and absorption rate depending on the type of insulin used. Consequently, the timing of food consumption must be regulated to correspond to the timing and action of the insulin prescribed.

Meals and snacks must be eaten according to peak insulin action, and the total number of calories and proportions of basic nutrients must be consistent from day to day. The constant release of insulin into the circulation makes the child prone to hypoglycemia between the three daily meals unless a snack is provided between meals and at bedtime. The distribution of calories should be calculated to fit the activity pattern of each child. For example, a child who is more active in the afternoon will need a larger snack at that time. This larger snack might also be split to allow some food at school and some food after school. Food intake should be altered to balance food, insulin, and exercise. Extra food is needed for increased activity.

Concentrated sweets are discouraged, and because of the increased risk for atherosclerosis in persons with DM, fat is reduced to 30% or less of the total caloric requirement. Dietary fiber has become increasingly important in dietary planning because of its influence on digestion, absorption, and metabolism of many nutrients. It has been found to diminish the rise in blood glucose after meals.

For growing children, food restriction should never be used for diabetes control, although caloric restrictions may be imposed for weight control if the child is overweight. In general, the child's appetite should be the guide for the amount of calories needed, with the total caloric intake adjusted to appetite and activity.

Exercise. Exercise is encouraged and never restricted unless indicated by other health conditions. Exercise lowers blood glucose levels, depending on the intensity and duration of the activity. Consequently, exercise should be included as part of diabetes management, and the type and amount of exercise should be planned around the child's interests and capabilities. However, in most instances, children's activities are unplanned, and the resulting decrease in blood glucose can be compensated for by providing extra snacks before and, if the exercise is prolonged, during the activity. In addition to a feeling of well-being, regular exercise aids in utilization of food and often results in a reduction of insulin requirements.

Hypoglycemia. Occasional episodes of hypoglycemia are an integral part of insulin therapy, and an objective of diabetes management is to achieve the best possible glycemic control while minimizing the frequency and severity of hypoglycemia. Even with good control, a child may frequently experience mild symptoms of hypoglycemia. If the signs and symptoms are recognized early and promptly relieved by appropriate therapy, the child's activity should be interrupted for no more than a few minutes.

! NURSING ALERT

Hypoglycemic episodes most commonly occur before meals or when the insulin effect is peaking.

The signs and symptoms of hypoglycemia are caused by both increased adrenergic activity and impaired brain function. The increased adrenergic nervous system activity plus increased secretion of catecholamines produce nervousness, pallor, tremulousness, palpitations, sweating, and hunger (Cryer, 2008). Weakness, dizziness, headache, drowsiness, irritability, loss of coordination, seizures, and coma are more severe responses and reflect CNS glucose deprivation and the body's attempts to elevate the serum glucose levels.

It is often difficult to distinguish between hyperglycemia and a hypoglycemic reaction (Table 46-3). Because the symptoms are similar and usually begin with changes in behavior, the simplest way to differentiate between the two is to test the blood glucose level. The blood glucose level is low in hypoglycemia, but in hyperglycemia, the glucose level is significantly elevated. Urinary ketones may be present after hypoglycemia as a result of starvation ketone production. In doubtful situations, it is safer to give the child some simple carbohydrate. This will help alleviate the symptoms in the case of hypoglycemia but will do little harm if the child is hyperglycemic.

Children are usually able to detect the onset of hypoglycemia, but some are too young to implement treatment. Parents should become adept at recognizing the onset of symptoms—for example, a change in a child's behavior, such as tearfulness or euphoria. In the majority of cases, 10 to 15 g of simple carbohydrate, such as 1 Tbsp of table sugar, will elevate the blood glucose level and alleviate the symptoms. The simpler the carbohydrate, the more rapidly it will be absorbed (8 oz of milk equals 15 g of carbohydrate). The rapidly releasing sugar is followed by a complex carbohydrate such as a slice of bread or a cracker and by a protein such as peanut butter or milk.

For a mild reaction, milk or fruit juice is a good food to use in children. Milk supplies them with lactose or milk sugar, as well as a

TABLE 46-3 COMPARISON OF MANIFESTATIONS OF HYPOGLYCEMIA AND HYPERGLYCEMIA

VARIABLE	HYPOGLYCEMIA	HYPERGLYCEMIA
Onset	Rapid (minutes)	Gradual (days)
Mood	Labile, irritable, nervous, weepy	Lethargic
Mental status	Difficulty concentrating, speaking, focusing, coordinating Nightmares	Dulled sensorium Confusion
Inward feeling	Shaky feeling Hunger Headache Dizziness	Thirst Weakness Nausea and vomiting Abdominal pain
Skin	Pallor Sweating	Flushed Signs of dehydration
Mucous membranes	Normal	Dry, crusty
Respirations	Shallow, normal	Deep, rapid (Kussmaul)
Pulse	Tachycardia, palpitations	Less rapid, weak
Breath odor	Normal	Fruity, acetone
Neurologic	Tremors	Diminished reflexes Paresthesia
Ominous signs	Late—Hyperreflexia, dilated pupils, seizure Shock, coma	Acidosis, coma
Blood:		
Glucose	Low: <60 mg/dL	High: ≥250 mg/dL
Ketones	Negative	High, large
Osmolarity	Normal	High
pH	Normal	Low (≤7.25)
Hematocrit	Normal	High
Bicarbonate	Normal	<20 mEq/L
Urine:		
Output	Normal	Polyuria (early) to oliguria (late)
Glucose	Negative	Enuresis, nocturia
Ketones	Negative or trace	High
Vision	Diplopia	Blurred vision

more prolonged action from the protein and fat (aids in decreased absorption). Other glucose sources include Insta-Glucose (cherry-flavored glucose), carbonated drinks (not sugarless), sherbet, gelatin, or cake icing. All children with diabetes should carry with them glucose tabs, Insta-Glucose, sugar cubes, or sugar-containing candy such as LifeSavers or Charms. A difficulty with candies or icing is that the child may learn to fake a reaction to get the sweets; therefore commercial treatment products such as Insta-Glucose or glucose tabs may be preferred.

Glucagon is sometimes prescribed for home treatment of hypoglycemia. It is available as an emergency kit that must be mixed at the time of use and is administered intramuscularly or subcutaneously. Glucagon functions by releasing stored glycogen from the liver and requires about 15 to 20 minutes to elevate the blood glucose level.

! NURSING ALERT

Vomiting may occur after administration of glucagon; therefore precautions against aspiration must be taken (e.g., placing the child on the side) because the child often becomes unconscious.

When the child is responsive, the lost glycogen stores are replaced by small amounts of sugar-containing fluid administered frequently until the child feels comfortable trying solid foods.

Morning Hyperglycemia. The management of elevated morning blood glucose levels depends on whether the increase is a true dawn phenomenon (insulin waning), or a rebound hyperglycemia (the Somogyi effect). Insulin waning is a progressive rise in blood glucose levels from bedtime to morning. It is treated by increasing the nocturnal insulin dose. The true dawn phenomenon shows relatively normal blood glucose level until about 3 AM, when the level begins to rise. The Somogyi effect may occur at any time but often entails an elevated blood glucose level at bedtime and a drop at 2 AM with a rebound rise following. The treatment for this phenomenon is decreasing the nocturnal insulin dose to prevent the 2 AM hypoglycemia. The rebound rise in the blood glucose level is a result of counterregulatory hormones (epinephrine, GH, and corticosteroids), which are stimulated by hypoglycemia. More frequent blood monitoring (especially at times of anticipated peak insulin action) will usually identify these conditions. Trace amounts of urinary ketones aid in identifying undetected hypoglycemia.

Illness Management. Illness alters diabetes management, and maintaining control is usually related to the seriousness of the illness. In a well-controlled child, an illness will run its course as it does in unaffected children. The goals during an illness are to restore euglycemia, treat urinary ketones, and maintain hydration. Blood glucose levels and urinary ketones should be monitored every 3 hours. Some hyperglycemia and ketonuria are expected in most illnesses, even with diminished food intake, and are an indication for increased insulin. Insulin should never be omitted during an illness, although dosage requirements may increase, decrease, or remain unchanged, depending on the severity of the illness and the child's appetite. Often the child will need supplemental insulin between usual dose times. If the child vomits more than once, if blood glucose levels remain above 240 mg/dL, or if urinary ketones remain high, the health care practitioner should be notified. Simple carbohydrates may be substituted for carbohydrate-containing exchanges in the meal plan. Although insulin and diet are important tools in sick-day care, fluids are the most important intervention. Fluids must be encouraged to prevent dehydration and to flush out ketones.

Therapeutic Management of Diabetic Ketoacidosis

Diabetic ketoacidosis, the most complete state of insulin deficiency, is a life-threatening situation. Management consists of rapid assessment, adequate insulin to reduce the elevated blood glucose level, fluids to overcome dehydration, and electrolyte replacement (especially potassium).

Because DKA constitutes an emergency situation, the child should be admitted to an intensive care facility for management. The priority is to obtain a venous access for administration of fluids, electrolytes, and insulin. The child should be weighed, measured,

and placed on a cardiac monitor. Blood glucose and ketone levels are determined at the bedside, and samples are obtained for laboratory measurement of glucose, electrolytes, BUN, arterial pH, Po_2, Pco_2, hemoglobin, hematocrit, white blood cell count and differential, calcium, and phosphorus.

Oxygen may be administered to patients who are cyanotic and in whom arterial oxygen is less than 80%. Gastric suction is applied to unconscious children to avoid the possibility of pulmonary aspiration. Antibiotics may be administered to febrile children after appropriate specimens are obtained for culture. A Foley catheter may or may not be inserted for urine samples and measurement. Unless the child is unconscious, a collection bag is usually sufficient for accurate assessments.

Fluid and Electrolyte Therapy. All patients with DKA experience dehydration (10% of total body weight in severe ketoacidosis) because of the osmotic diuresis, accompanied by depletion of electrolytes, sodium, potassium, chloride, phosphate, and magnesium. Serum pH and bicarbonate reflect the degree of acidosis. Prompt and adequate fluid therapy restores tissue perfusion and suppresses the elevated levels of stress hormones.

The initial hydrating solution is 0.9% saline solution. Traditionally, deficits have been replaced at a rate of 50% over the first 8 to 12 hours and the remaining 50% over the next 16 to 24 hours. Current trends suggest more cautious fluid management to reduce the risk for cerebral edema. The fluid deficit is replaced evenly over a period of 36 to 48 hours (Cooke and Plotnick, 2008).

! NURSING ALERT

Potassium must never be given until the serum potassium level is known to be normal or low and urinary voiding is observed. All maintenance IV fluids should include 20 to 40 mEq/L of potassium. Never give potassium as a rapid IV bolus, or cardiac arrest may result.

Serum potassium levels may be normal on admission, but after fluid and insulin administration, the rapid return of potassium to the cells can seriously deplete serum levels, with the attendant risk for cardiac dysrhythmias. As soon as the child has established renal function (is voiding at least 25 mL/hr) and insulin has been given, vigorous potassium replacement is implemented. The cardiac monitor is used as a guide to therapy, and configuration of T waves should be observed every 30 to 60 minutes to determine changes that might indicate alterations in potassium concentration (widening of the QT interval and the appearance of a U wave following a flattened T wave indicate hypokalemia; an elevated and spreading T wave and shortening of the QT interval indicate hyperkalemia).

Insulin should not be given until urinary ketones and a blood glucose level have been obtained. Continuous IV regular insulin is given at a dosage of 0.1 units/kg/hr. Insulin therapy should be started after the initial rehydration bolus because serum glucose levels fall rapidly after volume expansion. Blood glucose levels should decrease by 50 to 100 mg/dL/hr. When blood glucose levels fall to 250 to 300 mg/dL, dextrose is added to the IV solution. The goal is to maintain blood glucose levels between 120 and 240 mg/dL by adding 5% to 10% dextrose. Sodium bicarbonate is used conservatively; it is used for pH less than 7.0, severe hyperkalemia, or cardiac instability. Because sodium bicarbonate has been associated with an increased risk for cerebral edema, children receiving this substance must be carefully monitored for changes in level of consciousness (Brown, 2004).

When the critical period is over, the task of regulating the insulin dosage in relation to diet and activity is started. Children should be actively involved in their own care and are given responsibility according to their ability and the guidance of the nurse.

! NURSING ALERT

Because insulin can chemically bind to plastic tubing and in-line filters, thereby reducing the amount of medication reaching the systemic circulation, an insulin mixture is run through the tubing to saturate the insulin-binding sites before the infusion is started.

CARE MANAGEMENT

Children with DM may be admitted to the hospital at the time of their initial diagnosis; during illness or surgery; or for episodes of ketoacidosis, which may be precipitated by any of a variety of factors. Many children are able to keep the disease under control with periodic assessment and adjustment of insulin, diet, and activity as needed under the supervision of a health care practitioner. Under most circumstances, these children can be managed well at home and require hospitalization only for serious illnesses or upsets.

However, a small number of children with diabetes exhibit a degree of metabolic lability and have repeated episodes of DKA that require hospitalization, which interferes with their education and social development. These children appear to display a characteristic personality structure. They tend to be unusually passive and nonassertive and to come from families that are inclined to smooth over conflicts without resolution. Children in this type of setting experience emotional arousal with little, if any, opportunity or ability to resolve it. Other children from psychosocially dysfunctional families display behavioral and personality problems. This emotional stress causes an increased production of endogenous catecholamines, which stimulate fat breakdown, leading to ketonemia and ketonuria.

Hospital Management. Children with DKA require intensive nursing care. Vital signs should be observed and recorded frequently. Hypotension caused by the contracted blood volume of the dehydrated state may cause decreased peripheral blood flow, which can be particularly hazardous to the heart, lungs, and kidneys. An elevated temperature may indicate infection and should be reported so that treatment can be implemented immediately.

Careful and accurate records should be maintained, including vital signs (pulse, respiration, temperature, blood pressure), weight, IV fluids, electrolytes, insulin, blood glucose level, and intake and output. A urine collection device or retention catheter is used to obtain the urine measurements, which include volume, specific gravity, and glucose and ketone values. The volume relative to the glucose content is important because 5% glucose in a 300-mL sample is a significantly greater amount than a similar reading from a 75-mL sample. A diabetic flow sheet maintained at the bedside provides an ongoing record of the vital signs, urine and blood tests, amount of insulin given, and intake and output. The level of consciousness is assessed and recorded at frequent intervals. The comatose child generally regains consciousness fairly soon after initiation of therapy but is managed like any unconscious child until then.

When the critical period is over, the task of regulating insulin dosage to diet and activity is begun. The same meticulous records of intake and output, urine glucose and acetone levels, and insulin administration are maintained. Capable children should be actively involved in their own care and are given responsibility for keeping the intake and output record; testing the blood and urine; and, when appropriate, administering their own insulin—all under the supervision and guidance of the nurse (see Nursing Care Plan).

Child and Family Education. Several organizations are prepared to assist with education and dissemination of knowledge about diabetes. The American Diabetes Association,* Canadian Diabetes Association,† Juvenile Diabetes Research Foundation International,‡ and American Association of Diabetes Educators§ are valuable resources for a wide variety of educational materials. The National Institute of Diabetes and Digestive and Kidney Diseases* publishes a number of comprehensive annotated bibliographies, including "Educational Materials for and About Young People with Diabetes," a compilation of resource materials for children, siblings, parents, teachers, and health care professionals, and "Sports and Exercise for People with Diabetes."

Medical Identification. One of the first things the nurse should call to the parents' attention is the need for the child to wear some means of medical identification. Usually recommended is the MedicAlert identification, a stainless steel or silver- or gold-plated

NURSING CARE PLAN

The Child with Diabetes Mellitus

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
Risk for Injury related to insulin deficiency	Child will demonstrate normal blood glucose levels.	Obtain blood glucose level	To determine most appropriate dosage of insulin
Child's or Family's Defining Characteristics *(Subjective and Objective Data)*		Administer insulin as prescribed	To maintain normal blood glucose level
		Understand action of insulin, including differences in composition, time of onset, and duration of action for various preparations	To ensure accurate insulin administration
Polyphagia			
Polydipsia		Use aseptic techniques when preparing and administering insulin	To prevent infection
Polyuria			
Weight loss		Rotate sites	To enhance absorption of insulin
Enuresis or nocturia			
Abnormal blood profile—glucose, insulin			
Irritability			
Shortened attention span			
Fatigue			
Dry skin			
Blurred vision			
Headache			
Frequent infections			
Hyperglycemia			
Flushed skin			
Risk for Injury related to hypoglycemia	Child will exhibit no evidence of hypoglycemia.	Recognize signs of hypoglycemia early; be alert at times when blood glucose levels are lowest (before meals and snacks; 2-4 AM; after bursts of physical activity without additional food; or with delayed, omitted, or incompletely consumed meal or snack)	To prevent hypoglycemia
Child's or Family's Defining Characteristics *(Subjective and Objective Data)*		Test blood glucose	To evaluate glucose level
Shaky feeling		Offer 10-15 g of readily absorbed carbohydrates, such as orange juice, hard candy, or milk	To elevate blood glucose level and alleviate symptoms of hypoglycemia
Hunger			
Headache			
Dizziness		Follow with complex carbohydrate and protein, such as bread or cracker spread with peanut butter or cheese	To maintain blood glucose level
Difficulty concentrating, speaking, or focusing		Administer glucagons to unconscious or combative child; position child to minimize risk of aspiration because vomiting may occur	To elevate blood glucose level
Tremors			
Tachycardia			
Shallow respirations			
Can lead to convulsion, shock, and coma			

NURSING CARE PLAN

The Child with Diabetes Mellitus—cont'd

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
Deficient Knowledge (Diabetes Management) related to care of child with newly diagnosed diabetes mellitus	Child and family will have attitude conducive to learning.	Select methods, vocabulary, and content appropriate to learner's level	To maximize learning
		Allow time for family and child to begin to adjust to initial impact of diagnosis	To allow child and family to set pace
		Select environment conducive to learning	To promote learning
Child's or Family's Defining Characteristics *(Subjective and Objective Data)*		Involve all senses and use variety of teaching strategies, especially participation	To promote effective learning
		Provide pamphlets or other supplementary materials	To promote learning
Lack of understanding	Child and family will demonstrate understanding of meal planning.	Emphasize relationship between normal nutritional needs and disease	To encourage sense of normalcy
Inability to prepare and administer insulin		Become familiar with family's culture and food preferences	To include culture preferences in meal planning
Inability to follow meal planning guidelines		Teach or reinforce learners' understanding of basic food groups and prescribed meal plan	To reinforce existing knowledge base
Difficulty describing treatment plan		Help child and family estimate portion sizes by volume	To provide more practical method than weighing food
		Suggest low-carbohydrate snack items	To promote appropriate food choices
		Guide family in assessing labels of food products for carbohydrate content	To reinforce that consistency in carbohydrate portions is essential
	Child and family will demonstrate knowledge of and ability to administer insulin.	Teach child and family characteristics of insulins prescribed	To increase understanding that there are several insulin preparations
		Teach proper mixing of insulins	To prevent contaminating vials
		Teach injection procedure	To promote appropriate administration
		Teach basic techniques using orange or similar item	To build confidence
		Use demonstration and return demonstration techniques on another adult before injecting child	To minimize stress for child
		Help family and child work out set rotational pattern	To ensure maximum absorption of insulin and prevent hypertrophy at injection site
		Teach proper care of insulin and equipment	To prevent contamination and minimize complications
	Child and family will demonstrate ability to test blood glucose level.	Teach family and child, if old enough, blood glucose monitoring or use of equipment, interpretation of results, and care and maintenance of equipment	To ensure that child and family learn how to adjust insulin based on blood glucose level
	Child and family will demonstrate knowledge of management of hyperglycemia and hypoglycemia.	Instruct learners in how to recognize signs of hyperglycemia and hypoglycemia	To prevent delay of treatment
		Explain relationship of insulin needs to illness, activity, and intense emotion	To ensure appropriate treatment
		Teach how to adjust food, activity, and insulin at times of illness and during other situations that alter blood glucose levels	To ensure appropriate treatment
		Suggest carrying source of carbohydrate, such as sugar cubes or hard candy, in pocket	To prevent delay in treatment
		Instruct parents and child in how to treat hypoglycemia with food, simple sugars, or glucagons	To establish health practices that last a lifetime
	Child and family will demonstrate understanding of proper hygiene.	Emphasize importance of personal hygiene	To promote child's general health
		Encourage regular dental care and yearly ophthalmologic examinations	To minimize risk of infection
		Teach proper care of cuts and scratches; teach proper foot care	To prevent infection

identification bracelet that is visible and immediately recognizable. It contains a collect telephone number that medical personnel can call around the clock for medical records and personal information.

Nature of Diabetes. The better the parents understand the pathophysiology of diabetes and the function and action of insulin and glucagon in relation to caloric intake and exercise, the better they will understand the disease and its effects on the child. Parents need answers to a number of questions (voiced or unvoiced) to increase their confidence in coping with the disease. For example, they may want to know about the various procedures performed on their child and treatment rationale, such as what is being put in the IV fluid and the expected effect.

Meal Planning. Normal nutrition is a major aspect of the family education program. Diet instruction is usually conducted by the nutritionist, with reinforcement and guidance from the nurse. The emphasis is on adequate intake for age, consistent menus, complex carbohydrates, and consistent eating times. The family is taught how the meal plan relates to the requirements of growth and development, the disease process, and the insulin regimen. Meals and snacks are modified based on the child's preferences and current menu, preserving cultural patterns and preferences as much as possible. Extensive exchange lists are available that include foods compatible with most lifestyles.

Learning about foods within specific food groups helps in making choices. Weights and measures of foods are used as eye-training devices for defining serving sizes and should be practiced for about 3 months, with gradual progression to estimation of food portions. Even when the child and family become competent in estimating portion sizes, reassessment should take place weekly or monthly and when there is any change of brands.

Family members should also be guided in reading labels for the nutritional value of foods and food content. They need to become familiar with the carbohydrate content of food groups. Substitution with foods of equal carbohydrate content is the skill needed for successful carbohydrate counting. Substitution might be necessary if a food is not available in sufficient quantity or for the teenager who wishes to eat fast food with peers. The use of a multiple daily injection program lends flexibility to the timing of meals.

Lists of popular fast-food items and items served at the major fast-food chains can be obtained from the restaurants to help guide food selections. It is important that the child know the nutritional value of these items (the major chains are remarkably uniform), but the child should be cautioned to avoid high-fat and high-sugar/high-carbohydrate items; for example, the child could choose a plain hamburger instead of a double cheeseburger.

Children should use sugar substitutes in moderation in items such as soft drinks. Artificial sweeteners have been shown to be safe, but if there is any question about amounts, the physician, dietitian, or nurse specialist can provide guidelines based on body weight. Sugar-free chewing gum and candies made with sorbitol may be used in moderation by children with DM. Although sorbitol is less cariogenic than other varieties of sugar substitutes, it is an alcohol sugar that is metabolized to fructose and then to glucose. Furthermore, large amounts can cause osmotic diarrhea. Most dietetic foods contain sorbitol. They are more expensive than regular foods. Also, although a product may be sugar free, it is not necessarily carbohydrate free.

Traveling. Traveling requires planning, especially when a trip involves crossing time zones. A number of tips are included in pamphlets available free of charge. Suggestions for traveling encompass what will be needed from the health care practitioner before leaving, what and how much to take along, needs in transit, what to consider at the destination, and planning for when the child returns home. Planning is needed no matter what type of travel is considered—automobile, plane, bus, or train.

Insulin. Families need to understand the treatment method and the insulin prescribed, including the effective duration, onset, and peak action. They also need to know the characteristics of the various types of insulins, the proper mixing and dilution of insulins, and how to substitute another type when their usual brand is not available (insulin is a nonprescription drug). Insulin need not be refrigerated but should be maintained at a temperature between 15° and 29.4°C (59° and 85°F). Freezing renders insulin inactive.

Insulin bottles that have been "opened" (i.e., the stopper has been punctured) should be stored at room temperature or refrigerated for up to 28 to 30 days. After 1 month, these vials should be discarded. Unopened vials should be refrigerated and are good until the expiration date on the label. Diabetic supplies should not be left in a hot environment.

Injection Procedure. Learning to give insulin injections is a source of anxiety for both parents and children. It is helpful for the learner to know that this important aspect of care will become as routine as brushing the teeth. First, the basic injection technique is taught using an orange or similar item and sterile normal saline for practice. To gain children's confidence, the nurse can demonstrate the technique by giving a skillful injection to the parent and then having the parent return the demonstration by giving the nurse an injection. With practice and confidence, the parents will soon be able to give the insulin injection to their children and their children will trust them. Another effective strategy is to instruct the children and then have them teach the technique to the parents while the nurse observes. Both parents should participate, and as little time as possible should elapse between instruction and the actual injection, especially with parents and teenage learners.

Insulin can be injected into any area in which there is adipose (fat) tissue over muscle; the drug is injected at a 90-degree angle. Newly diagnosed children may have lost adipose tissue, and care should be exerted not to inject intramuscularly. The pinch technique is the most effective method for tenting the skin to allow easy entrance of the needle to subcutaneous tissues in children. The site selected will sometimes depend on whether children or parents administer the insulin. The arms, thighs, hips, and abdomen are usual injection sites for insulin. The children can reach the thighs, abdomen, and part of the hip and arm easily but may require help to inject other sites. For example, a parent can pinch a loose fold of skin of the arm while the child injects the insulin.

The parents and child are helped to work out a rotation pattern to various areas of the body to enhance absorption because insulin absorption is slowed by fat pads that develop in overused injection areas. The most efficient rotation plan involves giving about four to six injections in one area (each injection about 2.5 cm [1 inch] apart, or the diameter of the insulin vial from the previous injection) and then moving to another area.

It is important to remember that the absorption rate varies in different parts of the body (Table 46-4). The methodical use of one anatomic area and then movement to another (as described in the previous paragraph) minimizes variations in absorption rates. However, absorption is also altered by vigorous exercise, which enhances absorption from exercised muscles; therefore it is recommended that a site be chosen other than the exercising extremity (e.g., avoiding legs and arms when playing in a tennis tournament).

TABLE 46-4 ONSET AND DURATION OF ACTION RELATED TO INJECTION SITE

	SITE OF INJECTION			
	ABDOMEN	ARM	LEG	BUTTOCK
Rate	Very fast	Fast	Slow	Very slow
Duration	Very short	Short	Long	Very long

From Albisser AM, Sperlich M: Adjusting insulins, *Diabetes Educ* 18(3):211–218, 1992.

FIG 46-3 School-age children are able to administer their own insulin.

Injection sites for an entire month can be determined in advance on a simple chart. For example, a "paper doll" (body outline) can be constructed and insulin sites marked by the child. After injection, the child places the date on the appropriate site. To keep in practice, it is a good idea for the parent to give two or three injections a week in areas that are difficult for the child to reach. The same basic methodology is used when teaching children to give their own insulin injections (Fig. 46-3). They should practice first on an orange or a doll, building courage gradually. Other devices are available for insulin injection and may offer advantages to some children. Children who do not wish to give themselves injections can be taught to use a syringe-loaded injector (Inject-Ease). With the device, puncture is always automatic. Adolescents respond well to a self-contained and compact device resembling a fountain pen (NovoPen), which eliminates conventional vials and syringes. Preloaded pens may also cause less pain because the needle is not blunted by piercing the rubber top of the insulin vial (Rex, Jensen, and Lawton, 2006).

Continuous Subcutaneous Insulin Infusion. Some children are considered candidates for use of a portable insulin pump, and even some young children with unsatisfactory metabolic control can benefit from its use. The child and the parents are taught to operate the device, including the mechanics of the pump, battery changes, and alarm systems. A number of devices are on the market that vary in the basal rates they are able to deliver and in the cost of the equipment. Families can investigate the various devices and select the model that best suits their needs. Product information is available from pump manufacturers and distributors.*

Parents and children learn (1) the technical aspects of the pump and self-monitoring of blood glucose (SMBG); (2) prevention and treatment for hyperglycemia, sick-day management, and meal planning; (3) the effects of exercise, stress, and diet on blood glucose levels; and (4) decision-making strategies to evaluate blood glucose patterns and make adjustments in all aspects of the regimen.

Numerous blood glucose measurements (at least 4 times per day) are an essential part of infusion pump use. Intensive education and supervision are critical to obtaining maximum efficiency and control. This is particularly important if the family has been accustomed to a conventional insulin regimen. They must realize that simply wearing the pump will not normalize blood glucose. The pump is merely an insulin delivery device, and frequent, routine blood glucose determinations are necessary to adjust the insulin delivery rate.

The major problems with use of the insulin pump are inflammation from irritation and infection at the insertion site. The site should be cleaned thoroughly before the needle is inserted and then covered with a transparent dressing. The site is changed and rotated every 48 to 72 hours (this may vary) or at the first sign of inflammation. Nurses working where pumps are part of the therapeutic regimen should become familiar with the operation of the specific device being used and the protocol of disease management. Others should be aware of this management technique and be prepared to assist patients using the pump.

Monitoring. Nurses should also be prepared to teach and supervise blood glucose monitoring. SMBG is associated with few complications, and although it does not necessarily lead to improved metabolic control, it provides a more accurate assessment of blood glucose levels than can be obtained with the historical urine testing. Blood glucose monitoring has the added advantage that it can be performed anywhere (see Atraumatic Care box).

Blood for testing can be obtained by two different methods: manually or with a mechanical bloodletting device. A mechanical device is recommended for children, although the child and family should learn to use both methods in the event of mechanical failure. Several lancet devices are available, and each provides a means for obtaining a large drop of blood for testing (Fig. 46-4).

ATRAUMATIC CARE

Minimizing Pain of Blood Glucose Monitoring

- To enhance blood flow to the finger, hold it under warm water for a few seconds before the puncture.
- When obtaining blood samples, use the ring finger or thumb (blood flows more easily to these areas) and puncture the finger just to the side of the finger pad (more blood vessels and fewer nerve endings).
- To prevent a deep puncture, press the platform of the lancet device lightly against the skin and avoid steadying the finger against a hard surface.
- Use lancet devices with adjustable-depth tips. Begin with the shallowest setting.
- Use glucose monitors that require small blood samples (e.g., Ascensia Elite) to avoid repeated punctures.

*Medtronic, www.medtronicdiabetes.com; Accu-Chek, www.accu-chek.com; Animas, www.animas.com.

FIG 46-4 Child using a fingerstick device to obtain a blood sample.

FIG 46-5 Child using a blood glucose monitor and reagent strips to test his blood for glucose.

! NURSING ALERT

Caution children not to allow anyone else to use their lancet because of the risk for contracting hepatitis B virus or human immunodeficiency virus infection.

The blood sample may be obtained from fingertips or alternate sites such as the forearm. Alternate site testing requires a meter that can test a small volume of blood. Not all meters are capable of this.

Signs of redness and soreness at the site of finger puncture should be examined by the health care practitioner. It may be evidence of poor technique, poor hygiene, or poor skin healing relative to poor control. Many types of blood-testing meters are available for home use. Newer technology has brought about improvements in meter size and ease of use. The family should be shown features of several meters, including advantages and disadvantages, and allowed to choose equipment that best meets their needs.

The least expensive testing method uses a reagent strip to which blood is applied (Fig. 46-5). After blotting, the color change is compared against a color scale for an estimation of the blood glucose level. The strips can be cut in half (although not all professionals recommend this) to obtain two readings per strip. This method is not accepted practice but may be necessary for some families or situations.

Urine Testing. Testing for urinary ketones is recommended during times of illness and when blood glucose values are elevated. Information on a specific ketone-testing product should include correct procedure, storage, and product expiration. Families need a clear understanding of home management of ketones (fluids and additional insulin as directed by the health care team).

Signs of Hyperglycemia. Severe hyperglycemia is most often caused by illness, growth, emotional upset, or missed insulin doses. Emotional stress from school finals or examinations and physical response to immunizations are examples of causes of hyperglycemia. With careful glucose monitoring, any elevation can be managed by adjustment of insulin or food intake. Parents should understand how to adjust food, activity, and insulin at the time of illness or when the child is treated for an illness with a medication known to raise the blood glucose level (e.g., steroids). The hyperglycemia is managed by increasing insulin soon after the increased glucose level is noted. Health care professionals should be aware that adolescent girls often become hyperglycemic around the time of their menses and should be advised to increase insulin dosages if necessary.

Signs of Hypoglycemia. Hypoglycemia is caused by imbalances of food intake, insulin, and activity. Ideally, hypoglycemia should be prevented, and parents need to be prepared to prevent, recognize, and treat the problem. They should be familiar with the signs of hypoglycemia and instructed in treatment, including care of the child with seizures. Early signs are adrenergic, including sweating and trembling, which help raise the blood glucose level, similar to the reaction when an individual is startled or anxious. The second set of symptoms that follow an untreated adrenergic reaction is neuroglycopenic (also called *brain hypoglycemia*). These symptoms typically include difficulty with balance, memory, attention, or concentration; dizziness or lightheadedness; and slurred speech. Severe and prolonged hypoglycemia leads to seizures, coma, and possible death (Cryer, 2008). Hypoglycemia can be managed effectively as outlined in the Emergency box.

It is advisable for parents to plan for anticipated excitement or exercise. In addition, gastroenteritis may decrease insulin needs slightly as a result of poor appetite, vomiting, or diarrhea. If the blood glucose level is low but urinary ketones are present, the family should be aware of the increased need for simple carbohydrates and liquids.

Hygiene. All aspects of personal hygiene should be emphasized for children with diabetes. Children should be cautioned against wearing shoes without socks, wearing sandals, and walking barefoot. Correct nail and extremity care tailored to the individual child (with the guidance of a podiatrist) can begin health practices that last a lifetime. These children's eyes should be checked once a year unless the child wears glasses and then as directed by the ophthalmologist. Regular dental care is emphasized, and cuts and scratches should be treated with plain soap and water unless otherwise indicated. Diaper rash in infants and candidal infections in teens may indicate poor diabetes control.

Exercise. Exercise is an important component of the treatment plan. If the child is more active at one time of the day than at another time, food or insulin can be altered to meet that activity pattern. Food should be increased in the summer, when children tend to be more active. Decreased activity on return to school may require a

EMERGENCY

Hypoglycemia

Mild Reaction—Adrenergic Symptoms
- Give child 10 to 15 g of a simple, high-carbohydrate substance (preferably liquid (e.g., 3-6 oz of orange juice).
- Follow with starch-protein snack.

Moderate Reaction—Neuroglycopenic Symptoms
- Give child 10 to 15 g of a simple carbohydrate as above.
- Repeat in 10 to 15 minutes if symptoms persist.
- Follow with larger snack.
- Watch child closely.

Severe Reaction—Unresponsive, Unconscious, or Seizures
- Administer glucagon as prescribed.
- Follow with planned meal or snack when child is able to eat or add a snack of 10% of daily calories.

Nocturnal Reaction
- Give child 10 to 15 g of a simple carbohydrate.
- Follow with snack of 10% of daily calories.

decrease in food intake or increase in insulin dosage. Children who are active in team sports will need a snack about a half-hour before the anticipated activity. Races or other competition may call for a slightly higher food intake than at practice times.

Food intake will usually need to be repeated for prolonged activity periods, often as frequently as every 45 minutes to 1 hour. Families should be informed that if increased food is not tolerated, decreased insulin is the next course of action. If the timing of the exercise is changed so that the supper meal is delayed, the insulin in the second or third dose of the day may be moved back to precede the mealtime. Sugar may sometimes be needed during exercise periods for quick response. Elevated blood glucose levels after extreme activity may represent the body's adrenergic response to exercise. If the blood glucose level is elevated (>240 mg/dL) before planned exercise, urinary ketones should be checked and the activity may need be postponed until the blood glucose is controlled.

NURSING ALERT

Ketonuria in the presence of hyperglycemia is an early sign of ketoacidosis and a contraindication to exercise.

Record Keeping. Home records are an invaluable aid to diabetes self-management. The nurse and family devise a method to chart insulin administered, blood glucose values, urine ketone results, and other factors and events that affect diabetes control. The child and family are encouraged to observe for patterns of blood glucose responses to events such as exercise. If lapses in management occur (e.g., eating a candy bar), the child should be encouraged to note this and not be criticized for the transgression.

Self-Management. Self-management is the key to close control. Being able to make changes when they are needed rather than waiting until the next contact with health care professionals is important for self-management and gives the individual and family the feeling that they have control over the disease. Psychologically, this helps family members believe they are useful and participating members of the team. Allowing the child to learn to look at records objectively promotes independence in self-management support. As children grow and assume more responsibility for self-management, they develop confidence in their ability to manage their disease and confidence in themselves as persons. They learn to respond to the disease and to make more accurate interpretations and changes in treatment when they become adults.

Puberty is associated with decreased sensitivity to insulin that normally would be compensated for by an increased insulin secretion. Health care professionals should anticipate that pubertal patients will have more difficulty maintaining glycemic control. Insulin doses commonly need to be increased, often dramatically (Tfayli and Arsianian, 2007). Patients should be taught to give themselves additional doses of rapid-acting insulin (5% to 10% of their daily dose) when their blood glucose levels are increased. The use of supplemental rapid-acting insulin is preferred to withholding food in adolescents.

Child or Adolescent and Family Support. Just as the physiologic responses affect the child, the parents and other family members of the child with newly diagnosed DM experience various emotional responses to the crisis. Care in the acute setting is short but may create fears and frustrations. The prospect of a chronic illness in their child engenders all the feelings and concerns that are faced by parents of children with other chronic illnesses (see Chapter 36). The threat of complications and death is always present, as well as the continuing drain on emotional and financial resources.

Certain fears may develop as a result of past experiences with the disease. A severe insulin reaction with seizures can contribute to fear of repetition. If parents observe a seizure or the adolescent has one in a public place, the desire to maintain better control is reinforced. They must understand how to prevent problems and how to handle problems calmly and coolly if they occur, and they must understand the complexities of the body, the disease, and its complications. Young children usually adjust well to problems related to the disease. With toddlers and preschoolers, insulin injections and glucose testing may be difficult at first. However, they usually accept the procedures when the parents use a matter-of-fact approach, without calling attention to a "hurt," and treat the procedure like any other routine part of the child's life. After the injection, time with some special and positive attention, such as reading, talking, or another pleasant activity, is one way to convert children who initially refuse injections to those who accept them.

In the years before adolescence, children probably accept their condition most easily. They are able to understand the basic concepts related to their disease and its treatment. They are able to test blood glucose and urine, recognize food groups, give injections, keep records, and distinguish fear or excitement from hypoglycemia. They understand how to recognize, prevent, and treat hypoglycemia. However, they still need considerable parental involvement.

NURSING ALERT

Ongoing motivation to adhere to a regimen is difficult. An older child and parent (or another caregiver) may enjoy negotiating a day off when the responsibility for testing and recording blood glucose is delegated from the child to the caregiver (or vice versa).

Adolescents appear to have the most difficulty adjusting. Adolescence is a time of stress in trying to be perfect and similar to one's peers, and no matter what others say, having diabetes is being different. Some adolescents are more upset about not being able to have a candy bar than about injections, diet, and other aspects of management. If children can accept the difference as a part of life—in other words, that each person is different in some way—then, with adequate parental support, they should be able to adjust well (see Critical Thinking Case Study).

Camping and other special group activities are useful. At diabetes camp, children learn that they are not alone. As a result, they become more independent and resourceful in other settings. Useful information about such camps and organizations can be obtained from the American Diabetes Association. A list of accredited camps specifically for children and teenagers with diabetes is also available from the American Camping Association.*

CRITICAL THINKING CASE STUDY

Type 1 Diabetes Mellitus

Shelly, a 14-year-old adolescent with a 3-year history of type 1 DM, has been admitted to the pediatric intensive care unit for treatment of DKA. This is her fifth hospital admission for DKA in the past year. Rebecca's parents are divorced, and she has four younger siblings, none of whom has diabetes. Shelly's mother has maintained two jobs for the past 5 years and frequently leaves Shelly in charge of the household. In anticipation of her discharge, you are planning a patient education program for Shelly and her mother. What important issues regarding Shelly's unstable diabetes management must you consider to plan the education program?

1. Evidence—Is there sufficient evidence to draw conclusions about Shelly's recurrent episodes of DKA?
2. Assumptions—Describe an underlying assumption about each of the following:
   a. Type 1 DM in adolescence
   b. Type 1 DM and menses
   c. Emotional stress and elevated blood glucose levels
   d. Blood glucose monitoring for insulin management
3. What priorities for nursing care should be established for Shelly?
4. Does the evidence support your nursing intervention?

DKA, Diabetic ketoacidosis; *DM,* diabetes mellitus.

KEY POINTS

- The endocrine system has three components: the cells, which send chemical messages via hormones; target cells, which receive the messages; and the environment through which the chemicals are transported from the sites of synthesis to the sites of cellular action.
- Pituitary dysfunction is manifested primarily by growth disturbance.
- The main physiologic action of TH is to regulate the basal metabolic rate and control the processes of growth and tissue differentiation.
- Disorders of thyroid function include hypothyroidism, autoimmune thyroiditis, goiter, and hyperthyroidism.
- Therapy for hyperthyroidism is directed at slowing the rate of hormone secretion and may include drug therapy, thyroidectomy, or radioiodine therapy.
- Classic forms of hypoparathyroidism in childhood are idiopathic (deficient production of PTH) and pseudohypoparathyroidism (increased PTH production with end-organ unresponsiveness to PTH).
- The adrenal cortex secretes three important groups of hormones: glucocorticoids, mineralocorticoids, and sex steroids.
- Disorders of adrenal function include acute adrenocortical insufficiency, chronic adrenocortical insufficiency, Cushing syndrome, and CAH.
- Five categories of Cushing syndrome are pituitary, adrenal, ectopic, iatrogenic, and food dependent.
- Management of CAH includes assignment of a gender according to genotype; administration of cortisone; and, possibly, reconstructive surgery.
- DM is categorized as type 1 diabetes and type 2 diabetes.
- The focus of type 1 DM is insulin replacement, diet, and exercise.
- Education of families includes explanation of diabetes, meal planning, administering insulin injections, monitoring general hygienic practices, promoting exercise, record keeping, and observing for complications.

CHAPTER

47

Integumentary Dysfunction

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe the distribution and configuration of various skin lesions.
- List the benefits of a moist environment for wound healing.
- Discuss the nursing care related to therapies for skin disorders.
- Contrast the manifestations of and therapies for bacterial, viral, and fungal infections of the skin.
- Compare the skin manifestations related to age in children.
- Outline a care plan to prevent and treat diaper dermatitis.
- Outline a care plan for a child with atopic dermatitis.
- Formulate a teaching plan for an adolescent with acne.
- Describe the methods for assessing a burn wound.
- Discuss the physical and emotional care of a child with a severe burn wound.

INTEGUMENTARY DYSFUNCTION

Skin Lesions

Lesions of the skin result from a variety of etiologic factors. Skin lesions originate from (1) contact with injurious agents (infective organisms, toxic chemicals, and physical trauma), (2) hereditary factors, (3) external factors (e.g., allergens), or (4) systemic diseases (e.g., measles, lupus erythematosus, nutritional deficiency diseases). Responses to these agents or factors are highly individualized. An agent that is harmless to one individual may be damaging to another, and a single agent may produce varying degrees of response.

An important factor in the etiology of skin manifestations is the child's age. Infants are subject to "birthmark" malformations and atopic dermatitis (AD) that appear early in life, school-age children are susceptible to ringworm of the scalp, and acne is a characteristic skin disorder of puberty. Contact dermatitis, such as poison ivy, is seen only when the noxious agent is found in the environment. Tension and anxiety may produce, modify, or prolong skin conditions.

Skin of Younger Children

The major skin layers arise from different embryologic origins. Early in the embryonic period, a single layer of epithelium forms from the ectoderm and simultaneously the corium develops from the mesenchyme. In infants and small children, the epidermis is loosely bound to the dermis. This poor adherence causes the layers to separate easily during an inflammatory process to form blisters. This is especially true in preterm infants, who have a propensity to blister formation and separation of the skin with minor trauma such as the removal of adhesive tape. In contrast, the skin of older children is thinner than that of younger children, and the cells of all the strata are more compressed.

Pathophysiology of Dermatitis

More than half of the dermatologic problems in children are forms of dermatitis. This implies a sequence of inflammatory changes in the skin that are grossly and microscopically similar but diverse in course and causation. Acute responses produce intercellular and intracellular edema, the formation of intradermal vesicles, and an initial infiltration of inflammatory cells into the epidermis. In the dermis, there is edema, vascular dilation, and early perivascular cellular infiltration. The location and manner of these reactions produce the lesions characteristic of each disorder. The changes are usually reversible, and the skin ordinarily recovers without blemish unless complicating factors such as ulceration from the primary irritant, scratching, and infection are introduced or underlying vascular disease develops. In chronic conditions, permanent effects are seen that vary according to the disorder, the general condition of the affected individual, and the available therapy.

Diagnostic Evaluation

Although the history and subjective symptoms of skin lesions are explored first, the obvious objective characteristics of the lesions are often noted simultaneously. Many skin lesions are easily diagnosed after careful inspection.

History and Subjective Symptoms. Many cutaneous lesions are associated with local symptoms. The most common local symptom is itching (pruritus), which varies in intensity. Pain or tenderness often accompanies some skin lesions. Other skin sensations such as burning, prickling, stinging, or crawling are also described. Alterations in local feeling include absence of sensation (anesthesia); excessive sensitiveness (hyperesthesia); diminished sensation (hypesthesia or hypoesthesia); or abnormal sensation, such as burning or prickling (paresthesia). These symptoms may remain localized or migrate; may be constant or intermittent; and may be aggravated by a specific activity, such as exposure to sunlight.

It is important to determine whether the child has an allergic condition such as asthma or hay fever or history of a previous skin disease. AD, often associated with allergies, frequently begins in infancy. Important questions for the parent include when the lesion or symptom first appeared; whether it occurred with ingestion of a food or other substance, including any medication; and whether the condition was related to activity such as contact with plants, insects, or chemicals.

Objective Findings. The distribution, size, morphology, and arrangement of skin lesions provide significant information. Extrinsic causes usually result from physical, chemical, or allergic irritants or from an infectious agent such as bacteria, fungi, viruses, or animal parasites. Skin manifestations are also produced by intrinsic causes such as an infection (measles or chickenpox), drug sensitization, or other allergic phenomenon.

Types of Lesions. Skin lesions assume distinct characteristics that are related to the pathologic process. Nurses should become familiar with the common terms that are applied to skin lesions because these terms are used in the processes of record keeping and communication. These terms include:

- Erythema—A reddened area caused by increased amounts of oxygenated blood in the dermal vasculature
- Ecchymoses (bruises)—Localized red or purple discolorations caused by extravasation of blood into dermis and subcutaneous tissues
- Petechiae—Pinpoint, tiny, and sharp circumscribed spots in the superficial layers of the epidermis
- Primary lesions—Skin changes produced by a causative factor; common primary lesions in pediatric skin disorders are macules, papules, and vesicles
- Secondary lesions—Changes that result from alteration in the primary lesions, such as those caused by rubbing, scratching, medication, or involution and healing
- Distribution pattern—The pattern in which lesions are distributed over the body, whether local or generalized, and the specific areas associated with the lesions
- Configuration and arrangement—The size, shape, and arrangement of a lesion or groups of lesions (e.g., discrete, clustered, diffuse, or confluent)

Laboratory Studies. If a skin problem is related to a systemic disease (e.g., collagen or immunodeficiency disease), laboratory studies are performed to identify these conditions. Diagnostic techniques include microscopic examination, cultures, skin scrapings or biopsy, cytodiagnosis, patch testing, **Wood light** examination, allergic skin testing, and other laboratory tests such as blood count and sedimentation rate.

Wounds

Wounds are structural or physiologic disruptions of the skin that activate normal or abnormal tissue repair responses. Wounds are classified as acute or chronic. Acute wounds are those that heal uneventfully within 2 to 3 weeks. Chronic wounds are those that do not heal in the expected time frame or are associated with complications. Cofactors that disrupt or delay wound healing include compromised perfusion, malnutrition, and infection. In children, most wounds are acute and can be prevented from becoming chronic wounds through appropriate nursing care. Wounds are also classified as surgical and nonsurgical and then further classified in the same manner as burns: superficial, partial thickness, or full thickness (complex wounds that include muscle or bone).

Factors That Influence Healing

Wound care management has shifted from interventions aimed at maintaining a dry environment to those that promote a moist, crust-free environment that enhances the migration of epithelial cells across the wound and facilitates remodeling. Whereas an acute full-thickness wound kept in a moist environment usually reepithelializes in 12 to 15 days, the same wound when kept open to the air heals in about 25 to 30 days.

Numerous factors can delay healing (Table 47-1). For example, traditional practices, such as the use of antiseptics (hydrogen peroxide and povidone-iodine [Betadine] solutions), which were once thought to prevent infection, are now known to have a cytotoxic effect on healthy cells and minimal effect on controlling infections. Povidone-iodine may also be absorbed through the skin in neonates and young children.

General Therapeutic Management

Some skin disorders demand aggressive therapy, but by and large, the major aim of treatment is to prevent further damage, eliminate the cause, prevent complications, and provide relief from discomfort while tissues undergo healing (McCord and Levy, 2006). Factors that contribute to the development of dermatitis and that prolong the course of the disease should be eliminated when possible. The most common causative agents of dermatitis in infants, children, and adolescents are environmental factors (e.g., soaps, bubble baths, shampoos, rough or tight clothing, wet diapers, blankets, and toys) and the natural elements (e.g., dirt, sand, heat, cold, moisture, and wind). Dermatitis may also result from home remedies and medications.

Dressings

No one dressing meets the needs of all wounds. The traditional dry gauze dressing should not be used on open wounds because it allows the wound surface to dry, does little to prevent bacterial invasion, and adheres to the dried scab so that removal disturbs the newly regenerating epithelial cells. In most instances, traditional gauze dressings have been replaced by dressings that promote moist wound healing. Moist wound healing increases the rate of collagen synthesis and reepithelialization and decreases pain and inflammation. It also creates an environment for autolytic débridement of necrotic tissue, which creates a clean wound bed and enhances granulation. However, a balance must be achieved between creating a moist wound bed and maintaining a dry periwound area that protects the skin and wound from maceration. The dressing type and frequency of dressing changes help achieve this balance. The frequency of dressing changes is based on the presence of infection, the type of dressing, the location of the wound, and the amount of drainage. Dressings should always be changed when they are loose or soiled.

TABLE 47-1 FACTORS THAT DELAY WOUND HEALING

FACTOR	EFFECT ON HEALING
Dry wound environment	Allows epithelial cells to dry out and die; impairs migration of epithelial cells across wound surface
Nutritional deficiencies	
Vitamin A	Results in inadequate inflammatory response
Vitamin B_1	Results in decreased collagen formation
Vitamin C	Inhibits formation of collagen fibers and capillary development
Protein	Reduces supply of amino acids for tissue repair
Zinc	Impairs epithelialization
Immunocompromise	Results in inadequate or delayed inflammatory response
Impaired circulation	Inhibits inflammatory response and removal of debris from wound area Reduces supply of nutrients to wound area
Stress (pain, poor sleep)	Releases catecholamines that cause vasoconstriction
Antiseptics	
Hydrogen peroxide	Toxic to fibroblasts; can cause subcutaneous gas formation (mimics gas-forming infection)
Povidone-iodine	Toxic to white and red blood cells and fibroblasts
Chlorhexidine	Toxic to white blood cells
Medications	
Corticosteroids	Impair phagocytosis Inhibit fibroblast proliferation Depress formation of granulation tissue Inhibit wound contraction
Chemotherapy	Interrupts the cell cycle; damages DNA or prevents DNA repair
Antiinflammatory drugs	Decrease the inflammatory phase
Foreign bodies	Increase inflammatory response Inhibit wound closure
Infection	Increases inflammatory response Increases tissue destruction
Mechanical friction	Damages or destroys granulation tissue
Fluid accumulation	Accumulation in area inhibits tissues from approximating
Radiation	Inhibits fibroblastic activity and capillary formation May cause tissue necrosis
Diseases	
Diabetes mellitus	Inhibits collagen synthesis Impairs circulation and capillary growth Hyperglycemia impairs phagocytosis
Anemia	Reduces oxygen supply to tissues
Peripheral vascular disease	Reduces oxygen supply to wounds
Uremia	Decreases collagen and granulation tissue

They should be changed more frequently in areas where contamination is likely (e.g., the sacral area, the buttocks, the tracheal area) or when wound infection is suspected or present.

Topical Therapy

Several agents and methods are available for treatment. In selecting a therapeutic regimen, the practitioner considers (1) the choice of active ingredient, (2) the proper vehicle or base, (3) the cosmetic effect, (4) the cost, and (5) instructions for use. Several basic concepts must also be considered. Overtreatment is avoided. For example, when dermatitis is acute, topical applications should be mild and bland to avoid further irritation. Broken or inflamed skin, especially in children, is more absorbent than intact skin, and chemicals that are nonirritating to intact skin may be quite irritating to inflamed skin.

Topical applications may be applied to treat the disorder, reduce itching, decrease external stimuli, or apply external heat or cold. The emollient action of soaks, baths, and lotions provides a soothing film over the skin surface that reduces external stimuli. Ordinarily, lukewarm or cool applications offer the greatest relief.

! NURSING ALERT

Application of heat tends to aggravate most conditions, and its use is usually reserved for reducing specific inflammatory processes, such as folliculitis and cellulitis.

Ointments in a petrolatum base provide protection from moisture. Therefore this type of ointment is indicated around gastrostomy tubes, in skinfolds, and in the diaper area. Creams are absorbed by the skin and are used for areas where a nongreasy "feel" is desired (e.g., face, hands).

Topical Corticosteroid Therapy. Glucocorticoids are the therapeutic agents used most frequently for skin disorders. Their local antiinflammatory effects are merely palliative, so the medication must be applied until the condition undergoes a remission or the causative agent is eliminated. Corticosteroids are applied directly to the affected area, are essentially nonsensitizing, and have only minor side effects. As with the use of any steroids, their use in large amounts may mask signs of infection and symptoms may be exacerbated after termination of the drug. Families are cautioned that the medication cannot be used for all skin disorders. The concentrations available without prescription are not adequate for stubborn skin conditions (e.g., psoriasis) and may further aggravate inflammation caused by fungi or bacteria. Most parents and children apply too much topical hydrocortisone; therefore they should be counseled that it is both effective and economical to apply only a thin film and to massage it into the skin. Parents and children should also be advised to use the application for no more than 5 to 7 days because these agents may cause depigmentation and other changes in the skin.

Other Topical Therapies. Other topical treatments include chemical cautery (especially useful for warts), cryosurgery, electrodesiccation (chiefly used for warts, granulomas, and nevi), ultraviolet (UV) therapy (primarily used in psoriasis and acne), laser therapy (especially for birthmarks), and acne therapies such as dermabrasion and chemical peels. New drugs called topical immunomodulators are effective in reducing the itching of AD (eczema) and preventing the recurrence of "flares."

Systemic Therapy. Systemic drugs may be used as an adjunct to topical therapy in some dermatologic disorders. The drugs most frequently used are corticosteroids, antibiotics, and antifungal

agents. Corticosteroids are valuable because of their capacity to inhibit inflammatory and allergic reactions. The dosage is carefully adjusted and gradually tapered to the minimum dosage that is effective and tolerated. In infants and children, the dosage is larger than is usually calculated from body weight ratios. However, prolonged use may temporarily suppress growth.

Antibiotics are used in severe or widespread skin infections. However, because these drugs tend to produce hypersensitivity in some patients, they are used with caution. Antifungal agents are the only means for treating systemic fungal infections.

CARE MANAGEMENT

The child's subjective symptoms and the parent's history provide valuable information to help establish a diagnosis. Older children often describe the condition as painful, itching, or tingling or in other descriptive terms. However, much can be determined by also observing the younger child's behavior. Does the child scratch? Is the child restless or irritable? Does the child favor or avoid using a body part? A careful history provides important clues. Has the child had access to chemicals or been in the woods or around a woodpile? Has the child eaten a new food? Is the child taking medication? Has the child any known allergy? Do siblings or playmates have similar lesions? What soap or bubble bath is used for bathing?

It is important for nurses to not only describe but also assess skin lesions and wounds. The color, shape, and distribution of lesions and wounds are important. Individual lesions are described according to standard terminology. Sometimes two descriptors are used for a particular characteristic (e.g., maculopapular rash). To confirm or amplify the findings made by inspection, the nurse may gently palpate the skin to detect characteristics such as temperature, moisture, texture, elasticity, and edema. Wounds are assessed for depth of tissue damage, evidence of healing, and signs of infection.

! NURSING ALERT

Signs of wound infection are:

- Increased erythema, especially beyond the wound margin
- Edema
- Purulent exudate
- Pain
- Increased temperature

The frequency of wound assessment depends on the severity and complexity of the wound. For example, simple or chronic wounds are assessed weekly; infected or complex wounds are assessed daily. Wounds are measured at least weekly (height, width, and depth). The wound bed is assessed for color, drainage, odor, necrosis, granulation tissue, fibrin slough, undermining and condition of the wound edges, and the color and condition of the surrounding skin (Butler, 2007).

Therapeutic programs are designed to include general measures such as rest, protection, and relief of discomfort and specific treatments such as medication and physical techniques. Only a few skin diseases are contagious; therefore it is usually not necessary to isolate the affected child except from persons in danger of acquiring a secondary infection (e.g., a child receiving large doses of corticosteroids or other immunosuppressant drugs or a child with an immunologic deficiency disorder). However, if the skin manifestation is caused by a viral **exanthema,** such as measles or chickenpox, the child is prevented from exposing other susceptible children.

Wound Care

Parents can generally manage small skin lesions or wounds at home. The parents are instructed to wash their hands and then wash the wound gently with mild soap and water or normal saline. They are cautioned to avoid povidone-iodine, alcohol, and hydrogen peroxide because these products are toxic to wounds.

! NURSING ALERT

Do not put anything in a wound that you would not put in the eye. The safest solution is normal saline.

Open wounds are covered with a dressing, such as a commercial adhesive bandage, although larger wounds may benefit from the use of occlusive dressings. If occlusive dressings are applied, parents should learn how to apply and remove the dressings correctly. For example, hydrocolloid dressings adhere best if a wide margin is left around the wound and the dressing is pressed against intact skin until it adheres. If a dressing needs to be secured, a nonalcohol skin barrier can be applied to protect the skin or the wound can be "picture framed" with hydrocolloid dressing and dressing tape can be secured to the hydrocolloid. This method of securing the dressing protects the skin when the tape is removed. Montgomery straps or stretch netting can also be used to secure dressings and to avoid the use of tape.

! NURSING ALERT

Advise parents that the yellow gel forming under hydrocolloid dressings may look like pus and has a distinct odor (somewhat fruity) but is normal leakage.

Dressings are removed carefully to protect intact skin and the epithelial surface of the wound. When removing transparent or hydrocolloid dressings, the nurse or parent should raise one edge of the dressing and pull *parallel* to the skin to loosen the adhesive. The longer the dressings are left on, the easier they are to remove. Less frequent dressing changes decrease wound contamination.

Lacerations present a special challenge. The injured child and family are usually distressed by the bleeding. In particular, scalp lacerations tend to bleed profusely. Parental guilt and shock usually accompany the injury. The initial nursing intervention is to apply pressure to the area and to attempt to calm the child before further examination. Unless there is bleeding from a severed artery, the wound is cleansed with a forced jet of sterile tepid water or saline (via syringe) and examined for extent, depth, and presence of foreign material such as dirt, glass, or fabric fragments.

The location of the wound facilitates assessment. Wounds over bony areas may contain bone chips, and clear fluid seeping from severe head wounds may indicate cerebrospinal fluid. A pressure dressing is applied for transfer to medical care. After the child is in a medical facility, he or she is prepared for suturing.

Puncture wounds that do not require a tetanus booster are soaked in warm water and soap for several minutes. Causing the wound to rebleed may be helpful. An adhesive bandage can be applied if desired. Puncture wounds of the head, chest, or abdomen or those that could still contain a portion of the puncturing object must be evaluated carefully.

Parents are cautioned against opening blisters or kissing a wound "to make it better." The wound can easily become contaminated from germs in the human mouth. If scabs form, they are allowed to slough off without assistance; picking or early removal may cause

scarring and secondary infection. Parents are advised to seek medical help if there is evidence of infection.

Relief of Symptoms

Most therapeutic regimens for skin lesions are directed toward relief of pruritus, the most common subjective complaint. Cooling the affected area and increasing the skin pH with cool baths or compresses and alkaline applications (e.g., baking soda baths) help reduce the itching. Clothing and bed linens should be soft and lightweight to decrease the irritation from friction and stimulation.

During treatment, both the affected and unaffected skin are protected from damage and secondary infection. Preventing scratching is important. Older children can cooperate, although they may need to be reminded to stop scratching or rubbing. However, small or uncooperative children may require the use of devices such as mittens (especially during sleep) or special coverings. Keeping fingernails clean, short, and trimmed reduces the risk for secondary infection.

Antipruritic medications, such as diphenhydramine (Benadryl) or hydroxyzine (Atarax), may be prescribed for severe itching, especially if it disturbs the child's rest. Pain and discomfort are usually managed with nonpharmacologic measures and mild analgesia. Severe pain requires more potent medication. Occlusive dressings over wounds reduce pain. For suturing wounds, a topical anesthetic or intradermal buffered lidocaine should be used (see Pain Management, Chapter 30).

Topical Therapy

The specific type of topical therapy and the mode of application depend on the nature and location of the lesion. It is especially important to wash the hands before and after application of any topical therapy. The skin is assessed before the application and reassessed after treatment. Any observed changes are noted and described.

Wet compresses or dressings cool the skin by evaporation, relieve itching and inflammation, and cleanse the area by loosening and removing crusts and debris. A variety of ingredients, such as plain water or Burow solution (available without a prescription), can be applied on Kerlix gauze; plain gauze; or (preferably) soft cotton cloths such as freshly laundered handkerchiefs or strips from diaper, sheeting, or pillowcase material.

Dressings immersed in the desired solution are wrung out slightly and applied to the affected area wet but not dripping. They are applied flat and smooth in such a way that motion is not totally restricted—fingers are wrapped separately, and arms and legs are wrapped so that elbows and knees can bend. Dressings are held in place by Kerlix or other cotton wrap, tubular stockinette, mittens, and socks (two pairs—one to hold the dressings in place and the other to protect from movement). When evaporation begins to dry them, the dressings are removed, rewet in the solution, and reapplied using aseptic technique. The solution is *not* poured or applied with a syringe directly over the dressings. As fluid evaporates, the solution becomes more concentrated, and this could damage sensitive lesions.

Fresh solution at room temperature is applied at 2-, 3-, or 4-hour intervals and allowed to remain on the lesion for 20 to 90 minutes. Wet dressings are seldom continued after about 48 hours. The child is protected against chilling during treatment, and no more than 20% of the body is covered with a dressing at one time to avoid the risk for hypothermia. After treatment, the skin is dried thoroughly by patting with a towel. Lotion or other medication (if prescribed) is applied at this time.

When children are uncooperative in the use of wet dressings, soaks are often used for removal of crusts and for their mild astringent action. The same solutions are used as for wet compresses. Gaining young children's cooperation for hand or foot soaks is difficult unless the procedure is accompanied by play. Older infants and toddlers delight in playing with brightly colored objects or poker chips scattered over the bottom of the receptacle, and preschoolers can be challenged to hold a floating item beneath the water's surface. However, these activities require supervision; infants and small children place items in their mouths, and children easily lose control with water play. Washing dishes, cars, dolls, or doll clothes will also occupy time during soaks.

Although older children can cooperate, they, too, need something to do during the procedure, such as listening to music or a story or watching television. Placing the solution and the extremity in a plastic sealable bag is an effective method to soak a hand or foot.

Baths are useful in the treatment of widespread dermatitis by evenly distributing the soothing antipruritic and antiinflammatory effects of the solution, usually oatmeal or mineral oil preparations. The solution is added to a tub of lukewarm water. The temperature of the bath is tepid, and the treatment usually lasts 15 to 30 minutes. Therapeutic baths are more interesting when toy boats or other items for water play accompany the procedure.

Topical applications are applied to skin lesions to ease discomfort, prevent further injury, and facilitate healing. A thin application of the ointment or cream may be covered with a plastic film and anchored with adhesive, covered with a commercial transparent dressing, or wrapped in Kerlix gauze and held in place by a stretchy net dressing. Topical preparations are applied systematically with the contour of the body surface (not simply up and down). Children love to be "painted," and lotion applications can be fun when an ordinary paintbrush is used. Regardless of the type of preparation used, parents need detailed information on how to apply it and how long the preparation should remain on the skin.

! NURSING ALERT

Provide written instructions and demonstrate to parents the correct amount of topical medication to apply (e.g., size of a pea, thin film to cover). If more than one preparation is applied, mark the containers with numbers so the parents remember the correct order of application. Stress that more is not necessarily better with some medications, such as steroids.

Home Care and Family Support

Dermatologic conditions always involve the family, but few situations require hospitalization and most care is delivered at home. Because the family members must carry out the treatment plan, their cooperation is essential. Regimens that are simple to accomplish in the clinic, hospital, or primary care provider's office may be frustrating and baffling at home. The family may also need assistance in adapting equipment available for home therapy.

It is important that the child and family be given as detailed explanations as possible about both the expected and unexpected results of treatment, including any ill effects that might occur. If unexplained reactions develop, the family is directed to discontinue treatment and report the reactions to the appropriate person. The use of over-the-counter medicines is discouraged unless the preparations have been discussed with and approved by the health care provider.

Because the skin is the most visible portion of the body, defects in its surface alter its appearance and distress the child. Skin

problems may also result in rejection by others. Parents of other children may fear that their children will "catch" the disorder. Occasionally, the affected child's own family members reduce their interaction or physical contact with the child. This is seldom a problem with dermatitis of short duration, but chronic conditions can frequently create problems and affect the child's self-esteem.

INFECTIONS OF THE SKIN

Bacterial Infections

Normally, the skin harbors a variety of bacterial flora, including the major pathogenic varieties of staphylococci and streptococci. The degree of pathogenicity of the organism depends on its invasiveness and toxicity, the integrity of the skin, and the immune and cellular defenses of the host. Children with congenital or acquired immunodeficiency disorders (e.g., acquired immunodeficiency syndrome [AIDS]), those in a debilitated condition, those receiving immunosuppressant therapy, and those with a generalized malignancy such as leukemia or lymphoma are at risk for developing bacterial infections.

Because of the characteristic "walling-off" process of the inflammatory reaction (abscess formation), staphylococci are more difficult to treat and the local infected area is associated with an increase in bacteria all over the skin surface that serves as a source of continuing infection. In previous years, methicillin-resistant *Staphylococcus aureus* (MRSA) infections were seen primarily in nursing homes and hospitals. In recent years, the number of MRSA community-acquired infections has risen (Kaplan, 2006). All of these factors underline the importance of careful hand washing and cleanliness when caring for infected children and their lesions to prevent the spread of infection and as an essential prophylactic measure when caring for infants and small children. Common bacterial skin disorders are outlined in Table 47-2.

CARE MANAGEMENT

The major nursing functions related to bacterial skin infections are to prevent the spread of infection and to prevent complications. Impetigo contagiosa and MRSA infection can easily spread by self-inoculation; therefore caution the child against touching the involved area. Hand washing is mandatory before and after contact with an affected child. Also emphasize hand washing to both the child and the family. Many children with AD are colonized with MRSA in the nares and under the fingernails (Rosenthal, 2004). For many bacterial infections and for MRSA infection in particular, the child should be provided with washcloths and towels separate from those of other family members. The child's pajamas, underwear, and other clothes should be changed daily and washed in hot water. Razors used for shaving should be discarded after each use and not shared. To prevent recurrence, some infectious disease specialists recommend bathing in a chlorine bath once or twice weekly. A 5-minute soak of 2.5 mL of bleach diluted in 13 gallons of water or ½ cup of bleach diluted in a standard 50-gallon tub one-fourth filled with water could decrease community-acquired MRSA colonies by more than 99.9% (Fisher, Chain, Hair, et al., 2008; Kaplan, 2008). In addition, mupirocin can be applied to the nares of patients and families twice daily for 2 to 4 weeks to prevent reinfection (Dohil and Eichenfield, 2005).

Children and parents are often tempted to squeeze follicular lesions. They must be warned that squeezing will not hasten the resolution of the infection and that there is a risk for making the lesion worse or spreading the infection. No attempt should be made to puncture the surface of the pustule with a needle or sharp instrument. A child with a sty may waken with the eyelids of the affected eye sealed shut with exudate. The child or the parents are instructed to gently wipe the eyelid from the inner to the outer edge with warm water and a clean washcloth until the exudate is removed.

The child with limited cellulitis of an extremity is usually managed at home on a regimen of oral antibiotics and warm compresses. The parents are taught the procedures and instructed in administration of the medication. Children with more extensive cellulitis, especially around a joint with lymphadenitis or on the face, are usually admitted to the hospital for parenteral antibiotics with continued treatment at home. Nurses are responsible for teaching the family to administer the medication and apply compresses.

Viral Infections

Viruses are intracellular parasites that produce their effect by using the intracellular substances of the host cells. Composed of only a DNA or ribonucleic acid (RNA) core enclosed in an antigenic protein shell, viruses are unable to provide for their own metabolic needs or to reproduce themselves. After a virus penetrates a cell of the host organism, it sheds the outer shell and disappears within the cell, where the nucleic acid core stimulates the host cell to form more virus material from its intracellular substance. In a viral infection, the epidermal cells react with inflammation and vesiculation (as in herpes simplex) or by proliferating to form growths (warts).

Many of the communicable viral diseases of childhood are associated with rashes, and each rash is characteristic. The type of lesion and the configuration of rubeola, rubella, and chickenpox are described in Table 33-2. Other common viral disorders of the skin are outlined in Table 47-3.

Dermatophytoses (Fungal Infections)

The dermatophytoses (ringworm) are infections caused by a group of closely related filamentous fungi that invade primarily the stratum corneum, hair, and nails. These are superficial infections that live on, not in, the skin. They are confined to the dead keratin layers and are unable to survive in the deeper layers. Because the keratin is desquamated constantly, the fungus must multiply at a rate that equals the rate of keratin production to maintain itself; otherwise, the infection would be shed with the discarded skin cells. Common dermatophytoses are outlined in Table 47-4.

Dermatophytoses are designated by the Latin word *tinea,* with further designation related to the area of the body where they are found (e.g., tinea capitis [ringworm of the scalp]). Dermatophyte infections are most often transmitted from one person to another or from infected animals to humans. Diagnosis is made from microscopic examination of scrapings taken from the advancing periphery of the lesion, which almost always produces a scale.

CARE MANAGEMENT

When teaching families how to care for ringworm, the nurse should emphasize good health and hygiene. Because of the infectious nature of the disease, affected children should not exchange grooming items, headgear, scarves, or other articles of apparel that have been in proximity to the infected area with other children. Affected children are provided with their own towels and directed to wear a protective cap at night to avoid transmitting the fungus to bedding, especially if they sleep with another person. Because the infection can be acquired by animal-to-human transmission, all household

TABLE 47-2 BACTERIAL INFECTIONS

DISORDER AND ORGANISM	MANIFESTATIONS	MANAGEMENT	COMMENTS
Impetigo contagiosa (Fig. 47-1)—*Staphylococcus*	Begins as a reddish macule Becomes vesicular Ruptures easily, leaving superficial, moist erosion Tends to spread peripherally in sharply marginated irregular outlines Exudate dries to form heavy, honey-colored crusts Pruritus common *Systemic effects*—Minimal or asymptomatic	Careful removal of undermined skin, crusts, and debris by softening with 1:20 Burow solution compresses Topical application of bactericidal ointment Systemic administration of oral or parenteral antibiotics (penicillin) in severe or extensive lesions	Tends to heal without scarring unless secondary infection Autoinoculable and contagious Common in toddlers and preschoolers May be superimposed on eczema
Pyoderma—*Staphylococcus, Streptococcus*	Deeper extension of infection into dermis Tissue reaction more severe *Systemic effects*—Fever, lymphangitis	Soap and water cleansing Wet compresses Bathing with antibacterial soap as prescribed Do not share washcloths or towels Mupirocin to nares and lesions as prescribed Systemic antibiotics	Autoinoculable and contagious May heal with or without scarring
Folliculitis (pimple), furuncle (boil), carbuncle (multiple boils)—*Staphylococcus aureus*	Folliculitis—Infection of hair follicle Furuncle—Larger lesion with more redness and swelling at a single follicle Carbuncle—More extensive lesion with widespread inflammation and "pointing" at several follicular orifices *Systemic effects*—Malaise if severe	Skin cleanliness Local warm, moist compresses Topical application of antibiotic agents Systemic antibiotics in severe cases Incision and drainage of severe lesions followed by wound irrigations with antibiotics or suitable drain implantation	Autoinoculable and contagious Furuncle and carbuncle tend to heal with scar formation Never squeeze a lesion
Cellulitis—*Streptococcus, Staphylococcus, Haemophilus influenzae* (Fig. 47-2)	Inflammation of skin and subcutaneous tissues with intense redness, swelling, and firm infiltration Lymphangitis "streaking" frequently seen Involvement of regional lymph nodes common May progress to abscess formation *Systemic effects*—Fever, malaise	Oral or parenteral antibiotics Rest and immobilization of both affected area and child Hot, moist compresses to area	Hospitalization may be necessary for child with systemic symptoms Otitis media may be associated with facial cellulitis
Staphylococcal scalded skin syndrome—*S. aureus*	Macular erythema with "sandpaper" texture of involved skin Epidermis becoming wrinkled (in ≤2 days), and large bullae appearing	Systemic administration of antibiotics Gentle cleansing with saline, Burow solution, or 0.25% silver nitrate compresses	Infants subject to fluid loss; impaired body temperature regulation; and secondary infection, such as pneumonia, cellulitis, and septicemia Heals without scarring

FIG 47-1 Impetigo contagiosa. (From Weston WL, Lane AT: *Color textbook of pediatric dermatology,* ed 4, St Louis, 2007, Mosby.)

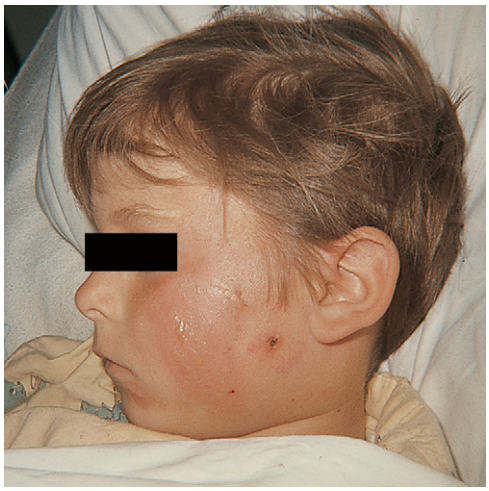

FIG 47-2 Cellulitis of cheek from a puncture wound. (From Weston WL, Lane AT: *Color textbook of pediatric dermatology,* ed 4, St Louis, 2007, Mosby.)

TABLE 47-3 VIRAL INFECTIONS

INFECTION	MANIFESTATIONS	MANAGEMENT	COMMENTS
Verruca (warts) *Cause*—Human papillomavirus (various types)	Usually well-circumscribed, gray or brown, elevated, firm papules with a roughened, finely papillomatous texture Occur anywhere but usually appear on exposed areas such as fingers, hands, face, and soles May be single or multiple Asymptomatic	Not uniformly successful Local destructive therapy, individualized according to location, type, and number—surgical removal, electrocautery, curettage, cryotherapy (liquid nitrogen), caustic solutions (lactic acid and salicylic acid in flexible collodion, retinoic acid, salicylic acid plasters), x-ray treatment, laser	Common in children Tend to disappear spontaneously Course unpredictable Most destructive techniques tend to leave scars Autoinoculable Repeated irritation will cause to enlarge Apply topical anesthetic *EMLA*
Verruca plantaris (plantar wart)	Located on plantar surface of feet and, because of pressure, are practically flat; may be surrounded by a collar of hyperkeratosis	Apply caustic solution to wart and wear foam insole with hole cut to relieve pressure on wart; soak 20 minutes after 2-3 days; repeat until wart comes out	Destructive techniques tend to leave scars, which may cause problems with walking Apply topical anesthetic *EMLA*
Herpes simplex virus Type I (cold sore, fever blister) Type II (genital)	Grouped, burning, and itching vesicles on inflammatory base, usually on or near mucocutaneous junctions (lips, nose, genitalia, buttocks) Vesicles dry, forming a crust followed by exfoliation and spontaneous healing in 8-10 days May be accompanied by regional lymphadenopathy	Avoidance of secondary infection Burow solution compresses during weeping stages Topical therapy (penciclovir) to shorten duration of cold sores Oral antiviral (acyclovir) for initial infection or to reduce severity in recurrence Valacyclovir (Valtrex), an oral antiviral, used for episodic treatment of recurrent genital herpes; reduces pain, stops viral shedding, and has a more convenient administration schedule than acyclovir	Heal without scarring unless secondary infection Type I cold sores prevented by using sunscreens protecting against UVA and UVB light to prevent lip blisters Aggravated by corticosteroids Positive psychologic effect from treatment May be fatal in children with depressed immunity
Varicella-zoster virus (herpes zoster; shingles)	Caused by same virus that causes varicella (chickenpox) Virus has affinity for posterior root ganglia, posterior horn of spinal cord, and skin; crops of vesicles usually confined to dermatome following along course of affected nerve Usually preceded by neuralgic pain, hyperesthesias, or itching May be accompanied by constitutional symptoms	Symptomatic Analgesics for pain Mild sedation sometimes helpful Local moist compresses Drying lotions sometimes helpful Ophthalmic variety: use systemic corticotropin (ACTH) or corticosteroids Acyclovir Lidocaine (Lidoderm) topical anesthetic	Pain in children usually minimal Postherpetic pain does not occur in children Chickenpox may follow exposure; isolate affected child from other children in a hospital or school May occur in children with depressed immunity; can be fatal
Molluscum contagiosum *Cause*—Pox virus Small, benign tumors	Flesh-colored papules with a central caseous plug (umbilicated) Usually asymptomatic	Cases in well children resolve spontaneously in about 18 months Treatment reserved for troublesome cases Apply topical anesthetic *EMLA* and remove with curette Use tretinoin gel 0.01% or cantharidin (Cantharone) liquid* Curettage or cryotherapy	Common in school-age children Spread by skin-to-skin contact, including autoinoculation and fomite-to-skin contact

ACTH, Adrenocorticotropic hormone; *EMLA,* eutectic mixture of lidocaine and prilocaine; *UVA,* ultraviolet A; *UVB,* ultraviolet B.
*Not available in the United States but can be purchased in Canada.

TABLE 47-4 DERMATOPHYTOSES (FUNGAL INFECTIONS)

DISEASE AND ORGANISM	MANIFESTATIONS	MANAGEMENT	COMMENTS
Tinea capitis—*Trichophyton tonsurans, Microsporum audouinii, Microsporum canis* (Fig. 47-3, *A*)	Lesions in scalp but may extend to hairline or neck Characteristic configuration of scaly, circumscribed patches or patchy, scaling areas of alopecia Generally asymptomatic but severe, deep inflammatory reaction may occur that manifests as boggy, encrusted lesions (kerions) Pruritic Microscopic examination of scales is diagnostic	Oral griseofulvin Oral ketoconazole for difficult cases Selenium sulfide shampoos Topical antifungal agents (e.g., clotrimazole, haloprogin, miconazole)	Person-to-person transmission Animal-to-person transmission Rarely, permanent loss of hair *M. audouinii* transmitted from one human being to another directly or from personal items; *M. canis* usually contracted from household pets, especially cats Atopic individuals more susceptible
Tinea corporis—*Trichophyton rubrum, Trichophyton mentagrophytes, M. canis, Epidermophyton* (see Fig. 47-3, *B*)	Generally round or oval, erythematous scaling patch that spreads peripherally and clears centrally; may involve nails (tinea unguium) *Diagnosis*—Direct microscopic examination of scales Usually unilateral	Oral griseofulvin Local application of antifungal preparation such as tolnaftate, haloprogin, miconazole, clotrimazole; apply 1 inch beyond periphery of lesion; continual application 1-2 weeks after no sign of lesion	Usually of animal origin from infected pets Majority of infections in children caused by *M. canis* and *M. audouinii*
Tinea cruris ("jock itch")—*Epidermophyton floccosum, T. rubrum, T. mentagrophytes*	Skin response similar to tinea corporis Localized to medial proximal aspect of thigh and crural fold; may involve scrotum in boys Pruritic *Diagnosis*—Same as for tinea corporis	Local application of tolnaftate liquid Wet compresses or sitz baths may be soothing	Rare in preadolescent children Health education regarding personal hygiene
Tinea pedis ("athlete's foot")—*T. rubrum, Trichophyton interdigitale, E. floccosum*	On intertriginous areas between toes or on plantar surface of feet Lesions vary: Maceration and fissuring between toes Patches with pinhead-size vesicles on plantar surface Pruritic *Diagnosis*—Direct microscopic examination of scrapings	Oral griseofulvin Local applications of tolnaftate liquid and antifungal powder containing tolnaftate Acute infections—Compresses or soaks followed by application of glucocorticoid cream Elimination of conditions of heat and perspiration by clean, light socks and well-ventilated shoes; avoidance of occlusive shoes	Most frequent in adolescents and adults; rare in children, but occurrence increases with wearing of plastic shoes Transmission to other individuals rare despite general opinion to contrary Ointments not successful
Candidiasis (moniliasis)—*Candida albicans*	Grows in chronically moist areas Inflamed areas with white exudate, peeling, and easy bleeding Pruritic *Diagnosis*—Characteristic appearance	Amphotericin B, nystatin ointment, or other antifungal preparations to affected areas	Common form of diaper dermatitis (see Fig. 47-8) Oral form common in infants Vaginal form in older girls May be disseminated in immunosuppressed children

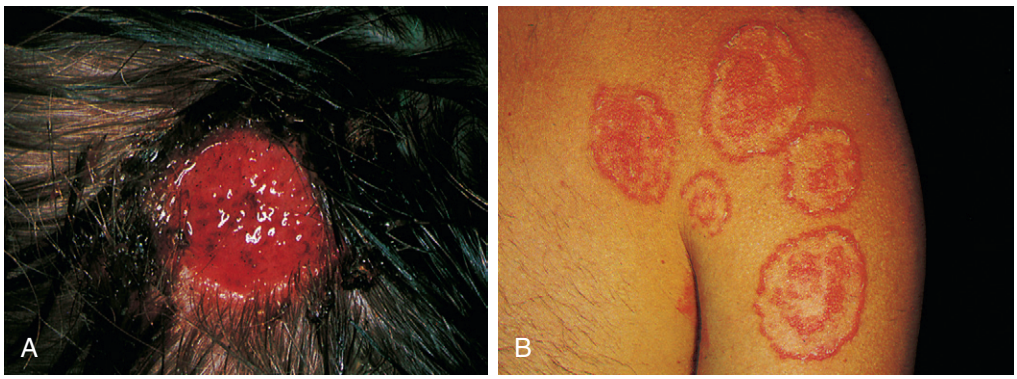

FIG 47-3 A, Tinea capitis. **B,** Tinea corporis. Both infections are caused by *Microsporum canis,* the "kitten" or "puppy" fungus. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 4, St Louis, 2004, Mosby.)

pets should be examined for the disorder. Other sources of infection are seats with headrests (theater seats), seats in public transportation vehicles, helmets, and gymnasium mats.

Both 2% ketoconazole and 1% selenium sulfide shampoos may reduce colony counts of dermatophytes. These shampoos can be used in combination with oral therapy to reduce the transmission of disease to others. The shampoo should be applied to the scalp for 5 to 10 minutes at least 3 times per week. The child may return to school after the therapy is initiated.

Alternately, if the child is treated with the drug *griseofulvin,* the therapy frequently continues for weeks or months, and because subjective symptoms subside, children or parents may be tempted to decrease or discontinue the drug. The nurse should emphasize to family members the importance of maintaining the prescribed dosage schedule and of taking the medication with high-fat foods for best absorption. They are also instructed regarding possible drug side effects, such as headache, gastrointestinal upset, fatigue, insomnia, and photosensitivity. For children who take the drug over many months, periodic testing is required to monitor for leukopenia and assess liver and renal function. Newer antifungal medications such as terbinafine, itraconazole, and fluconazole may be used when there are adverse reactions to griseofulvin. These drugs are being studied to determine their efficacy and safety in treating tinea capitis in children but are not approved by the U.S. Food and Drug Administration (FDA) for this indication.

Systemic Mycotic (Fungal) Infections

Mycotic (systemic or deep fungal) infections have the capacity to invade the viscera, as well as the skin. The most common infections are the lung diseases, which are usually acquired by inhalation of fungal spores. These fungi produce a variable spectrum of disease, and some are common in certain geographic areas. They are not transmitted from person to person but appear to reside in the soil, from which their spores are airborne. The cutaneous lesions caused by deep fungal infections are granulomatous and appear as ulcers, plaques, nodules, fungating masses, and abscesses. The course of deep fungal diseases is chronic with slow progression that favors sensitization (Table 47-5).

TABLE 47-5 SYSTEMIC MYCOSES

DISORDER AND ORGANISM	SKIN MANIFESTATIONS	SYSTEMIC MANIFESTATIONS	MANAGEMENT	COMMENTS
North American blastomycosis—*Blastomyces dermatitidis*	Chronic granulomatous lesions and microabscesses in any part of body Initial lesion is a papule; undergoes ulceration and peripheral spread	Pulmonary symptoms, such as cough, chest pain, weakness, and weight loss May have skeletal involvement, with bone destruction and formation of cutaneous abscesses	IV administration of amphotericin B	Usual portal of entry is lungs Source of infection unknown Noninfectious Pulmonary infections may be mild and self-limiting and require no treatment Progressive disease often fatal
Cryptococcosis—*Cryptococcus neoformans (Torula histolytica)*	Usually on face; acneiform, firm, nodular, painless eruption	CNS *manifestations*—Headache, dizziness, stiff neck, and signs of increased intracranial pressure Low-grade fever, mild cough, lung infiltration	IV amphotericin B; may be administered intrathecally for CNS involvement 5-Fluorocytosine for meningitis Excision and drainage of local lesions	Acquired by inhalation of dust but may enter through skin Prognosis serious Noninfectious Increased incidence in persons receiving corticosteroids with lymphoreticular malignancies or type 2 diabetes
Histoplasmosis—*Histoplasma capsulatum*	Not distinctive or uniform but most appear as punched-out or granulomatous ulcers	General systemic symptoms may include pallor, diarrhea, vomiting, irregular spiking temperature, hepatosplenomegaly, and pulmonary symptoms Any tissue of body may be involved with related symptoms	IV amphotericin B for severe cases Oral ketoconazole	Organism cultured from soil, especially where contaminated with fowl droppings Fungus enters through skin or mucous membranes of mouth and respiratory tract Endemic in Mississippi and Ohio River valleys Disseminated diseases most common in infants and children
Coccidioidomycosis (valley fever)—*Coccidioides immitis*	Erythema nodosum Erythema multiforme Erythematous maculopapular rash	Primary lung disease usually asymptomatic May be sign of acute febrile illness Disseminated disease is serious	IV amphotericin B IV miconazole (synthetic imidazole) Intraventricular miconazole plus oral ketoconazole for CNS involvement Surgical resection of persistent pulmonary cavities	Inhalation of aerospores from soil Endemic in southwestern United States Usually resolves spontaneously Increased incidence in dark-skinned races (Filipino, African-American, Mexican, Asian)

CNS, Central nervous system; *IV,* intravenous.

SKIN DISORDERS RELATED TO CHEMICAL OR PHYSICAL CONTACTS

Contact Dermatitis

Contact dermatitis is an inflammatory reaction of the skin to chemical substances, natural or synthetic, that evoke a hypersensitivity response or direct irritation. The initial reaction occurs in an exposed region, most commonly the face and neck, backs of the hands, forearms, male genitalia, and lower legs. Early in the reaction, there is usually a sharp delineation between inflamed and normal skin that ranges from a faint, transient erythema to massive bullae on an erythematous swollen base. Itching is a constant symptom.

The cause may be a primary irritant or a sensitizing agent. A primary irritant is one that irritates any skin. A sensitizing agent produces an irritation on those individuals who have met the irritant or something chemically related to it, have undergone an immunologic change, and have become sensitized. Prior exposure is not necessarily a factor in the reaction. A sensitizer irritates in relatively low concentrations only persons who are allergic to it.

In infants, contact dermatitis occurs on the convex surfaces of the diaper area (see Diaper Dermatitis, p. 1511). Other agents that produce contact dermatitis include plants (poison ivy, oak, and sumac), animal irritants (wool, feathers, and furs), metal (nickel found in jewelry and the snaps on sleepers and denim), vegetable irritants (oleoresins, oils, and turpentine), synthetic fabrics (e.g., shoe components), dyes, cosmetics, perfumes, and soaps (including bubble baths). The list is endless.

The major goal in treatment is to prevent further exposure of the skin to the offending substance. Provided there is no further irritation, the skin's normal recuperative powers will often produce healing without treatment. Otherwise, treatment of contact dermatitis is based on severity. Mild cases are treated with topical steroids. Mild to moderately severe cases may require a 2-week course of strong topical corticosteroids. Very severe cases require systemic corticosteroids.

CARE MANAGEMENT

Nurses frequently detect evidence of contact dermatitis during routine physical assessments. Skin manifestations in specific areas suggest limited contact, such as around the eyes (mascara), areas of the body covered by clothing but not protected by undergarments (wool), or areas of the body not covered by clothing (UV injury). Generalized involvement is more likely to be caused by bubble bath or soap. Often nurses can determine the offending agent and counsel families regarding management. However, if the lesions persist, are extensive, or show evidence of infection, medical evaluation is indicated.

Poison Ivy, Oak, and Sumac

Contact with the dry or succulent portions of any of three poisonous plants (ivy, oak, and sumac) produces localized, streaked or spotty, oozing, and painful impetiginous lesions. The offending substance in these plants is an oil, urushiol, that is extremely potent. Sensitivity to urushiol is not inborn but is developed after one or two exposures and may change over a lifetime. All parts of the plants contain the oil, including dried leaves and stems (Fig. 47-4, *A*). Even smoke from burning brush piles can produce a reaction.

Animals do not seem to be affected by the oil; however, dogs or other animals that have run or played in the plants may carry the sap on their fur, and animals that eat the plants can transfer the oil in their saliva. Shoes, tools, and toys can transfer the oil. Golf balls that have been in the rough are another source of contact.

Urushiol takes effect as soon as it touches the skin. It penetrates through the epidermis and bonds with the dermal layer, where it initiates an immune response. The full-blown reaction is evident after about 2 days, with redness, swelling, and itching at the site of contact. Several days later, streaked or spotty blisters oozing serum from damaged cells produce the characteristic impetiginous lesions (Fig. 47-4, *B*). The lesions dry and heal spontaneously, and itching stops by 10 to 14 days.

Therapeutic Management

As soon as an exposure is realized, there is no time to waste. The earlier the skin is cleansed, the greater the chance of removing the urushiol before it attaches to the skin. The exposed skin can be cleansed with isopropyl alcohol followed by water. A shower with soap and warm water should follow. Clothes, tools, shoes, and any other objects that had contact with the plants should be cleaned with alcohol and then water.

Treatment of the lesions includes calamine lotion, soothing Burow solution compresses, or Aveeno baths to relieve discomfort. Topical corticosteroid gel is effective for prevention or relief of inflammation, especially when applied before blisters form. Oral corticosteroids may be needed for severe reactions, and a sedative such as diphenhydramine may be ordered.

CARE MANAGEMENT

When it is known that the child has made contact with the plant, the area is immediately flushed (preferably within 15 minutes) with *cold* running water to neutralize the urushiol not yet bonded to the skin. If there is a stream nearby, an effective method is to have the child enter the water (clothes and all) and allow the water to rinse the oil from both skin and clothing. Harsh soap is contraindicated because it removes protective skin oils and dilutes the urushiol, allowing it to spread; hard scrubbing irritates the skin. All clothing that has come in contact with the plant is removed with care and thoroughly laundered in hot water and detergent. Every effort is made to prevent the child from scratching the lesions. Although the lesions do not spread by contact with the blister serum or from scratching, they can become secondarily infected.

Prevention. Prevention is best accomplished by avoiding contact and removing the plant from the environment. All children, especially those known to be sensitive, should be taught to recognize the plant. Information regarding means for destroying plants can be obtained from the U.S. Department of Agriculture or U.S. Forestry Service. Home garden sprays that kill broad-leaf plants or all vegetation (e.g., Roundup or Spectracide) are ineffective. If poisonous plants are growing in a public community area, the local authorities should be contacted to remove the plants. A cream that protects exposed skin from poison oak and ivy is Ivy Block.

Drug Reactions

Adverse reactions to drugs are seen more often in the skin than in any other organ, although any organ of the body can be affected. The reaction may be a result of toxicity related to drug concentration, individual intolerance to the average dosage of the drug, or an allergic or idiosyncratic response. The manifestations may be associated with side effects or secondary effects of a drug, either of which are unrelated to its primary pharmacologic actions.

Although any drug is capable of producing a reaction in the susceptible individual, some drugs have a tendency to produce a

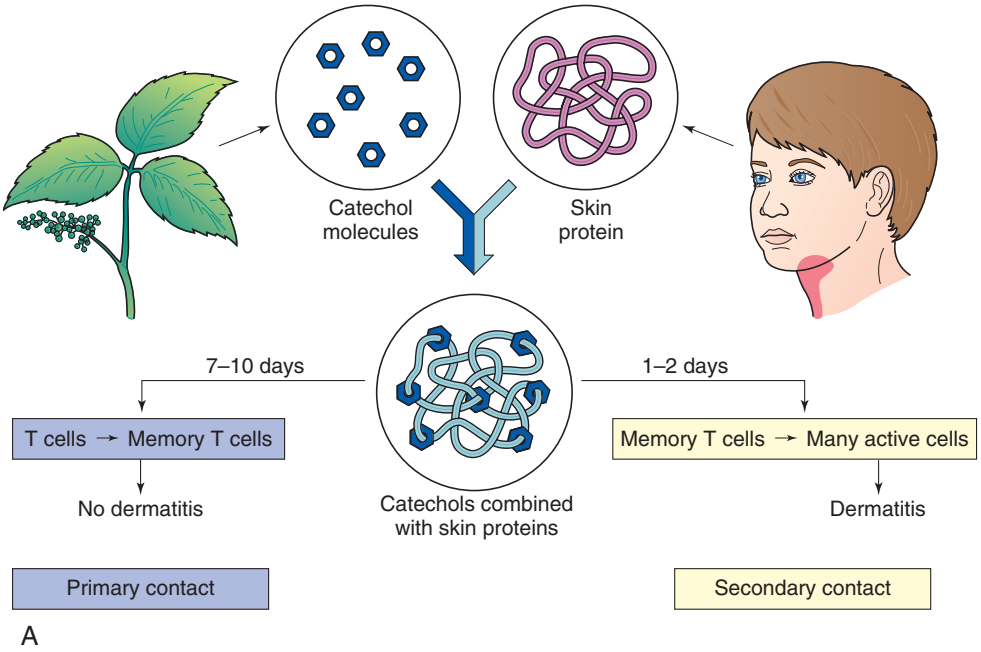

FIG 47-4 **A,** Development of allergic contact dermatitis. **B,** Poison ivy lesions; note the "streaked" blisters surrounding one large blister. (*A,* From McCance K, Huether S: *Pathophysiology: the biological basis for disease in adults and children,* ed 6, St Louis, 2010, Mosby. *B,* From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

particular reaction consistently and others are more likely to produce an untoward effect. Many are allergenic responses that occur after a previous administration of the drug, even a topical application. Other factors influence a drug response in a particular individual. For example, the incidence increases with the amount and number of drugs given.

! NURSING ALERT

Intravenous (IV) drugs are more likely to cause a reaction than oral drugs. Stop the drug but maintain the infusion with normal saline.

Manifestations of drug reactions may be delayed or immediate. A period of 7 days is usually required for a child to develop sensitivity to a drug that has never been administered previously. With prior sensitivity, the manifestations appear almost immediately. Rashes are the most common manifestation of adverse drug reactions in children. However, individual drug reactions may vary from a single lesion to extensive, generalized epidermal necrosis such as that seen in Stevens-Johnson syndrome (see Table 47-8). Cutaneous manifestations can resemble almost any skin disease and can be seen in almost any degree of severity. With few exceptions, the distribution of a drug eruption is widespread because it results from a circulating agent; appears as an inflammatory response with itching; is sudden in onset; and may be associated with constitutional symptoms such as fever, malaise, gastrointestinal upsets, anemia, or liver and kidney damage.

In most cases, treatment for simple cutaneous reactions consists of discontinuing the drug. Sometimes a decision is made to continue the drug (e.g., an antibiotic in an infant or small child) until the cause of the rash is clearly indicated. In urticarial-type eruptions, antihistamines may be ordered, and for widespread and severe lesions, corticosteroids are beneficial. Severe anaphylactic reactions are a medical emergency (see Anaphylaxis, Chapter 42).

CARE MANAGEMENT

The most effective means of management is prevention. Parents always remember a severe reaction. A careful history will elicit evidence of a previous drug reaction. The history should include the name of the drug, nature of the reaction, drug dosage, and how soon after administration the reaction occurred (see Chapter 29).

Nurses who suspect that a rash is caused by a medication should withhold any further dose and report the eruption to the health care practitioner. Frequent offenders in drug reactions are penicillin and sulfonamides, and nurses must be alert to this possibility. However, even common drugs, including aspirin, barbiturates, chemical agents in some foods, flavoring agents, and preservatives, are capable of producing an undesired response. Persons who have severe reactions should wear a medical identification bracelet or necklace in case of emergency or inadvertent administration of the offending drug.

Foreign Bodies

Parents can remove small wooden splinters with a needle and tweezers that have been sterilized with alcohol or a flame. The area around the sliver is washed with soap and water before removal is attempted. The sliver is exposed with the needle and then grasped firmly by the tweezers and pulled out. Some foreign bodies, such as a fishhook, pieces of glass, a difficult-to-see object, or a deeply embedded object (e.g., a needle in a foot or near a joint), require medical evaluation.

Small cactus prickles or spines are troublesome to remove, but the following methods may prove helpful:

- Apply a thin layer of water-soluble household glue and cover it with gauze; when the glue dries, peel off the gauze.
- Apply hair removal wax or body sugar, let it dry, and remove.
- Place cellophane tape, sticky side down, over the spines and lift it off.

SKIN DISORDERS RELATED TO ANIMAL CONTACTS

ARTHROPOD BITES AND STINGS

Bites and stings account for a significant amount of mild to moderate discomfort in children. Most bites and stings are managed by simple symptomatic measures, such as compresses, calamine lotion, and prevention of secondary infection. Arthropods include insects and arachnids, such as mites, ticks, spiders, and scorpions. Most arthropods in the United States, including tarantulas, are relatively harmless. Although all spiders produce venom that is injected via fangs, some are unable to pierce the skin and others produce venom that is insufficiently toxic to be harmful. Only scorpions and two spiders—the brown recluse and the black widow—inject venom deadly enough to require immediate attention. Children bitten by these arachnids must receive medical attention as soon as possible. Major offending creatures, their manifestations, and management are outlined in Table 47-6.

When a hymenopteran (bees in particular) stings, its barbed stinger penetrates the skin. As long as the stinger remains in the skin, the muscles push the stinger deeper and the venom is pumped into the wound. The best approach is to remove the stinger as quickly as possible and to get away from the vicinity of other insects to prevent further injury. Children who have become sensitized to hymenopteran bites may demonstrate a severe systemic response that can be life threatening. One sting can produce generalized urticaria, respiratory difficulty (from laryngeal edema), hypotension, and death. Intramuscular administration of epinephrine provides immediate relief and must be available for emergency use.

Hypersensitive children should wear a medical identification bracelet. They should also have a kit that contains epinephrine and a hypodermic syringe. Families are reminded to check the expiration date on the kit and to replace an outdated one. They should determine whether a nurse is available at the school and find out what the school policy is regarding administration of drugs. If a school nurse is not present, someone at the school should be designated to inject the epinephrine in case of an emergency.

Scabies

Scabies is an endemic infestation caused by the scabies mite, *Sarcoptes scabiei*. Lesions are created as the impregnated female burrows into the stratum corneum of the epidermis (never into living tissue) to deposit her eggs and feces. The inflammatory response and intense itching occur after the host becomes sensitized to the mite, approximately 30 to 60 days after initial contact. If the person has been previously sensitized to the mite, the response occurs within 48 hours after exposure. After this time, the areas over which the mite has traveled will begin to itch and develop the characteristic eruption (Box 47-1). Consequently, mites will not necessarily be located at all sites of eruption.

There is great variability in the type of lesions. Infants often develop an eczematous eruption; therefore the observer must look for discrete papules, burrows, or vesicles.

CARE MANAGEMENT

The treatment of scabies is the application of a scabicide. The drug of choice in children and infants older than 2 months is permethrin 5% cream (Elimite). Alternative drugs are 10% crotamiton, ivermectin, or 1% lindane cream or lotion. Lindane can be neurotoxic and is contraindicated in several age-groups. Lindane should be reserved for treatment of patients who fail to respond to other preparations (American Academy of Pediatrics [AAP], 2009).

Ivermectin, an oral medication, may be used to treat scabies in patients with secondary excoriations for whom topical scabicides are irritating and not well tolerated or whose infestation is refractory (AAP, 2009). However, the safety and efficacy of ivermectin for children younger than 5 years or children weighing less than 15 kg (33 lb) have not been established.

Because of the length of time between infestation and physical symptoms (30-60 days), all persons who were in close contact

BOX 47-1 CLINICAL MANIFESTATIONS OF SCABIES

Lesion

Children—Minute grayish brown, threadlike (mite burrows), pruritic
Black dot at end of burrow (mite)

Infants—Eczematous eruption, pruritic

Distribution

Generally in intertriginous areas—Interdigital, axillary-cubital, popliteal, inguinal

Children older than 2 years—Primarily hands and wrists

Children younger than 2 years—Primarily feet and ankles

TABLE 47-6 SKIN LESIONS CAUSED BY ARTHROPODS

MECHANISM AND CHARACTERISTIC	MANIFESTATIONS	MANAGEMENT
Insect Bites—Flies, Gnats, Mosquitoes, Fleas		
Mechanism	Hypersensitivity reaction	***Treatment***
Foreign protein in insects' saliva introduced when skin is penetrated for a blood-sucking meal	Papular urticaria Firm papules; may be capped by vesicles or excoriated Little or no reaction in nonsensitized person	Use antipruritic agents and baths. Administer antihistamines. Prevent secondary infection.
Distribution		***Prevention***
Almost everywhere—Fleas, mosquitoes, ants Suburbs and rural areas—Bees Urban areas—Hornets, wasps, yellow jackets		Avoid contact. Remove focus, such as treating furniture, mattresses, carpets, and pets, where insects may live. Apply insect repellent when exposure is anticipated.
Chiggers—Harvest Mites		
Mechanism	Same as insect bites	Avoid contact, especially in areas of tall grass and underbrush.
Attach with claws and secrete a digestive substance that liquefies the host's epidermis	Favor warm areas of body, especially intertriginous areas and areas covered with clothing	Apply insect repellant when exposure is anticipated. Administer systemic steroids for extensive bites.
Manifestations		
Erythematous papules Intense itching		
Hymenopterans—Bees, Wasps, Hornets, Yellow Jackets, Fire Ants		
Mechanism	*Local reaction*—Small red area, wheal, itching, and heat	***Treatment***
Injection of venom through stinging apparatus Venom contains histamine; allergenic proteins; and often a spreading factor, hyaluronidase Severe reactions caused by hypersensitivity or multiple stings	*Systemic reactions*—May be mild to severe, including generalized edema, pain, nausea and vomiting, confusion, respiratory embarrassment, and shock	Carefully scrape off stinger or pull out stinger as quickly as possible. Cleanse with soap and water. Apply cool compresses. Apply common household product (e.g., lemon juice, paste made with aspirin or baking soda). Administer antihistamines. *Severe reactions*—Administer epinephrine, corticosteroids; treat for shock.
		Prevention
		Teach child to wear shoes; to avoid wearing bright clothing, flowery prints, shiny jewelry, or perfumed grooming products (cologne, scented hairspray), which might attract the insect; and to avoid places where the insect may be contacted. Hypersensitive children should wear medical identification to indicate allergy and therapy needed; family should keep emergency medication and be taught its administration.
Black Widow Spider		
Mechanism	Mild sting at time of bite	***Treatment***
Venom injected through a clawlike appendage; has neurotoxic action	Area becomes swollen, painful, and erythematous Dizziness, weakness, and abdominal pain May produce delirium, paralysis, seizures, and (if large amount of venom absorbed) death	Cleanse wound with antiseptic. Apply cool compresses. Administer antivenin. Administer muscle relaxant, such as calcium gluconate; analgesics or sedatives; hydrocortisone or diazepam intravenously.
Characteristics		***Prevention***
Shiny black spider, with a body about 1.25 cm (0.5 inch) long and a red or orange hourglass-shaped marking on underside Avoids light and bites in self-defense		Teach children to avoid places that harbor the spider (e.g., woodpiles).

TABLE 47-6 SKIN LESIONS CAUSED BY ARTHROPODS—cont'd

MECHANISM AND CHARACTERISTIC	MANIFESTATIONS	MANAGEMENT
Brown Recluse Spider		
Mechanism	Mild sting at time of bite	***Treatment***
Venom injected via fangs	Transient erythema followed by bleb or blister; mild to severe pain in 2-8 hours; purple, star-shaped area in 3-4 days; necrotic ulceration in 7-14 days (Fig. 47-5)	Apply cool compresses locally.
Venom contains powerful necrotoxin	Systemic reactions may include fever, malaise, restlessness, nausea, vomiting, and joint pain	Administer antibiotics, corticosteroids.
Characteristics	Generalized petechial eruption	Relieve pain.
Slender spider, with long legs and body length of 1-2 cm (0.4-0.8 inch); color is fawn to dark brown; recognized by fiddle-shaped mark on head	Wounds heal with scar formation	Wound may require skin graft.
Shy; bites only when annoyed or surprised		***Prevention***
Prefers dark areas where seldom disturbed		Teach children to avoid possible nesting sites.
Scorpions		
Mechanism	Intense local pain, erythema, numbness, burning, restlessness, vomiting	***Treatment***
Sting by means of a hooked caudal stinger that discharges venom	Ascending motor paralysis with seizures, weakness, rapid pulse, excessive salivation, thirst, dysuria, pulmonary edema, coma, and death	Delay absorption of venom by keeping child quiet; place involved area in dependent position.
Venom of more venomous species contains hemolysins, endotheliolysins, and neurotoxins	Some species produce only local tissue reaction with swelling at puncture site (distinctive)	Administer antivenin.
Characteristics	Symptoms subside in a few hours	Relieve pain.
Usual habitat southwestern United States	Deaths occur among children younger than 4 years, usually in first 24 hours	Admit to pediatric intensive care unit for surveillance.
		Prevention
		Teach children to avoid possible nesting sites.
Ticks		
Mechanism	Tick usually attached to skin, head embedded	***Treatment***
In process of sucking blood, head and mouth parts are buried in skin	Produce firm, discrete, intensely pruritic nodules at site of attachment	Grasp tick with tweezers (forceps) as close as possible to point of attachment.
Characteristics	May cause urticaria or persistent localized edema	Pull straight up with steady, even pressure; if using bare hands, use a tissue to touch tick during removal; wash hands thoroughly with soap and water.
Feed on blood of mammals		Remove any remaining part (e.g., head) with sterile needle.
Significant in humans because of pathologic organism carried		Cleanse wounds with soap and disinfectant.
May be vectors of various infectious diseases, such as Rocky Mountain spotted fever, Q fever, tularemia, relapsing fever, Lyme disease, tick paralysis		***Prevention***
Must attach and feed for 1-2 hours to transmit disease		Teach children to avoid areas where prevalent.
Usual habitat is wooded area		Inspect skin (especially scalp) after being in wooded areas.
		(See discussion on p. 1510.)

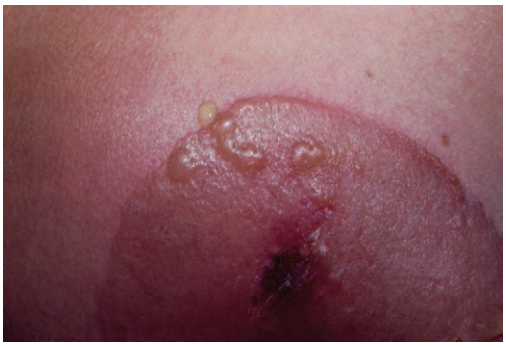

FIG 47-5 Brown recluse spider bite. Note central necrosis surrounded by purplish area and blisters. (From Weston WL, Lane AT: *Color textbook of pediatric dermatology,* ed 4, St Louis, 2007, Mosby.)

with the affected child need treatment. This may include boyfriends or girlfriends, babysitters, grandparents, and immediate family members. The objective is to treat as thoroughly as possible the first time. Enough medication for the entire family should be prescribed, with 2 oz allowed for each adult and 1 oz for each child.

Pediculosis Capitis

Pediculosis capitis (head lice) is an infestation of the scalp by *Pediculus humanus capitis,* a common parasite in school-age children. The adult louse lives only about 48 hours when away from a human host, and the life span of the average female is 1 month. The female lays her eggs at night at the junction of a hair shaft and close to the skin because the eggs need a warm environment. The nits, or eggs, hatch in approximately 7 to 10 days. Itching is usually the only symptom.

Common areas involved are the occipital area, behind the ears, and the nape of the neck (Box 47-2).

Diagnostic Evaluation

Diagnosis is made by observation of the white eggs (nits) firmly attached to the hair shafts (Fig. 47-6). Because of their brief life span and mobility, adult lice are more difficult to locate. Nits must be differentiated from dandruff, lint, hair spray, and other items of similar size and shape. Scratch marks or inflammatory papules, caused by secondary infection, may also be found on the scalp in the vulnerable areas.

Therapeutic Management

Treatment consists of the application of pediculicides and manual removal of nit cases. The drug of choice for infants and children is permethrin 1% cream rinse (Nix), which kills adult lice and nits. This product and preparations of pyrethrin with piperonyl butoxide (RID or A-200 Pyrinate) can be obtained without a prescription and are more effective and safer than lindane (Strong and Johnstone, 2008). Most experts advise a second treatment at 7 to 10 days to ensure a cure (AAP, 2009). However, pyrethrin products are contraindicated for individuals with contact allergy to ragweed or turpentine. If neither permethrin nor pyrethrin products are effective, the prescription drug *0.5% malathion,* which has been approved for treatment of head lice, can be used. However, malathion contains flammable alcohol, must remain in contact with the scalp for 8 to 12 hours, and is not recommended for children younger than 2 years.

Because of concerns that head lice may be developing resistance to chemical shampoos and that repeated exposure of children to strong chemicals on the scalp may be unwise, effective nonchemical control measures are essential. Removal of nits from the child's hair with a metal nit comb at least every 2 or 3 days is a control measure following treatment with a pediculicide (Mumcuoglu, Barker, Burgess, et al., 2007).

BOX 47-2 CLINICAL MANIFESTATIONS OF PEDICULOSIS

- Pruritus (caused by crawling insects and insect saliva on skin)
- Nits observable on hair shaft (see Fig. 47-6)

Distribution

- Occipital area
- Behind ears
- Nape of neck
- Eyebrows and eyelashes (occasionally) (caused by pubic lice)

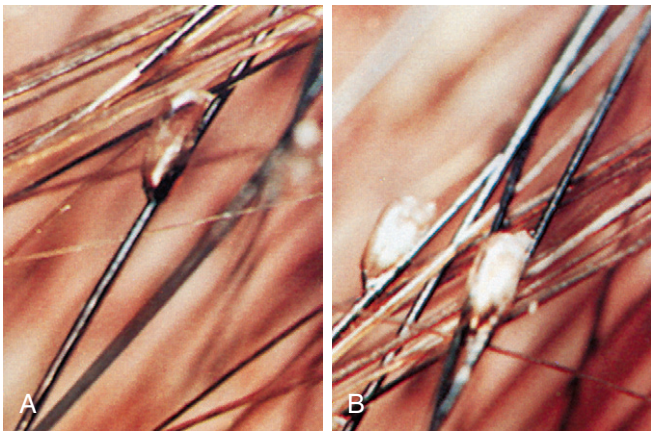

FIG 47-6 A, Empty nit case. **B,** Viable nits. (From *The contemporary approach to the control of head lice in schools and communities,* Pittsburgh, 1991, SmithKline Beecham.)

CARE MANAGEMENT

An important nursing role is educating the parents about pediculosis. Nurses should emphasize that *anyone* can get pediculosis; it has no respect for age, socioeconomic level, or cleanliness. Lice do not jump or fly, but they can be transmitted from one person to another on personal items. Lice are more likely to infest Caucasian children, those with straight hair, and girls. Children are cautioned against sharing combs, hair ornaments, hats, caps, scarves, coats, and other items used on or near the hair. Children who share lockers are more likely to become infested, and slumber parties place children at risk. Lice are not carried or transmitted by pets.

Nurses or parents should carefully inspect children who scratch their heads more than usual for bite marks, redness, and nits. The hair is systematically spread with two flat-sided sticks or tongue depressors, and the scalp is observed for any movement that indicates a louse. Nurses should wear gloves when examining the hair. Lice are small and grayish tan, have no wings, and are visible to the naked eye. The nits, or eggs, appear as tiny whitish oval specks adhering to the hair shaft about 6 mm (0.25 inch) from the scalp. The adherent nature of the nits distinguishes them from dandruff, which falls off readily. Empty nit cases, indicating hatched lice, are translucent rather than white and are located more than 6 mm from the scalp (see Fig. 47-6).

If evidence of infestation is found, it is important to treat the child according to the directions on the label of the pediculicide. Parents are advised to read the directions carefully before beginning treatment. The child is made as comfortable as possible during the application process because the pediculicide must remain on the scalp and hair for several minutes. Playing "beauty parlor" while shampooing is a useful strategy. The child lies supine with the head over a sink or basin and covers the eyes with a dry towel or washcloth. This prevents medication, which can cause chemical conjunctivitis, from splashing into the eyes. If eye irritation occurs, the eyes must be flushed well with tepid water. It is not necessary to remove the nits after treatment because only live lice cause infestation. However, because none of the pediculicides is 100% effective in killing all the eggs, the makers of some pediculicides recommend manual removal of the nits after treatment. An extra-fine-tooth comb that is included in many commercial pediculicides or is available at community pharmacies facilitates manual removal. If the comb is ineffective in removing the nit cases, the examiner should remove them by scraping them off the strands of hair with his or her fingernails.

Live lice survive for up to 48 hours away from the host, but nits are shed into the environment and are capable of hatching in 7 to 10 days; retreatment may be required. Therefore measures must be taken to prevent further infestation (see Community Focus box). Spraying with insecticide is not recommended because of the danger to children and animals. Families should also be advised that the pediculicide is relatively expensive, especially when several members of the household require treatment. Families may be inclined to try home remedies such as vinegar or petroleum jelly to treat the lice, but most are ineffective. A study by Pearlman (2004) showed that dry-on pediculicide lotions may effectively treat lice without the use

of current shampoos with neurotoxins, nit removal, or extensive housecleaning.

Prevention. The increasing incidence of pediculosis in schoolchildren is a serious concern for school nurses, parents, and community health agencies. However, school head lice screening programs have not proven to have a significant effect on the incidence of head lice in the school setting; parent education programs may be more helpful in the management of head lice. Children with head lice should be allowed to return to school after proper treatment. Both the American Academy of Pediatrics (AAP) and the National Association of School Nurses discourage a "no nit" policy for schools.

RICKETTSIAL DISEASES

The organisms responsible for a number of disorders are transmitted to human beings via arthropods (Table 47-7). Mammals become infected only through the bites of infected lice, fleas, ticks, and mites, all of which serve as both infectors and reservoirs. Rickettsiae are intracellular parasites, similar in size to bacteria that inhabit the alimentary tract of a wide range of natural hosts. Rickettsial diseases are more common in temperate and tropical climates where humans live in association with arthropods. Infection in humans is incidental (except epidemic typhus) and not necessary for the survival of the rickettsial species. However, after the organism invades a human, it causes a disease that varies in intensity from a benign, self-limiting illness to a disease that is fulminating and fatal.

COMMUNITY FOCUS

Preventing the Spread and Recurrence of Pediculosis

- Machine wash all washable clothing, towels, and bed linens in hot water and dry them in a hot dryer for at least 20 minutes. Dry-clean nonwashable items.
- Thoroughly vacuum carpets, car seats, pillows, stuffed animals, rugs, mattresses, and upholstered furniture.
- Seal nonwashable items in plastic bags for 14 days if unable to dry-clean or vacuum.
- Soak combs, brushes, and hair accessories in lice-killing products for 1 hour or in boiling water for 10 minutes.
- In day-care centers, store children's clothing items such as hats and scarves and other headgear in separate cubicles.
- Discourage the sharing of items such as hats, scarves, hair accessories, combs, and brushes among children in group settings such as day-care centers.
- Avoid physical contact with infested individuals and their belongings, especially clothing and bedding.
- Inspect children in a group setting regularly for head lice.
- Provide educational programs on the transmission of pediculosis, its detection, and treatment.

Adapted from Chin J, editor: *Control of communicable diseases manual,* Washington, DC, 2000, American Public Health Association.

TABLE 47-7 ERUPTIONS CAUSED BY RICKETTSIAE

DISORDER, ORGANISM, AND HOST	MANIFESTATIONS	MANAGEMENT	COMMENTS
Rocky Mountain spotted fever—*Rickettsia rickettsii* *Arthropod*—Tick *Transmission*—Tick *Mammal source*—Wild rodents, dogs	*Gradual onset*—Fever, malaise, anorexia, myalgia *Abrupt onset*—Rapid temperature elevation, chills, vomiting, myalgia, severe headache Maculopapular or petechial rash primarily on extremities (ankles and wrists) but may spread to other areas, characteristically on palms and soles	***Control*** Protection from tick bite by wearing proper apparel, tick repellent Tetracycline or chloramphenicol Vigorous supportive therapy	Usually self-limiting in children Onset in children may resemble any infectious disease Severe disease rare in children Inspect children and dogs regularly if they play in wooded areas See Table 47-6 for management of ticks
Epidemic typhus— *R. prowazekii* *Arthropod*—Body louse *Transmission*—Infected feces into broken skin *Mammal source*—Humans	Abrupt onset of chills, fever, diffuse myalgia, headache, malaise Maculopapular rash becoming petechial 4-7 days later, spreading from trunk outward	***Control*** Immediate destruction of vectors Tetracycline or chloramphenicol Supportive treatment	Patient should be isolated until deloused See discussion on p. 1508 for management of pediculosis Excreta from infected lice also in dust; disinfect patient's clothing, bedding, and possessions and wash in hot water
Endemic typhus—*R. typhi* *Arthropod*—Rat fleas or lice *Transmission*—Flea bite; inhaling or ingesting flea excreta *Mammal source*—Rats	Headache, arthralgia, backache followed by fever; may last 9-14 days Maculopapular rash after 1-8 days of fever; begins in trunk and spreads to periphery; rarely involves face, palms, soles	***Control*** Eliminate rat reservoir, insect vectors, or both Tetracycline or chloramphenicol Supportive treatment	Fairly common in United States Shorter duration than epidemic typhus Mild, seldom fatal illness Difficult to distinguish from epidemic typhus
Rickettsialpox—*R. akari* *Arthropod*—Mouse mite *Transmission*—Mite *Mammal source*—House mouse	Maculopapular rash after primary lesion; eschar at site of bite; fever, chills, headache	***Control*** Eradication of rodent reservoir and mite vector Tetracycline or chloramphenicol Supportive treatment	Self-limiting nonfatal disease Endemic in New York City Found in many cities in United States

FIG 47-7 Lyme disease. Note annular red rings in erythema chronicum migrans. (From Weston WL, Lane AT: *Color textbook of pediatric dermatology,* ed 4, St Louis, 2007, Mosby.)

Lyme Disease

Lyme disease is the most common tickborne disorder in the United States. It is caused by the spirochete *Borrelia burgdorferi,* which enters the skin and bloodstream through the saliva and feces of ticks, especially the deer tick (Moreno, 2011). Most cases of Lyme disease are reported in the Northeast from southern Maine to northern Virginia. The disease may initially appear in any of three stages:

- **Stage 1** consists of the tick bite at the time of inoculation, followed in 3 to 31 days by the development of erythema migrans at the site of the bite (Fig. 47-7).
- **Stage 2,** the most serious stage of the disease, is characterized by systemic involvement of neurologic, cardiac, and musculoskeletal systems that appears several weeks after the cutaneous phase is completed.
- **Stage 3,** or the late stage, includes musculoskeletal pain that involves the tendons, bursae, muscles, and synovia. Arthritis may occur, and late neurologic problems include deafness and chronic encephalopathy.

Diagnostic Evaluation

Diagnosis is best made clinically during the early stages by recognizing the characteristic rash, erythema migrans. Serologic testing may be used to establish the diagnosis in later stages of the disease.

Therapeutic Management

Early and appropriate treatment is essential to prevent complications. Children older than 8 years are treated with oral doxycycline; amoxicillin is recommended for children younger than 8 years (Centers for Disease Control and Prevention [CDC], 2009). For patients who are allergic to penicillin, alternative drugs include cefuroxime or erythromycin. Most experts treat individuals with early Lyme disease for 14 to 21 days. Persons who have removed ticks from themselves should be monitored closely for signs and symptoms of tickborne diseases for 30 days; in particular, they should be monitored for erythema migrans, a red expanding skin lesion at the site of the tick bite that may suggest Lyme disease. People who develop a skin lesion or viral infection–like illness within 1 month of an attached tick should seek prompt medical attention (Wormser, Dattwyler, Shapiro, et al., 2006). Treatment of erythema migrans most often prevents development of later stages of Lyme disease.

CARE MANAGEMENT

The major thrust of nursing care should be educating parents to protect their children from exposure to ticks. Children should avoid tick-infested areas or wear light-colored clothing so that ticks can be spotted easily, tuck pant legs into socks, and wear a long-sleeved shirt tucked into pants when in wooded areas. Parents and children need to perform regular tick checks when they are in infested areas (with special attention to the scalp, neck, armpits, and groin areas) (Network to Reduce Lyme Disease in School-Aged Children, 2010). Parents should also be alert for signs of the skin lesion, especially if their children have been in tick-infested areas. Insect repellents containing diethyltoluamide (DEET) and permethrin can protect against ticks, but parents should use these chemicals cautiously. Although there have been reports of serious neurologic complications in children resulting from frequent and excessive application of DEET repellants, the risk is low when they are used properly. Products with DEET should be applied sparingly according to label instructions and not applied to a child's face, hands, or any areas of irritated skin. After the child returns indoors, treated skin should be washed with soap and water. Information about Lyme disease can be obtained from the American Lyme Disease Foundation, Inc.*

PET AND WILD ANIMAL BITES

Animal bites are common in childhood. However, children are bitten more often by animals belonging to the family or to neighbors than by stray animals. The majority of victims of dog bites are boys between the ages of 5 and 9 years (CDC, 2003). Most dog or cat injuries are to the upper extremities. Small children are likely to be bitten or scratched on the head, face, and neck because they tend to put their heads near the animal's head and flail their arms rather than protecting their heads (Kaye, Belz, and Kirschner, 2009). Animal bites are potentially serious because of the likelihood of significant infection. Injuries vary in intensity from small puncture wounds to complete evulsion of tissue that is associated with significant crush injury.

Therapeutic Management

General wound care consists of rinsing the wound with copious amounts of saline or lactated Ringer solution under pressure via a large syringe and of washing the surrounding skin with mild soap. A clean pressure dressing is applied, and the extremity is elevated if the wound is bleeding. Medical evaluation is advised because of the danger of tetanus and rabies, although dogs in most urban areas must be immunized against rabies. Bites from wild animals, such as squirrels, bats, raccoons, foxes, and skunks, are also dangerous.

Prophylactic antibiotics are indicated for puncture wounds and wounds in areas that may prove to be cosmetically or functionally impaired if infected. Extensive lacerations are débrided and loosely sutured to allow drainage in the event of infection. Tetanus toxoid is administered according to standard guidelines (see Immunizations, Chapter 31), and rabies protocol is followed (see Rabies, Chapter 45). Injuries to poorly vascularized areas, such as the hands, are more likely to become infected than those in more vascularized areas, such as the face; puncture wounds are more likely to become infected than lacerations.

CARE MANAGEMENT

The most important aspect related to animal bites is prevention. Children should understand animal behavior and develop respect for animals (see Community Focus box). Parents should monitor their children's behavior with dogs and instruct them not to tease

*PO Box 466, Lyme, CT 06371; e-mail: inquire@aldf.com; www.aldf.com.

COMMUNITY FOCUS

Animal Safety

- Teach children to avoid all strange animals, especially wild, sick, or injured ones, that may be carriers of rabies (use the same techniques used in teaching children not to talk to strangers).
- Teach children to avoid dangerous and nervous animals in the neighborhood.
- Vaccinate your own dog against rabies.
- Never permit children to break up an animal fight even when their own pet is involved. Use a rake, broom, or garden hose to separate animals.
- Teach children the danger of mistreating or teasing pets (animals will bite if mauled, annoyed, or frightened).
- Spay or neuter your pets (spaying or neutering reduces aggression, not protectiveness).
- Avoid direct eye contact with a threatening dog and remain motionless until a threatening dog leaves the area.
- Never hold your face close to an animal.
- Teach children not to disturb an animal that is eating; sleeping; or caring for young puppies, kittens, and so on.
- Never tease; pull the tail; or take away food, a bone, or a toy with which an animal is playing.
- Never approach a strange dog that is confined or restrained; do not keep animals confined with short ropes or chains (this can make them aggressive or vicious, especially when teased).
- Do not run, ride a bicycle, or skate in front of a dog (it will startle the dog); teach children the importance of avoiding bike routes where dogs are known to chase vehicles.
- Do not allow an inexperienced child or adult to feed a dog (if the person pulls back when the animal moves to take the food, this can frighten and startle the animal).
- If a dog is asleep or unaware of your presence or has not seen you approach, speak to the animal to make it aware of your presence to avoid startling the animal.
- Allow a dog to see and sniff a child before the child attempts to pet the animal.
- Do not permit a child to lead a large dog.
- Train or socialize a dog for appropriate behavior; avoid aggressive play with pets.
- Do not adopt pets for children until children demonstrate their maturity and ability to handle and care for pets.

From Humane Society of the United States: *Preventing and avoiding dog bites,* Washington, DC, 1998, Author.

or surprise dogs, invade their territory, interfere with their feeding or sleeping, take their toys, or interact with sick or injured dogs or dogs with pups. Parents who are considering getting a pet, especially a dog, for themselves or their children should select a dog that has a high level of sociability with and is unlikely to be a danger to children.

Human Bites

Children often acquire lacerations from the teeth of other humans in rough play, during fights, or as victims of child abuse. Many preschool children bite others out of frustration or anger. Because human dental plaque and gingiva harbor pathogenic organisms, all human bites should receive attention. Delayed treatment increases the risk for infection.

If the laceration is less than 6 mm (0.25 inch) in length, the wound can be treated at home. The wound is washed vigorously with soap and water, and a pressure dressing is applied to stop bleeding. Ice applications minimize discomfort and swelling. Increased pain or redness at the wound site is an indication that the child should receive medical attention for antibiotic therapy. Tetanus toxoid is needed if the child is insufficiently immunized. Wounds larger than 6 mm should receive medical attention.

Cat Scratch Disease

Cat scratch disease is the most common cause of regional lymphadenitis in children and adolescents. It usually follows the scratch or bite of an animal (a cat or kitten in 99% of cases). The disease is usually a benign, self-limiting illness that resolves spontaneously in about 2 to 4 months. Diagnosis is made on the basis of (1) history of contact with a cat or kitten, (2) the presence of regional lymphadenopathy for several days, and (3) serologic identification of the causative organism by indirect fluorescent antibody assay or polymerase chain reaction test. The disease may persist for several months before gradual resolution. In some children, especially those who are immunocompromised, the adenitis may progress to suppuration and serious complications. Treatment is primarily supportive, but antibiotic therapy may hasten the resolution of adenopathy in the disease (CDC, 2002).

MISCELLANEOUS SKIN DISORDERS

A number of miscellaneous skin lesions occur in children. Some occur as a result of congenital disorders and are inherited as an autosomal dominant trait (Table 47-8). Ichthyoses are a heterogeneous group of disorders characterized by scaling that create challenging problems in treatment. These disorders are not discussed in detail here because of their wide variability.

SKIN DISORDERS ASSOCIATED WITH SPECIFIC AGE-GROUPS

Several common dermatologic conditions are confined to children in specific age-groups. These conditions include diaper, atopic, and seborrheic dermatitis, which occur predominantly in infants, and acne, which is most common in adolescence.

Diaper Dermatitis

Diaper dermatitis is common in infants and one of several acute inflammatory skin disorders caused either directly or indirectly by wearing diapers. The peak age of occurrence is 9 to 12 months, and the incidence is greater in bottle-fed infants than in breastfed infants.

Pathophysiology and Clinical Manifestations

Diaper dermatitis is caused by prolonged and repetitive contact with an irritant (e.g., urine, feces, soaps, detergents, ointments, friction). Although the irritant in the majority of cases is urine and feces, a combination of factors contributes to irritation.

Prolonged contact of the skin with diaper wetness produces higher friction, greater abrasion damage, increased transepidermal permeability, and increased microbial counts. Healthy skin is less resistant to potential irritants.

Although ammonia was once thought to cause diaper rash because of the association between the strong odor on diapers and dermatitis, ammonia alone is not sufficient. The irritant quality of urine is related to an increase in pH from the breakdown of urea in the presence of fecal urease. The increased pH promotes the activity of fecal enzymes, principally the proteases and lipases, which act as

TABLE 47-8 MISCELLANEOUS SKIN DISORDERS

DISEASE AND CAUSATIVE AGENT	LOCAL MANIFESTATIONS	MANAGEMENT	COMMENTS
Urticaria—Usually allergic response to drugs or infection	Development of wheals Vary in size and configuration and tend to appear quickly, spread irregularly, and fade within a few hours May be constant or intermittent, sparse or profuse, small or large, discrete or confluent May be acute, chronic, or recurrent in acute attacks	Local soothing and antipruritic applications Antihistamines Epinephrine or ephedrine Cortisone in severe cases Severe upper respiratory tract involvement may require tracheostomy	Known etiologic agents should be avoided May be accompanied by malaise, fever, lymphadenopathy Severe cases may involve mucous membranes, internal organs, and joints Obstruction to air passages constitutes medical emergency (see Chapter 40)
Intertrigo—Mechanical trauma and aggravating factors of excessive heat, moisture, and sweat retention	Red, inflamed, moist, partially denuded, marginated areas, the shape of which is determined by location Appears where opposing skin surfaces rub together, such as intergluteal folds, groin, neck, and axilla Excessive moisture and obesity are often factors	Affected areas kept clean and dry Skinfolds kept separated with a generous supply of nonmedicated powder Expose to air and light Remove excess clothing	A form of diaper irritation Prevent recurrence by keeping susceptible areas clean and dry Frequently associated with overheating from too much clothing; common in tracheostomy patients with short necks and copious secretions
Psoriasis—Unknown; hereditary predisposition; may be triggered by stress	Round, thick, dry, reddish patches covered with coarse, silvery scales over trunk and extremities; first lesions commonly appear in scalp; facial lesions more common in children than in adults Affected cells proliferate at a much more rapid rate than normal cells	Tar preparations in combination with UVB light or natural sunlight Topical corticosteroids Topical vitamin D analog *calcipotriene* Phenol and saline solutions followed by a tar shampoo to remove scales Keratolytic agents (salicylic acid) Acitretin Emollients may provide relief	Uncommon in children younger than 6 years Patients are otherwise healthy Coal tar acts synergistically with UVB light Keratolytic agents enhance absorption of corticosteroids Humidifiers may help in winter
Alopecia*			
Alopecia areata	Sudden onset of asymptomatic, noninflammatory, round, bald patches in hairy parts of body	Psychologic support Inducement of allergic contact dermatitis to stimulate growth of hair Minoxidil (peripheral vasodilator)	Family history in 10%-26% of cases Some concern regarding drug therapy safety Refer to support groups*
Traumatic alopecia	Traction alopecia around scalp margins from tight hair styles (e.g., braids, pony tails, corn rows)	Counseling regarding hair styling, use of hair cosmetics, hot combs, rollers	More prevalent in African-American children and adolescents Prolonged traction can produce fibrosis of hair root and permanent loss
Trichotillomania	Compulsive hair pulling	Determine and treat cause	Chronic hair pulling may require psychologic therapy
Tinea capitis	See Table 47-4	See Table 47-4	See Table 47-4
Erythema multiforme (Stevens-Johnson syndrome)—Unknown; associated with ingestion of some drugs; often follows upper respiratory tract infection	Erythematous papular rash Lesions enlarge by peripheral expansion, develop central vesicle Involves most skin surfaces except scalp May extend to mucous membranes, especially oral, ocular, and urethral	Symptomatic and supportive Maintain adequate intake of fluids (oral or intravenous), calories, and protein Moist wound care, hydrogels such as CarraGauze, Vaseline, or Aquaphor Appropriate treatment of complications Diligent monitoring of urine volume and specific gravity, hemoglobin and hematocrit, serum electrolyte levels, total body weight	Rash often preceded by fever and malaise Complications include renal failure and severe eye disease Respiratory involvement in a number of cases Self-limiting, but recovery may extend for weeks; skin lesions may subside without scarring; mucous membrane lesions may persist for months Recurrence rate, 20%; mortality rate as high as 10% High mutation rate
Neurofibromatosis—Inherited disorder; autosomal dominant inheritance pattern	Café-au-lait spots, pigmented nevi, axillary freckling Slow-growing cutaneous and subcutaneous neurofibromas	Symptomatic treatment of associated manifestations (e.g., speech defects, seizures, skeletal defects [scoliosis, kyphosis], learning disabilities) Surgical removal of troublesome tumors	Refer to support groups† Family needs to know about genetic implications

irritants. Fecal enzymes also increase the permeability of skin to bile salts, another potential irritant in feces.

The eruption of diaper dermatitis is manifested primarily on convex surfaces or in folds. The lesions represent a variety of types and configurations. Eruptions involving the skin in most intimate contact with the diaper (e.g., the convex surfaces of buttocks, inner thighs, mons pubis, scrotum) but sparing the folds are likely to be caused by chemical irritants, especially from urine and feces (Fig. 47-8). Other causes are detergents or soaps from inadequately rinsed cloth diapers or the chemicals in disposable wipes. Perianal involvement is usually the result of chemical irritation from feces, especially diarrheal stools. *Candida albicans* infection produces perianal inflammation and a maculopapular rash with satellite lesions that may cross the inguinal fold (Fig. 47-9). It is seen in up to 90% of infants with chronic diaper dermatitis and should be considered in diaper rashes that are recalcitrant to treatment.

FIG 47-8 Irritant diaper dermatitis. Note the sharply demarcated edges. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

FIG 47-9 Candidiasis of diaper area. Note the beefy red central erythema with satellite pustules. (From Paller AS, Mancini AJ: *Hurwitz clinical pediatric dermatology,* ed 4, St Louis, 2011, Saunders.)

CARE MANAGEMENT

Nursing interventions are aimed at altering the three factors that produce dermatitis: wetness, pH, and fecal irritants. The most significant factor amenable to intervention is the moist environment created in the diaper area. Changing the diaper as soon as it becomes wet eliminates a large part of the problem, and removing the diaper to expose healthy skin to air facilitates drying. The use of a hair dryer or heat lamp is not recommended because these devices can cause burns.

Diaper construction has a significant impact on the incidence and severity of diaper dermatitis. Superabsorbent disposable paper diapers reduce diaper dermatitis. They contain an absorbent gelling material that binds water tightly to decrease skin wetness, maintains pH control by providing a buffering capacity, and decreases skin irritation by preventing mixing of urine and feces in the diaper. Another advance in diapers is the addition of an inner layer or top sheet that is impregnated with petrolatum (as in Pampers Swaddler with Absorb-Away Liner).

Guidelines for controlling diaper rash are presented in the Family-Centered Care box. A common misconception about using cornstarch on skin is that it promotes the growth of *C. albicans.* Neither cornstarch nor talc promotes the growth of fungi under conditions normally found in the diaper area. Cornstarch is more effective in reducing friction and tends to cake less than talc when the skin is wet. On the basis of these properties and its safety in terms of inhalation injury, cornstarch is the preferred product. Talc should not be used.

FAMILY-CENTERED CARE

Controlling Diaper Rash

- Keep skin dry*:
  - Use superabsorbent disposable diapers to reduce skin wetness.
  - If using cloth diapers, use only overwraps that allow air to circulate; avoid rubber pants.
  - Change diapers as soon as soiled—especially with stool—whenever possible, preferably once during the night.
  - Expose healthy or only slightly irritated skin to air, not heat, to dry completely.
- Apply ointment, such as zinc oxide or petrolatum, to protect skin, especially if skin is very red or has moist, open areas:
  - Avoid removing skin barrier cream with each diaper change; remove waste material and reapply skin barrier cream.
  - To completely remove ointment, especially zinc oxide, use mineral oil; do not wash vigorously.
- Avoid overwashing the skin, especially with perfumed soaps or commercial wipes, which may be irritating:
  - May use a moisturizer or nonsoap cleanser, such as cold cream or Cetaphil, to wipe urine from skin.
  - Gently wipe stool from skin using water and mild soap, such as Dove.
  - When traveling, fill an old baby wipe container with soft paper towels and warm water.

*Powder helps keep the skin dry, but talc is dangerous if breathed into the lungs. Plain cornstarch or cornstarch-based powder is safer. When using any powder product, first shake it into your hand and then apply it to the diaper area. Store the container away from the infant's reach; keep the container closed when not in use.

Atopic Dermatitis (Eczema)

Eczema or eczematous inflammation of the skin refers to a descriptive category of dermatologic diseases and not to a specific etiology. AD is a type of pruritic eczema that usually begins during infancy and is associated with an allergic contact dermatitis with a hereditary tendency (atopy) (Jacob, Yang, Herro, et al., 2010). AD manifests in three forms based on the child's age and the distribution of lesions:

1. Infantile (infantile eczema)—Usually begins at 2 to 6 months of age; generally undergoes spontaneous remission by 3 years of age
2. Childhood—May follow the infantile form; occurs at 2 to 3 years of age; 90% of children have manifestations by age 5 years
3. Preadolescent and adolescent—Begins at about 12 years of age; may continue into the early adult years or indefinitely

The diagnosis of AD is based on a combination of history and morphologic findings (Box 47-3). Children with AD have a lower threshold for cutaneous itching compared with children who do not have AD, and many authorities believe the dermatologic manifestations appear subsequent to scratching from the intense pruritus (Alanne, Nermes, Soderlund, et al., 2011). For example, infants rub their faces against bed linen, and their crawling (a form of scratching) results in irritation of knees and elbows. Lesions disappear if the scratching is stopped.

The majority of children with infantile AD have a family history of eczema, asthma, food allergies, or allergic rhinitis, which strongly supports a genetic predisposition. The cause is unknown but appears to be related to abnormal function of the skin, including alterations in perspiration, peripheral vascular function, and heat tolerance. Manifestations of the chronic disease improve in humid climates and get worse in the fall and winter, when homes are heated and environmental humidity is lower. The disorder can be controlled but not cured. A recent study of 134 infants with AD showed that itching and scratching and sleep disturbance were specific features detracting from quality of life in these young children (Alanne, Nermes, Soderlund, et al., 2011).

Therapeutic Management

The major goals of management are to (1) hydrate the skin, (2) relieve pruritus, (3) reduce flare-ups or inflammation, and (4) prevent and control secondary infection. The general measures for managing AD focus on reducing pruritus and other aspects of the disease. Management strategies include avoiding exposure to skin irritants or allergens; avoiding overheating; and administrating medications such as antihistamines, topical immunomodulators, topical steroids, and (sometimes) mild sedatives as indicated.

Enhancing skin hydration and preventing dry, flaky skin are accomplished in a number of ways, depending on the child's skin characteristics and individual needs. A tepid bath with a mild soap (Dove or Neutrogena), no soap, or an emulsifying oil followed immediately by application of an emollient (within 3 minutes) assists in trapping moisture and preventing its loss. Bubble baths and harsh soaps should be avoided. The bath may need to be repeated once or twice daily, depending on the child's status; excessive bathing without emollient application only dries out the skin. Some lotions are not effective, and emollients should be chosen carefully to prevent excessive skin drying. Aquaphor, Cetaphil, and Eucerin are acceptable lotions for skin hydration. A nighttime bath followed by emollient application and dressing in soft cotton pajamas may help alleviate most nighttime pruritus.

BOX 47-3 CLINICAL MANIFESTATIONS OF ATOPIC DERMATITIS

Distribution of Lesions

Infantile form—Generalized, especially cheeks, scalp, trunk, and extensor surfaces of extremities (Fig. 47-10)

Childhood form—Flexural areas (antecubital and popliteal fossae, neck), wrists, ankles, and feet

Preadolescent and adolescent form—Face, sides of neck, hands, feet, and antecubital and popliteal fossae (to a lesser extent)

Appearance of Lesions

Infantile Form

- Erythema
- Vesicles
- Papules
- Weeping
- Oozing
- Crusting
- Scaling
- Often symmetric

Childhood Form

- Symmetric involvement
- Clusters of small erythematous or flesh-colored papules or minimally scaling patches
- Dry and may be hyperpigmented
- Lichenification (thickened skin with accentuation of creases)
- Keratosis pilaris (follicular hyperkeratosis) common

Adolescent or Adult Form

- Same as childhood manifestations
- Dry, thick lesions (lichenified plaques) common
- Confluent papules

Other Physical Manifestations

- Intense itching
- Unaffected skin dry and rough
- African-American children likely to exhibit more papular or follicular lesions than do Caucasian children
- May exhibit one or more of the following:
  - Lymphadenopathy, especially near affected sites
  - Increased palmar creases (many cases)
  - Atopic pleats (extra line or groove of lower eyelid)
  - Prone to cold hands
  - Pityriasis alba (small, poorly defined areas of hypopigmentation)
  - Facial pallor (especially around nose, mouth, and ears)
  - Bluish discoloration beneath eyes ("allergic shiners")
  - Increased susceptibility to unusual cutaneous infections (especially viral)

Sometimes colloid baths, such as the addition of 2 cups of cornstarch to a tub of warm water, provide temporary relief of itching and may help the child sleep if given before bedtime. Cool wet compresses are soothing to the skin and provide antiseptic protection.

Oral antihistamine drugs such as hydroxyzine or diphenhydramine usually relieve moderate or severe pruritus. Nonsedating antihistamines such as loratadine (Claritin) or fexofenadine (Allegra) may be preferred for daytime pruritus relief. Because pruritus increases at night, a mildly sedating antihistamine may be needed.

FIG 47-10 Atopic dermatitis. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

Occasional flare-ups require the use of topical steroids to diminish inflammation. Low-, moderate-, or high-potency topical corticosteroids are prescribed, depending on the degree of involvement, the area of the body to be treated, the child's age, the potential for local side effects (striae, skin atrophy, and pigment changes), and the type of vehicle to be used (e.g., cream, lotion, ointment). Patients receiving topical corticosteroid therapy for chronic conditions should be evaluated for risk factors for suboptimal linear growth and reduced bone density. Topical immunomodulators, a new nonsteroidal treatment for AD, are best used at the beginning of a "flare-up" just as the skin becomes red and itches. Two newer immunomodulator medications used in children with AD are tacrolimus and pimecrolimus (Walling and Swick, 2010). Tacrolimus is available in two ointment strengths (0.03% and 0.1%); the 0.03% concentration has been approved for use in children 2 years of age and older (Doss, Kamoun, Dubertret, et al., 2010). Pimecrolimus is available in a 1% cream that has no systemic accumulation or effects. This drug is approved for use in children with mild to moderate AD. Both drugs can be used freely on the face without worrying about steroid side effects.

If secondary skin infections occur in children with AD, these infections are managed with appropriate systemic antibiotics. In a subgroup of patient with moderate to severe AD, the disease may require systemic treatment (Ricci, Dondi, Patrizi, et al., 2009).

CARE MANAGEMENT

Assessment of the child with AD includes a family history for evidence of atopy, a history of previous involvement, and any environmental or dietary factors associated with the present and previous exacerbations. The skin lesions are examined for type, distribution, and evidence of secondary infection. Parents are interviewed regarding the child's behavior, especially in relation to scratching, irritability, and sleeping patterns. Exploration of the family's feelings and methods of coping is also important.

The nursing care of the child with AD is challenging. Controlling the intense pruritus is imperative if the disorder is to be successfully managed because scratching leads to new lesions and may cause secondary infection. In addition to the medical regimen, other measures can be taken to prevent or minimize the scratching. Fingernails and toenails are cut short, kept clean, and filed frequently to prevent sharp edges. Gloves or cotton stockings can be placed over the hands and pinned to shirtsleeves. One-piece outfits with long sleeves and long pants also decrease direct contact with the skin. If gloves or socks are used, the child needs time to be free from such restrictions. An excellent time to remove gloves, socks, or other protective devices is during the bath or after receiving sedative or antipruritic medication.

Conditions that increase itching are eliminated when possible. Woolen clothes or blankets, rough fabrics, and furry stuffed animals are removed from the child's environment. Because heat and humidity cause perspiration (which intensifies itching), proper dress for climatic conditions is essential. Pruritus is often precipitated by exposure to the irritant effects of certain components of common products such as soaps, detergents, fabric softeners, perfumes, and powders. Most children experience less itching when soft cotton fabrics are worn next to the skin. During cold months, synthetic fabrics (not wool) should be used for overcoats, hats, gloves, and snowsuits. Exposure to latex products, such as gloves and balloons, should also be avoided.

Clothes and sheets are laundered in a mild detergent and rinsed thoroughly in clear water (without fabric softeners or antistatic chemicals). Putting the clothes through a second complete wash cycle without using detergent reduces the amount of residue remaining in the fabric.

Preventing infection is usually accomplished by preventing scratching. Baths are given as prescribed; the water is kept tepid; and soaps (except as indicated), bubble baths, oils, and powders are avoided. Skinfolds and diaper areas need frequent cleansing with plain water. A room humidifier or vaporizer may benefit children with extremely dry skin. The skin lesions are examined for signs of infection—usually honey-colored crusts or pustules with surrounding erythema. Any signs of infection are reported to the health care practitioner.

Wet soaks and compresses are applied and medications for pruritus or infection are administered as directed. The family is given explicit instructions on the preparation and use of soaks, special baths, and topical medications, including the order of application if more than one is prescribed. It is important to emphasize that one thick application of topical medication is *not* equivalent to several thin applications and that excessive use of an agent (particularly steroids) can be hazardous. If children have difficulty remaining still for a 10- or 15-minute soak, bath, or dressing application, these can be carried out at naptime or when the child is engrossed in watching television, listening to a story, or playing with tub toys.

Diet modification is another source of frustration to parents. When a hypoallergenic diet is prescribed, parents need help to understand the reason for the diet and the guidelines for avoiding hyperallergenic foods (see Guidelines box). Because hypoallergenic diets take time before visible effects are apparent, parents need reassurance that results may not be seen immediately. If airborne allergens make eczema worse, the family is counseled about "allergy proofing" the home (see Asthma, Chapter 40).

Family Support. Parents are assured that the lesions will not produce scarring (unless secondarily infected) and that the disease is not contagious. However, the child may have repeated exacerbations and remissions. Spontaneous and permanent remission takes place at approximately 2 to 3 years of age in most children with the infantile disorder.

During acute phases, emotional stress can become intense for the family. They need time to discuss negative feelings and to be reassured that these feelings are normal. Stress tends to aggravate the

GUIDELINES

Preventing Atopy in Children

Identify Children at Risk
- Family history of allergy
- Increased immunoglobulin E in cord blood and postnatal serum
- Dry, flaky skin

Prenatal Precautions (Last Trimester)
- Avoid any known food allergens
- Avoid milk and other dairy products, peanuts, and eggs
- Minimize ingestion of other hyperallergenic foods

Postnatal Precautions
- Breast milk or casein-whey hydrolysate formula (e.g., Nutramigen, Pregestimil, Alimentum) exclusively for at least 6 months
- No solid food for first 6 months
- No cow's milk or soy formula for 12 months
- No eggs, fish, corn, citrus, peanuts, nuts, or chocolate for 12 to 18 months
- One new food added at 5- to 7-day intervals to identify possible reaction

Environmental Control
- Limited exposure to dust, molds, furry animals, and cigarette smoke

Data from Johnstone D: Strategy for intervention of food allergy in infants, *Int Pediatr* 4(4):319–325, 1989; Wood RA: Prospects for the prevention of allergy in children, *Curr Opin Pediatr* 8(6):601–605, 1995; Zeiger R, Heller S, Mellon M, et al: Effectiveness of dietary manipulation in the prevention of food allergy in infants, part II, *J Allergy Clin Immunol* 78(1 Pt 2):224–238, 1986.

severity of the condition. Therefore efforts to relieve as much anxiety as possible in both the parents and the child have a beneficial emotional and physical effect.

Seborrheic Dermatitis

Seborrheic dermatitis is a chronic, recurrent, inflammatory reaction of the skin. It occurs most commonly on the scalp (cradle cap) but may involve the eyelids (blepharitis), external ear canal (otitis externa), nasolabial folds, and inguinal region. The cause is unknown, although it is more common in early infancy, when sebum production is increased. The lesions are characteristically thick, adherent, yellowish, scaly, oily patches that may or may not be mildly pruritic. Unlike AD, seborrheic dermatitis is not associated with a positive family history for allergy and is common in infants shortly after birth and in adolescents after puberty. Diagnosis is made primarily on the basis of the appearance and the location of the crusts or scales.

CARE MANAGEMENT

Cradle cap may be prevented with adequate scalp hygiene. Frequently, parents omit shampooing the infant's hair for fear of damaging the "soft spots," or fontanels. The nurse should discuss how to shampoo the infant's hair and emphasize that the fontanel is similar to skin anywhere else on the body—it does not puncture or tear with mild pressure.

When seborrheic lesions are present, the treatment is directed at removing the crusts. Parents are taught the appropriate procedure to clean the scalp. Education may need to include a demonstration. Shampooing should be done daily with a mild soap or commercial baby shampoo; medicated shampoos are not necessary, but an antiseborrheic shampoo containing sulfur and salicylic acid may be used. Shampoo is applied to the scalp and allowed to remain on the scalp until the crusts soften. Then the scalp is thoroughly rinsed. A fine-tooth comb or a soft facial brush helps remove the loosened crusts from the strands of hair after shampooing.

Acne

Acne vulgaris is the most common skin problem treated by physicians during patients' adolescence. Acne is not caused by dirt but by testosterone, a hormone present in boys and girls that increases during puberty. It stimulates the sebaceous glands of the skin to enlarge, or produce oil, and plug the pores. Whiteheads, blackheads, and pimples are present in teenage acne.

Half of the adolescent population experience acne by the end of the teenage years. Although the disorder can appear before the age of 10 years, the peak incidence occurs in middle to late adolescence (age 16 to 17 years in girls and 17 to 18 years in boys). It is more common in boys than in girls. The degree to which an individual is affected may range from nothing more than a few isolated comedones to a severe inflammatory reaction. Although the disease is self-limiting and not life threatening, it has great significance to adolescents. Health care professionals should not underestimate the impact that acne has on teens.

Numerous factors affect the development and course of acne. Its distribution in families and a high degree of concordance in identical twins suggest hereditary factors. Premenstrual flare-ups of acne occur in nearly 70% of adolescent girls, suggesting a hormonal cause. Studies do not indicate a clear association between stress and acne, but adolescents commonly cite stress as a cause for acne outbreaks. Cosmetics containing lanolin, petrolatum, vegetable oils, lauryl alcohol, butyl stearate, and oleic acid can increase comedone production. Exposure to oils in cooking grease can be a precursor in adolescents who work over fast-food restaurant hot oils. There is no known link between dietary intake and the development or worsening of acne.

Pathophysiology

Contributors to acne development include sebum secretion, abnormal desquamation of follicles, bacterial growth, and inflammation (Kim and Armstrong, 2011). Comedogenesis (formation of comedones) results in a noninflammatory lesion that may be either an open comedone ("blackhead") or a closed comedone ("whitehead"). Inflammation occurs with the proliferation of *Propionibacterium acnes,* which draws in neutrophils, causing inflammatory papules, pustules, nodules, and cysts (Fig. 47-11).

Therapeutic Management

Successful management of acne depends on a cooperative effort among the health care provider, the adolescent, and the parents. Unlike many other dermatologic conditions, acne lesions resolve slowly and improvement may not be apparent for at least 6 weeks. Individual comedones can take several weeks to months to resolve, and papules and pustules usually resolve in about 1 week. The multifactorial causes of acne necessitate a combined approach for successful treatment. Treatment consists of general measures of care and specific treatments determined by the type of lesions involved.

General Measures. Improvement of the adolescent's overall health status is part of the general management. Adequate rest, moderate exercise, a well-balanced diet, reduction of emotional

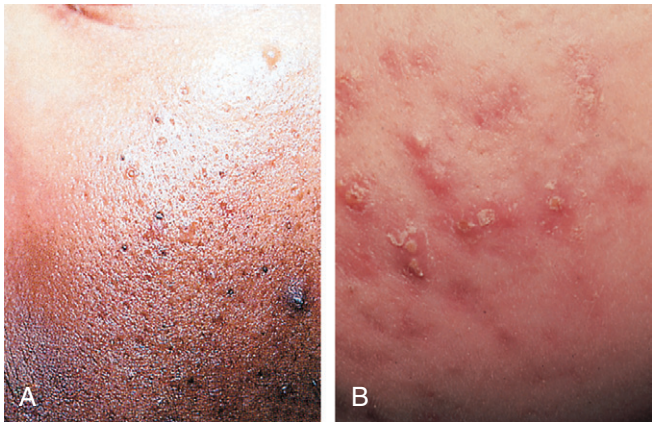

FIG 47-11 Acne vulgaris. **A,** Acne vulgaris. **B,** Comedones with a few inflammatory pustules. (From Zitelli BJ, McIntire SC, Nowalk AJ: *Zitelli and Davis' atlas of pediatric physical diagnosis,* ed 6, St Louis, 2012, Saunders.)

stress, and elimination of any foci of infection are all part of general health promotion.

Cleansing. Dirt or oil on the surface of the skin does not cause acne. Gentle cleansing with a mild cleanser once or twice daily is usually sufficient. Antibacterial soaps are ineffective and may be too drying when used in combination with topical acne medications. For some adolescents, hygiene of the hair and scalp appears to be related to the clinical activity of the acne. Acne on the forehead may improve with brushing the hair away from the forehead and more frequent shampooing.

Medications. Treatment success depends on commitment from the adolescent. Before prescribing treatment, the health care practitioner should determine the adolescent's level of comfort and readiness to begin treatment.

Tretinoin (Retin-A) is the only drug that effectively interrupts the abnormal follicular keratinization that produces microcomedones—the invisible precursors of the visible comedones. Tretinoin alone is usually sufficient for management of comedonal acne (Kim and Armstrong, 2011). Tretinoin is available as a cream, gel, or liquid. This drug can be extremely irritating to the skin and requires careful patient education for optimal usage. The patient should be instructed to begin with a pea-size dot of medication, which is divided into the three main areas of the face and then gently rubbed into each area. The medication should not be applied for at least 20 to 30 minutes after washing to decrease the burning sensation. The avoidance of the sun and the daily use of sunscreen must be emphasized because sun exposure can result in severe sunburn. Adolescents should be advised to apply the medication at night and to use a sunscreen with a sun protection factor (SPF) of at least 15 in the daytime.

Topical benzoyl peroxide is an antibacterial agent that inhibits the growth of *P. acnes* organisms. It is effective against both inflammatory and noninflammatory acne and is an effective first-line agent. This medication is available as a cream, lotion, gel, or wash. The patient should be informed that the medication may have a bleaching effect on sheets, bedclothes, and towels. The adolescent can be reassured that skin bleaching will not occur. Accommodation to the medication can be gained with a gradual increase in the strength and frequency of application.

When inflammatory lesions accompany the comedones, a topical antibacterial agent may be prescribed. These agents are used to prevent new lesions and to treat preexisting acne. Clindamycin, erythromycin, metronidazole, azelaic acid, and the combination of either benzoyl peroxide and erythromycin (Benzamycin) or benzoyl peroxide and glycolic acid are all choices for topical antibacterial therapy. The combination of 5% benzoyl peroxide and 3% erythromycin is especially beneficial, although the exact mechanism of action is not understood (Kim and Armstrong, 2011).

Systemic antibiotic therapy is used when moderate to severe acne does not respond to topical treatments. Oral antibiotics such as tetracycline, erythromycin, minocycline, and doxycycline are considered safe to use (Fanelli, Kupperman, Lautenbach, et al., 2011; Leyden and Del Rosso, 2011).

Young women with mild to moderate acne may respond well to topical treatment and the addition of an oral contraceptive pill (OCP). OCPs reduce the endogenous androgen production and decrease the bioavailability of the woman's circulating androgens. Both of these actions result in decreased acne.

Isotretinoin, 13-cis-retinoic acid (Accutane), is a potent and effective oral agent that is reserved for severe cystic acne that has not responded to other treatments. Isotretinoin is the only agent available that affects factors involved in the development of acne. However, treatment with isotretinoin should be managed *only* by a dermatologist. Adolescents with multiple, active, deep dermal or subcutaneous cystic and nodular acne lesions are treated for 20 weeks. Multiple side effects can occur, including dry skin and mucous membranes, nasal irritation, dry eyes, decreased night vision, photosensitivity, arthralgia, headaches, mood changes, aggressive or violent behaviors, depression, and suicidal ideation. Adolescents taking this drug should be monitored for depression, depressive symptoms, and suicidal ideation (Misery, 2011). The drug should be given only at the recommended doses for no longer than the recommended duration. The most significant side effects of this drug are the teratogenic effects. Isotretinoin is absolutely contraindicated in pregnant women. Sexually active young women must use an effective contraceptive method during treatment and for 1 month after treatment. Patients receiving isotretinoin should also be monitored for elevated cholesterol and triglyceride levels. Significant elevation may require discontinuation of the medication.

CARE MANAGEMENT

Because acne is so common and its appearance may seem so mild, the health care provider may underestimate the relative importance of the disease to the adolescent. The nurse should assess the individual adolescent's level of distress, current management, and perceived success of any regimen before initiating a referral. If adolescents do not perceive the acne to be a problem, they may lack motivation to follow the treatment plan.

The nurse can provide ongoing support for the adolescent when a treatment plan is initiated. The family is also encouraged to support the adolescent in his or her efforts. Use of medications and basic skin care information should be discussed in detail with the adolescent. Written instructions should accompany the verbal discussion. Information to dispel myths regarding the use of abrasive cleansing products can prevent unnecessary costs and trauma to the skin.

Teenagers need education about the factors that aggravate and damage the skin, such as too vigorous scrubbing. In addition, picking, squeezing, and manual expression with fingernails break down the ductal walls of lesions and cause the acne to worsen. Mechanical irritation, such as vinyl helmet straps that

rub areas predisposed to acne, can also cause the development of lesions.

THERMAL INJURY

Burns

Burn injuries are usually attributed to extreme heat sources but may also result from exposure to cold, chemicals, electricity, or radiation. Most burns are relatively minor and do not require definitive medical treatment. However, burns involving a large body surface area, critical body parts, or the geriatric or pediatric population often benefit from treatment in specialized burn centers. The American Burn Association has established criteria to guide decisions regarding the severity of injury and the need for transfer for specialized care.*

When burns are categorized according to the patient's age and type of injury, the following patterns become apparent: (1) hot-water scalds are most frequent in toddlers; (2) flame-related burns are more common in older children; (3) 10% to 20% of documented cases of child abuse include burn injuries (Herndon, 2007); and (4) children playing with matches or lighters account for 1 in 10 house fires.

The extent of tissue destruction is determined by the intensity of the heat source, the duration of contact or exposure, the conductivity of the tissue involved, and the rate at which the heat energy is dissipated by the skin. A brief exposure to high-intensity heat from a flame can produce burn injuries similar to those induced by long exposure to less intense heat in hot water.

Characteristics of Burn Injury

The physiologic responses, treatment modalities, prognosis, and disposition of the injured child are all directly related to the *amount of tissue destroyed.* Therefore the severity of the burn injury is assessed on the basis of the percentage of total body surface area (TBSA) burned and depth of the burn. Among children in the school-age group or younger age-groups, a burn that is 10% TBSA can be life threatening if not treated correctly. Other important factors in determining the seriousness of the injury are the location of the wounds, the child's age and general health, the causative agent, the presence of respiratory involvement, and any associated injury or condition.

Type of Injury. The majority of burns result from contact with thermal agents such as a flame, hot surfaces, or hot liquids. Electrical injuries caused by household current have the greatest incidence in young children, who insert conductive objects into electrical outlets and bite or suck on connected electrical cords (Herndon, 2007). These burns occur most commonly during the spring and summer months and are also associated with risk-taking behaviors in boys. Direct contact with high- or low-voltage current, as well as lightning strikes, is the most frequent mechanism of injury. The resistance of the tissue and the path of the electric current are responsible for the damage incurred. Electric current travels through the body following the path of least resistance, which involves the tissues, fluid, blood vessels, and nerves. A more localized burn is produced if skin resistance is high at the area of contact, and a more systemic pattern of injury is produced if skin resistance is low. Often compared with a crush injury, serious electrical trauma results from current passing through vital organs, muscle compartments, and nerve or vascular pathways. Loss of limbs, cardiac fibrillation, respiratory collapse, and burns are common occurrences after exposure to electrical energy. Criteria for admission, as derived from evidence-based practice for electrical burn injuries, includes a history of loss of consciousness, electrocardiographic (ECG) changes, 10% TBSA affected, or the need for monitoring an affected extremity. Cardiac monitoring is therefore included in standard burn care when ECG changes are identified on admission (Arnoldo, Klein, and Gibran, 2006).

Chemical burns are seen in the pediatric population and can cause extensive injury. The severity of injury is related to the chemical agent (acid, alkali, or organic compound) and the duration of contact. The mechanism of injury differs from that in other burns in that there is a chemical disruption and alteration of the physical properties of the exposed body area. Noxious agents exist in many cleaning products commonly found in the home. In addition to concern for localized damage, the potential for systemic toxicity must be addressed. Of particular concern is the exposure of the eyes to chemical agents, the ingestion of caustic substances, and inhalation of toxic gases produced from chemicals.

Extent of Injury. The extent of a burn is expressed as a percentage of the TBSA. This is most accurately estimated by using specially designed age-related charts (Fig. 47-12). It is more efficient to use a chart designed to assign body proportions to children of different ages.

Depth of Injury. A thermal injury is a three-dimensional wound that is also assessed in relation to depth of injury. Traditionally, the terms *first, second,* and *third degree* have been used to describe the depth of tissue injury. However, with the current emphasis on wound healing, these have been replaced by more descriptive terms based on the extent of destruction to the epithelializing elements of the skin (Fig. 47-13).

Superficial (first-degree) burns are usually of minor significance. This type of injury involves the epidermal layer only. There is often a latent period followed by erythema. Tissue damage is minimal, and there is no blistering. The protective functions of the skin remain intact, and systemic effects are rare. Pain is the predominant symptom, and the burn heals in 5 to 10 days without scarring. A mild sunburn is an example of a superficial burn.

Partial-thickness (second-degree) burns involve the epidermis and varying degrees of the dermal layer. These wounds are painful, moist, red, and blistered. With superficial partial-thickness burns, dermal elements are intact and the wound should heal in approximately 14 to 21 days with variable amounts of scarring (Fig. 47-14). The wound is extremely sensitive to temperature changes, exposure to air, and light touch. Although classified as second-degree or partial-thickness burn, deep dermal burns resemble full-thickness injuries in many respects except that sweat glands and hair follicles remain intact. The burn may appear mottled, with pink, red, or waxy white areas exhibiting blisters and edema formation. Systemic effects are similar to those encountered with full-thickness burns. Although many of these wounds heal spontaneously, healing time may be extended beyond 21 days. These burn wounds often heal with extensive scarring.

Full-thickness (third-degree) burns are serious injuries that involve the entire epidermis and dermis and extend into subcutaneous tissue (Fig. 47-15). Nerve endings, sweat glands, and hair follicles are destroyed. The burn varies in color from red to tan, waxy white, brown, or black and is distinguished by a dry, leathery appearance (Fig. 47-16). Normally, full-thickness burns lack sensation in the area of injury because of the destruction of nerve endings. However, most full-thickness burns have superficial and partial-thickness burned areas at the periphery of the burn, where nerve

endings are intact and exposed. As the peripheral fibers regenerate, painful sensations return. Consequently, children often experience severe pain related to the size and depth of the burn. Full-thickness wounds are not capable of reepithelialization and require surgical excision and grafting to close the wound.

Fourth-degree burns are full-thickness burns that involve underlying structures such as muscle, fascia, and bone. The wound appears dull and dry, and ligaments, tendons, and bone may be exposed (see Fig. 47-16).

TABLE 47-9 SEVERITY GRADING SYSTEM ADOPTED BY THE AMERICAN BURN ASSOCIATION

	MINOR*	MODERATE	MAJOR
Partial-thickness burns (% TBSA)	<10	10-20	>20
Full-thickness burns			All
Treatment	Usually outpatient; may require 1-day to 2-day admission	Admission to hospital, preferably one with expertise in burn care	Admission to a burn center

From Vaccaro P, Trofino RB: Care of the patient with minor to moderate burns. In Trofino RB, editor: *Nursing care of the burn-injured patient,* Philadelphia, 1991, FA Davis.
TBSA, Total body surface area.
*Minor burns exclude any burn involving the face, hands, feet, perineum, or crossing joints; electrical burns; any injury complicated by the presence of inhalation injury or concomitant trauma; and children with psychosocial factors affecting the injury.

Severity of Injury. Burns are classified as minor, moderate, or major, which is useful in determining the disposition of the patient for treatment. Burn patients are categorized as (1) those with a major burn injury, who require the services and facilities of a specialized burn center; (2) those with a moderate burn, who may be treated in a hospital with expertise in burn care; and (3) those with minor injuries, who may be treated on an outpatient basis. The extent and depth of the burn (Table 47-9), the causative agent, the body area involved, the patient's age, and concomitant injuries and illnesses determine the severity of the injury.

Because the skin of infants is so thin, they are likely to sustain deeper injuries compared with older children. Children younger than 2 years, especially 6 months or younger, have a significantly higher mortality rate than older children with burns of similar magnitude. Acute or chronic illnesses or superimposed injuries also complicate burn care and response to treatment.

Inhalation Injury. Trauma to the tracheobronchial tree often follows inhalation of heated gases and toxic chemicals produced during combustion. Although direct thermal injury to the upper airway may occur, heat damage below the vocal cords is rare. Inspired heated air is cooled in the upper airway before reaching the trachea. Reflex closure of the cords and laryngospasm also prevent full inhalation. However, evidence of direct thermal injury to the upper airway includes burns of the face and lips, singed nasal hairs, and laryngeal edema. Clinical manifestations may be delayed as long as 24 to 48 hours. Wheezing, increasing secretions, hoarseness, wet rales, and carbonaceous secretions are signs of respiratory tract involvement. Upper airway obstruction is often associated with burn shock and fluid resuscitation. In such situations, endotracheal intubation may also be necessary to preserve a patent airway.

Inhalation of carbon monoxide is suspected when the injury has occurred in an enclosed space. Mucosal erythema and edema followed by sloughing of the mucosa are manifestations of respiratory

		Wound Appearance	Wound Sensation	Course of Healing
Partial-Thickness Burn	1st Degree	Epidermis remains intact and without blisters Erythema; skin blanches with pressure	Painful	Discomfort lasts 48–72 hours. Desquamation occurs in 3–7 days.
Partial-Thickness Burn	2nd Degree	Wet, shiny, weeping surface Blisters Wound blanches with pressure	Painful Very sensitive to touch, air currents	Superficial partial-thickness burn heals in <21 days. Deep partial-thickness burn requires >21 days for healing. Healing rates vary with burn depth and presence or absence of infection.
Full-Thickness Burn	3rd Degree	Color variable (i.e., deep red, white, black, brown) Surface dry Thrombosed vessels visible No blanching	Insensate (↓ pinprick sensation)	Autografting is required for healing.
Full-Thickness Burn	4th Degree	Color variable Charring visible in deepest areas Extremity movement limited	Insensate	Amputation of extremities is likely. Autografting is required for healing.

FIG 47-13 Classification of burn depth according to depth of injury. (From Black JM: *Medical-surgical nursing: clinical management for positive outcomes,* ed 8, Philadelphia, 2008, Saunders.)

tract injury. A mucopurulent membrane replaces the mucosal lining and seriously compromises respiration and ventilation. A significant increase in mortality has been observed when inhalation injury and pneumonia are both present. Deep burns, especially those encircling the thorax, may cause restriction of chest excursion as a result of edema and inelastic eschar formation. Young children are particularly at risk because of the pliability of the skeletal structure.

Pathophysiology

Thermal injuries produce both local and systemic effects that are related to the extent of tissue destruction. In superficial burns, the tissue damage is minimal. In partial-thickness burns, there is considerable edema and more severe capillary damage. With a major burn greater than 30% TBSA, there is a systemic response involving an increase in capillary permeability, allowing plasma proteins, fluids, and electrolytes to be lost. Maximum edema formation in a small wound occurs about 8 to 12 hours after injury. After a larger injury, hypovolemia, associated with this phenomenon, will slow the rate of edema formation, with maximum effect at 18 to 24 hours.

Another systemic response is anemia, caused by direct heat destruction of red blood cells (RBCs), hemolysis of injured RBCs, and trapping of RBCs in the microvascular thrombi of damaged cells. A long-term decrease in the number of RBCs may occur as a result of increased RBC fragility. Initially, there is an increased blood flow to the heart, brain, and kidneys, with decreased blood flow to the gastrointestinal tract. There is an increase in metabolism to maintain body heat, providing for the increased energy needs of the body.

Complications. Thermally injured children are subject to a number of serious complications, both from the wound and from systemic alterations resulting from the injury. The immediate threat to life is related to airway compromise and profound shock. During healing, infection—both local and systemic sepsis—is the primary complication. Mortality associated with thermal trauma in children increases with the severity of injury and decreases as age advances. In children older than 3 years, the mortality rate is similar to that of adults. Below this age, the survival rate with burns and their associated complications lessens considerably.

A less apparent respiratory tract injury is inhalation of carbon monoxide. Carbon monoxide has a greater affinity for hemoglobin than does oxygen, thereby depriving peripheral tissues and oxygen-dependent organs (e.g., the heart and brain) of the oxygen needed for survival. Treatment for either of these two problems is 100% oxygen, which reverses the situation rapidly.

Pulmonary problems are a major cause of fatality in children with either thermal burns or complications in the respiratory tract. Early in the postburn period, most pulmonary infections result from nosocomial exposure, immobility, and abdominal distention. The hematogenous variety occurs later and is related to the septic burn wound or other foci, such as phlebitis at the site of an invasive intravenous (IV) line. Respiratory problems include inhalation injuries, aspiration in unconscious patients, bacterial pneumonia, pulmonary edema, pulmonary embolus, post-traumatic pulmonary insufficiency, and atelectasis. The most common cause of respiratory failure in the pediatric age-group is bacterial pneumonia, which requires prolonged intubation and sometimes a tracheostomy. Tracheostomies increase the incidence of serious complications and are performed only in extreme cases.

A less common complication is pulmonary edema resulting from fluid overload or acute respiratory distress syndrome (ARDS) in association with gram-negative sepsis. ARDS results from pulmonary capillary damage and leakage of fluid into the interstitial spaces of the lung. A loss of compliance and interference with oxygenation are the consequences of pulmonary insufficiency in conjunction with systemic sepsis.

Wound Sepsis. Sepsis is a critical problem in the treatment of burns and an ever-present threat after the shock phase. Decreased level of consciousness and lethargy are early signs of sepsis. Initially, burn wounds are relatively pathogen free unless they are contaminated with potentially infectious material, such as dirt or polluted water. However, dead tissue and exudate provide a fertile field for bacterial growth. On approximately the third postburn day, early colonization of the wound surface by a preponderance of gram-positive organisms (primarily staphylococci) changes to predominantly gram-negative opportunistic organisms, particularly *Pseudomonas aeruginosa.* By the fifth postburn day, bacterial invasion is well under way beneath the surface of the burn wound. Early surgical excision of eschar together with placement of autograft reduces the incidence of sepsis.

Therapeutic Management

Emergency Care. The initial management of the burn patient begins at the scene of injury. The first priority is to stop the burning process (see Emergency box). The child should then be transported immediately to the nearest medical facility for treatment and evaluation. The child and the family are usually extremely frightened and anxious; sensitivity to their emotional state and reassurance should be provided during the transport process.

Stop the Burning Process. The chief aim of rescue in flame burns is to smother the fire, not fan it. Children tend to panic and run, which spreads the flames and makes assistance more difficult. The injured child should be placed in a horizontal position and rolled in a blanket, rug, or similar article, with care taken not to cover the head and face because of the danger of inhalation of toxic fumes. If nothing is available, the victim should lie down and roll over

EMERGENCY

Burns

Minor Burns

- Stop the burning process:
  - Apply cool water to the burn or hold the burned area under cool running water.
  - Do not use ice.
- Do not disturb any blisters that form unless the injury is from a chemical substance.
- Do not apply anything to the wound.
- Cover with a clean cloth if risk for damage or contamination.
- Remove burned clothing and jewelry.

Major Burns

- Stop the burning process:
  - Flame burns—smother the fire.
  - Place victim in the horizontal position.
  - Roll victim in a blanket or similar object; avoid covering the head.
- Assess for an adequate airway and breathing.
- If child is not breathing, begin mouth-to-mouth resuscitation.
- Remove burned clothing and jewelry.
- Cover wound with a clean cloth.
- Keep victim warm.
- Transport to medical aid.
- Begin intravenous and oxygen therapy as prescribed.

slowly to extinguish the flames. Remaining in the vertical position may cause the hair to ignite or the inhalation of flames, heat, or smoke.

Major burns with large amounts of denuded skin should not be cooled. Heat is rapidly lost from burned areas, and additional cooling leads to a drop in core body temperature and potential circulatory collapse. Wet dressings also promote vasoconstriction because of cooling, resulting in impaired circulation to the burned area and increased tissue damage. Chemical burns require continuous flushing with large amounts of water before transport to a medical facility. The use of neutralizing agents on the skin is contraindicated because a chemical reaction is initiated and further injury may result. If the chemical is in powder form, the addition of water may spread the caustic agent. The powder should be brushed off if possible before flushing the area.

Burned clothing is removed to prevent further damage from smoldering fabric and hot beads of melted synthetic materials. Jewelry is removed to eliminate the transfer of heat from the metal and constriction resulting from edema formation. This also provides access to the wound and prevents painful removal later.

Assess the Victim's Condition. As soon as the flames are extinguished, the child is assessed. Airway, breathing, and circulation are the primary concerns. Cardiopulmonary complications may result from exposure to electric current, inhalation of toxic fumes and smoke, hypovolemia, and shock. Emergency measures are instituted as appropriate.

Cover the Burn. The burn wound should be covered with a clean dry cloth to prevent contamination, decrease pain by eliminating air contact, and prevent hypothermia. No attempt should be made to treat the burn. Application of topical ointments, oils, or other home remedies is contraindicated.

Transport the Child to Medical Aid. The child with an extensive burn is not given anything by mouth to avoid aspiration in the presence of paralytic ileus and upper airway edema and to prevent water intoxication. The child is transported to the nearest medical facility. If this cannot be accomplished within a relatively short period, IV access should be established, if possible, with a large-bore catheter. Oxygen is administered, if available, at 100%. A report of the initial assessment, associated trauma, and any interventions implemented is given to the medical facility assuming care of the child.

Provide Reassurance. Providing reassurance and psychologic support to both the family and the child helps immeasurably during the period of postinjury crisis. Reducing anxiety conserves energy the family and child will need to cope with the physiologic and emotional stress of injury.

Minor Burns. Treatment of burns classified as minor can usually be managed adequately on an outpatient basis when it is determined that the parent can be relied on to carry out instructions for care and observation. Patients with less-than-optimum circumstances may require close follow-up to ensure adherence with treatment.

The wound is cleansed with a mild soap and tepid water. **Débridement** of the wound includes removal of any embedded debris, chemicals, and devitalized tissue. Removal of intact blisters remains controversial. Some authorities argue that blisters provide a barrier against infection; others maintain that blister fluid is an effective medium for the growth of microorganisms. However, blisters should be broken if the injury is from a chemical agent to control absorption. Most health care practitioners favor covering the wound with an antimicrobial ointment to reduce the risk for infection and to provide some form of pain relief. The dressing consists of nonadherent fine-mesh gauze placed over the ointment and a light wrap of gauze dressing that avoids interference with movement. This helps keep the wound clean and protect it from trauma. The caregiver is instructed to wash the wound, reapply the dressing, and return the child to the office or clinic as directed for wound observation. The frequency of dressing changes may vary from every other day to once a day.

Some health care practitioners prefer an occlusive dressing, such as a hydrocolloid, which is placed over the wound after cleansing. Hydrogel dressings, which are soothing and nonadherent, may also be used. The dressing is changed when leakage occurs—at regular intervals or at least weekly. This method eliminates the discomfort associated with frequent dressing changes but limits visualization of the wound surface.

If there is a high probability of infection or other complications or if there is doubt about the ability to carry out instructions, the caregiver may be directed to bring the patient in daily for dressing changes and inspection. Another option is have a nurse make a home visit to inspect the wound and change the dressing. Frequent removal of the dressing is an effective mode of débridement. Soaking the dressing in tepid water or normal saline before removal helps loosen the dressing and debris and reduce discomfort. Burns of the face are usually treated by an open method. The wound is washed and débrided in the same manner, and a thin film of antimicrobial ointment is applied.

A tetanus history is obtained on admission. If there is no history of immunization or if more than 5 years have passed since the last immunization, tetanus prophylaxis is administered. A mild analgesic such as acetaminophen is usually sufficient to relieve discomfort; the antipyretic effect of the drug also alleviates the sensation of heat.

Most minor burns heal without difficulty; however, hospitalization is indicated if the wound margin becomes erythematous, gross purulence is noted, or the child develops evidence of systemic reaction, such as fever or tachycardia. The child should also be evaluated for functional impairment, and the caregiver should be instructed in the exercise and ambulation program. After wound healing, an evaluation of scar maturation and range of motion will indicate any need for further therapy.

Major Burns. The first priority is airway maintenance. The inhalation of noxious agents or respiratory burns is suggested when there is a history of injury in an enclosed space; edema of the oral and nasal membranes; thermal injury to the face, nares, and upper torso; hyperemia; and blisters or evidence of trauma to the upper respiratory passages. When respiratory involvement is suspected or evident, 100% oxygen is administered and blood gas values, including carbon monoxide levels, are determined.

If the child exhibits changes in sensorium, air hunger, or other signs of respiratory distress, an endotracheal tube is inserted to maintain the airway. When severe edema of the face and neck is anticipated, intubation is performed before swelling makes intubation difficult or impossible. Controlled intubation is preferred to an emergency intubation. Intubation allows for the delivery of humidified oxygen, the removal of secretions from respiratory passages, and the provision of ventilatory support. When full-thickness burns encircle the chest, constricting eschar may limit chest wall excursion and ventilation of the child becomes more difficult. Escharotomy of the chest relieves this constriction and improves ventilation.

Fluid Replacement Therapy. The objectives of fluid therapy are to (1) compensate for water and sodium lost to traumatized areas and interstitial spaces, (2) reestablish sodium balance, (3) restore circulating volume, (4) provide adequate perfusion, (5) correct acidosis, and (6) improve renal function.

Fluid replacement is required during the first 24 hours because of fluid shifts that occur after the injury. Various formulas are used to calculate fluid needs, and the one adopted depends on the preference of the health care practitioner. Crystalloid solutions are used during this initial phase of therapy. Parameters such as vital signs (especially heart rate), urinary output volume, adequacy of capillary filling, and state of sensorium determine adequacy of fluid resuscitation.

After the initial 24-hour period, theoretically there is a capillary seal and capillary permeability is restored. Colloid solutions such as albumin, Plasma-Lyte, or fresh-frozen plasma are useful in maintaining plasma volume. However, children with burn injuries usually require fluids in excess of their calculated maintenance and replacement volume. Reasons for this may include underestimation of burn size (particularly in pediatric patients), pulmonary injury that sequesters resuscitation fluid in the lung, electrical injury with greater tissue destruction than that which is visible, and a delay in the initiation of fluid resuscitation. Irreversible burn shock that persists despite aggressive fluid resuscitation remains a significant cause of death in the immediate postburn period. Fluid balance may continue to be a problem throughout the course of treatment, especially during periods in which there may be considerable evaporative loss from the wound.

Nutrition. The enhanced metabolic requirements and catabolism in severe burns make nutritional needs of paramount importance and often difficult to satisfy. To avoid protein breakdown, the diet must provide sufficient calories to meet the increased metabolic needs and enough protein. Hypoglycemia can result from the stress of the burn injury because the liver glycogen stores are rapidly depleted.

A high-protein, high-calorie diet is encouraged. Many children have poor appetites and are unable to meet energy requirements solely by oral feeding. Oral feedings are encouraged unless the child is intubated or paralytic ileus persists. Most children with burns in excess of 25% TBSA require supplementation with tube feeding. Early and continued nutritional support is an important part of therapy for seriously burned patients. Enteral feeding provides direct nourishment to the gastrointestinal tract and helps reverse the defective gut barrier that accompanies burn shock (Purdue, 2007). Children who require enteral supplementation must be monitored for feeding intolerance and tube malposition. The nurse should also monitor and report any abdominal distention, diarrhea, or electrolyte and metabolic deviations. If nutritional requirements cannot be met entirely by the enteral route, parenteral hyperalimentation is used to supplement intake. However, enteral feeding increases blood flow in the intestinal tract, preserves gastrointestinal function, and minimizes bacterial translocation by decreasing mucosal atrophy of the intestines. These factors make enteral feeding the preferred route of nutritional support (Herndon, 2007).

To facilitate growth and proliferation of epithelial cells, administration of vitamins A and C is begun early in the postburn period. Zinc is also supplemented because of its important role in wound healing and epithelialization.

Medication. Antibiotics are usually not administered prophylactically. The administration of systemic antibiotics to control wound colonization is not indicated because decreased circulation to the injured area prevents delivery of the medication to areas of deepest injury. Surveillance cultures and monitoring of the clinical course provide the most reliable indicators of developing infection. Appropriate antibiotics are instituted to treat the specific identified organism. Otitis media should not be overlooked as a source of fever in the pediatric population (Herndon, 2007).

Some form of sedation and analgesia is required in the care of burned children. Morphine sulfate is the drug of choice for severe burn injuries. Morphine has extensive distribution but is metabolized rapidly; continuous infusion or frequent administration is needed for pain management in burns. Morphine is administered intravenously and titrated to individual needs. The unstable circulatory status and edema formation preclude intramuscular or subcutaneous administration. When combined, midazolam (Versed) and fentanyl (Sublimaze) also provide excellent IV sedation and analgesia to control procedural pain in children with burns (Herndon, 2007). The oral form of fentanyl, Oralet, provides effective analgesia in a convenient form that children can suck. Dosage monitoring is important because tolerance to opioids may develop. IV analgesics are most effective when they are administered just before the onset of procedural pain.

The use of short-acting anesthetic agents, such as propofol (Diprivan) and nitrous oxide, has proved beneficial in eliminating procedural pain. Pharyngeal reflexes remain intact, thus ensuring a patent airway. Propofol is an IV sedative hypnotic agent that produces sedation in less than 1 minute and lasts only a few minutes. Nitrous oxide is a useful short-term analgesic when given in a mixture of gases on a fixed ratio of 50% nitrous oxide and 50% oxygen (Annequin, Carbajal, Chauvin, et al., 2000). Initiation of action is approximately 1 minute, with peak effect reached in 3 to 5 minutes. Nitrous oxide is useful to alleviate anxiety and raise the threshold of pain during procedures. The child may self-administer the nitrous oxide mixture with assistance. For any conscious or unconscious sedation, the child must be monitored continuously during the procedure (see Preoperative Care, Chapter 39; and Pain Assessment and Pain Management, Chapter 30).

Management of the Burn Wound. After the initial period of shock and the restoration of fluid balance, the primary concern is the burn wound. The objectives of wound management include prevention of infection, removal of devitalized tissue, and closure of the wound. The application of dressings and topical antimicrobial therapy reduce pain by minimizing the exposure to air.

Primary Excision. In children with large, full-thickness burn wounds, excision is performed as soon as the patient is hemodynamically stable after initial resuscitation. Because the burn wound precipitates an exaggerated physiologic response, many complications do not resolve until the eschar is excised and the wound is closed. Early excision of deep partial- and full-thickness burns reduces the incidence of infection and the threat of sepsis.

Débridement. Partial-thickness wounds require débridement of devitalized tissue to promote healing. Débridement is painful and requires analgesia and a sedative before the procedure. Medications given for pain need to be readily available during this procedure and may need to be titrated up during the procedure. Hydroxyzine and diphenhydramine are often needed for itching that occurs after whirlpool and débridement. The itching becomes particularly bothersome as the burns heal.

Hydrotherapy is used to cleanse the wound and involves soaking in a tub or showering at least once a day for no more than 20 minutes. The water acts to loosen and remove sloughing tissue, exudate, and topical medications. Hydrotherapy helps cleanse not only the wound but also the entire body and aids in maintenance of range of motion. Mesh gauze serves to entrap the exudative slough and is readily removed during hydrotherapy. Any loose tissue is carefully trimmed away before the wound is redressed.

Topical Antimicrobial Agents. Methods used for managing the burn wound include:

- Exposure—Wounds are left open to air; crust forms on partial-thickness wounds, and eschar forms on full-thickness burns.
- Open—Topical antimicrobial agent is applied directly to the wound surface, and the wound is left uncovered.
- Modified—Antimicrobial agent is applied directly or impregnated into thin gauze and applied to the wound; gauze or net secures the area.
- Occlusive—Antimicrobial agent is impregnated in gauze or applied directly to the wound; multiple layers of bulky gauze are placed over the primary layer and secured with gauze or net.

All of these methods provide wound coverage and use some type of topical agent. Topical agents do not eliminate organisms from the wound but can effectively inhibit bacterial growth. To be effective, a topical application must be nontoxic, capable of diffusing through eschar, harmless to viable tissue, inexpensive, and easy to apply. A topical ointment should not encourage the development of resistant strains of bacteria and should produce minimal electrolyte derangement. A variety of specific agents are available; examples include Bacitracin, silver sulfadiazine (Thermazene), collagenase (Santyl), and mafenide acetate (Sulfamylon). Some topical agents are packaged and prepared on a fine-meshed gauze that allows ease of application. The gauze provides necessary protection for the wound, maximizes patient comfort, increases rate of healing, decreases the necessity for frequent dressing changes, and is cost effective. Examples include a nanocrystalline film of pure silver (Acticoat), a hydrofiber with ionic silver (Aquacel Ag), a flexible nylon mesh matrix with oat-beta glucan and silver (Glucan Silver Matrix), and a silicone foam dressing with silver (Mepilex Ag).

Biologic Skin Coverings. Permanent coverage of extensive burns is a prolonged process that requires repeated operative procedures using general anesthesia for atraumatic care in débridement and grafting. Early closure shortens the period of metabolic stress and decreases the likelihood of burn wound sepsis. In the acute phase, biologic dressings cover and protect the wound from contamination, reduce fluid and protein loss, increase the rate of epithelialization, reduce pain, and facilitate movement of joints to retain range of motion.

Allograft (homograft) skin is obtained from human cadavers that are screened for communicable diseases. Allograft is particularly useful in the coverage of surgically excised deep partial- and full-thickness wounds in extensive burns when available donor sites are limited. Severe immunosuppression occurs in massively burned children, and the allograft becomes adherent. The allograft can remain in place until suitable donor sites become available. Typically, rejection is seen approximately 3 to 4 weeks after application (Herndon, 2007). The availability of tissue banks and a supply of suitable donors limit the use of allografts.

Xenograft from a variety of species, most notably pigs, is commercially available. In large burns, the porcine xenograft is commonly applied when extensive early débridement is indicated to cover a partial-thickness burn; this provides a temporary covering for the wound until an available autograft can be applied to the full-thickness areas (Herndon, 2007). Pigskin dressings are replaced every 1 to 3 days. They are particularly effective in children with partial-thickness scald burns of the hands and face because they allow relatively pain-free movement, which reduces contracture formation and has the added benefit of improving appetite and morale.

FIG 47-17 Removal of split-thickness skin graft with a dermatome.

When applied early to a superficial partial-thickness injury, biologic dressings stimulate epithelial growth and faster wound healing. However, biologic dressings must be applied to clean wounds. If the dressing covers areas of heavy microbial contamination, infection occurs beneath the dressing. In the case of partial-thickness burns, such infection may convert the wound to a full-thickness injury.

Synthetic skin coverings are available for the management of partial-thickness burn wounds. Ideally, the dressing should provide the properties of human skin, including adherence, elasticity, durability, and hemostasis. Synthetic skin substitutes are readily available, have an indefinite shelf life, and are relatively inexpensive.

Synthetic dressings are composed of a variety of materials and can be used successfully in the management of superficial partial-thickness burns and donor sites. Examples include adherent elastic films; hydroactive materials; or colloidal suspensions that are usually permeable to air, vapor, and fluids.

Biobrane is a flexible silicone-nylon membrane bonded to collagenous peptides of porcine skin. Calcium alginate is another treatment for donor sites. As with biologic dressings, it is important that the wound be free of debris before the dressing is applied. Body temperature elevation or evidence of purulence, erythema, or cellulitis around the wound edges may indicate that the wound has become infected beneath the dressing. If this occurs, prompt discontinuance of the synthetic dressing is indicated. All synthetic dressings are reputed to hasten wound healing and reduce discomfort.

Permanent Skin Coverings. Permanent coverage of deep partial- and full-thickness burns is usually accomplished with a split-thickness skin graft. This graft consists of the epidermis and a portion of the dermis removed from an intact area of skin by a special instrument, the dermatome (Fig. 47-17). With extensive burns, it is often difficult to find enough viable skin to cover the wounds; therefore available donor sites and special techniques are used. Split-thickness skin grafts may be sheet graft or mesh graft.

Sheet Graft. A sheet of skin removed from the donor site is placed intact over the recipient site and sutured in place; this is used in areas where cosmetic results are most visible (Fig. 47-18).

Mesh Graft. A sheet of skin is removed from the donor site and passed through a mesher, which produces tiny slits in the skin that allow the skin to cover 1.5 to 9 times the area of the sheet graft; this results in a less desirable cosmetic and functional outcome (Fig. 47-19).

FIG 47-18 Sheet graft.

FIG 47-19 Mesh graft.

The donor site is dressed with synthetic wound coverings or fine-mesh gauze until the dressing separates at 10 to 14 days when the wound is healed. Dressings are not changed on donor sites to avoid damage to newly healed, delicate epithelium. Healed donor sites are available for reharvesting in patients with extensive burns and limited undamaged skin, but the quality of skin is decreased when multiple grafts are taken.

Artificial Skin. The development of Integra, a product that allows the dermis to regenerate, has produced significant improvement in burn wound healing and decreased scar formation. It is applied to partial- and full-thickness burns. The two-layer membrane is made of collagen (a fibrous protein from animal tendons and cartilage) and silicone rubber (i.e., Silastic). The Silastic layer is peeled off after the dermis is formed. The application of artificial skin does not replace the grafting procedure, but it prepares the burn wound to accept an ultrathin autograft. Advantages include faster healing of the burn wound when integrity of the dermis is restored, faster healing of donor sites with the use of ultrathin grafts, and restoration of sweat glands and hair follicles. A disadvantage is its high cost.

Cultured Epithelium. When burns are extensive and donor sites for split-thickness skin grafting are limited, it is possible to culture cells from a full-thickness skin biopsy and produce coherent sheets that can be applied to clean, excised full-thickness wounds. Epithelial cell culture grafts offer the possibility of an unlimited source of autografts in patients with extensive burns. Cultured epithelial autografts are effective in early wound closure. The child's own skin is fractionated and cultured in a porcine media to form a thin epithelial layer that is applied to the burn wound. This technique offers an improved rate of survival in patients with extensive burns and limited donor sites.

Prognosis. Children differ from adults in their responses to thermal injury, and the mortality rates in young children are significantly higher than those in older children and adults. Mortality is greatest for children younger than 48 months. Many children who do survive have long-term functional and cosmetic impairments.

CARE MANAGEMENT

Because the care of burned children encompasses a broad range of skills, nursing care has been divided into segments that correspond with the major phases of burn treatment. The acute phase, also referred to as the *emergent* or *resuscitative phase,* involves the first 24 to 48 hours. The management phase extends from the completion of adequate resuscitation through wound coverage. The rehabilitative phase begins when the majority of the wounds have healed and rehabilitation has become the predominant focus of the care plan. This phase continues until all reconstructive procedures and corrective measures are accomplished (often a period of months or years).

Acute Phase. The primary emphasis during the emergent phase is the treatment of burn shock and the management of pulmonary status. Monitoring vital signs, output, fluid infusion, and respiratory parameters are ongoing activities in the hours immediately after injury. IV infusion is begun immediately and is regulated to maintain a urinary output of at least 1 to 2 mL/kg in children weighing less than 30 kg (66 lb); an output of 30 to 50 mL/hr is expected in children weighing more than 30 kg. Urinary output and specific gravity, vital signs, laboratory data, and objective signs of adequate hydration guide the rate of fluid administration.

Children who are hospitalized with burns require constant observation and assessment for complications. Alterations in electrolyte balance produce clinical symptoms of confusion, weakness, cardiac irregularities, and seizures. Changes in respiratory function and gas exchange are reflected clinically by restlessness, irritability, increased work of breathing, and alterations in blood gas values. The loss of protective function of the skin exposes burned children to increased risk for hypothermia. Edema formation and circulatory impairment result in the loss of sensation and deep, throbbing pain.

! NURSING ALERT

Evaluate the burned extremity and check the pulse every hour. If unable to palpate, use Doppler to ascertain loss of circulation and pulse. If the pulse is lost, escharotomy may be necessary to relieve the edema causing pressure on blood vessels to restore adequate circulation.

Burn centers maintain a pictorial record of wounds to record progress and for legal purposes (if child abuse is suspected). Burn wounds are treated according to the protocol of the specific burn center. The burn team monitors infection control procedures and ensures that staff and visitors comply with established protocols to prevent cross-contamination in the burn unit.

Throughout the acute phase of care, the psychosocial needs of the children and their families should not be overlooked. The child

is frightened, uncomfortable, and often confused. Children may be isolated from familiar persons and surroundings; the overwhelming physical needs at this time are the primary focus of the staff and parents. In addition to feeling concern for their child, the family experiences guilt, which may be related to the fact that the parents did not or could not protect their child from injury. Consistency in the information presented and in the attitude of the staff creates a sense of familiarity and stability during the acute phase of care. Consistent caregivers can also help decrease the patient's and family's anxiety and provide coordination of care. For example, when many teams of consultants and specialists are involved in the child's care, appointing a burn team "spokesperson" decreases the confusion and enhances communication regarding the child's care.

Management and Rehabilitative Phases. After the patient's condition is stabilized, the management phase begins. The multidisciplinary team concentrates on preventing wound infections, closing the wound as quickly as possible, and managing the numerous complications. Although the rehabilitative phase begins when permanent wound closure has been achieved, rehabilitation issues are identified on admission and are included in the care plan throughout the hospital course.

! NURSING ALERT

In a pediatric burn patient, a decreased level of consciousness, increased restlessness, and lethargy are some of the first signs of overwhelming sepsis and may indicate inadequate hydration. Assessment of capillary refill and pulses is another important indicator of the adequacy of hydration. With inadequate hydration, a spiking fever and diminished bowel sounds accompanied by paralytic ileus are noted and progressively increase over 48 to 72 hours, after which the temperature falls to subnormal limits. At this time, the wound deteriorates, the white blood cell count is depressed, and septic shock becomes manifest.

Comfort Management. The severe pain of the wound and resultant therapies, the anxiety generated by these experiences, sleep deprivation, itching related to wound healing, and the conscious and unconscious interpretations of traumatic events contribute to the psychologic behaviors commonly observed in children with burns. It is always difficult to deal with a child in pain, and inflicting pain on a helpless child is contrary to the empathic nature of nursing. Interventions to promote comfort may include medications (including IV morphine, fentanyl, or midazolam and short-term anesthetics such as propofol), relaxation techniques, distraction therapy, behavioral techniques, operant conditioning (e.g., tokens, star chart), and family participation.

Children need age-appropriate explanations before all procedures. When children appear to accept pain with little or no response, psychologic consultation may be needed. Consistency in caregivers is important. If this is not possible, a carefully developed multidisciplinary care plan is necessary to provide consistency.

Care of the Burn Wound. The nurse has a major responsibility for cleansing, débriding, and applying topical medications and dressings to the burn wound. Pain medication should be administered so that the peak effect of the drug coincides with the procedure. Children who have an understanding of the procedure to be performed and some perceived control demonstrate less maladaptive behavior. Children also respond well to participating in decisions (see Atraumatic Care box).

Outer dressings are removed. Any dressings that have adhered to the wound can be more easily removed by applying tepid water or normal saline. Loose or easily detached tissue is débrided during the cleansing process. In dressing the wound, it is important that all areas be clean, that medication be amply applied, and that no two burned surfaces touch each other (e.g., fingers or toes; ears touching the side of the head). If they are touching, the burned surfaces will heal together, causing deformity or dysfunction.

ATRAUMATIC CARE

Reducing the Stress of Burn Care Procedures

- Have all materials ready before beginning.
- Administer appropriate analgesics and sedatives.
- Remind the child of the impending procedure to allow sufficient time to prepare.
- Allow the child to test and approve the temperature of the water.
- Allow the child to select the area of the body on which to begin.
- Allow the child to request a short rest period during the procedure.
- Allow the child to remove the dressings if desired.
- Provide something constructive for the child to do during the procedure (e.g., holding a package of dressings or a roll of gauze).
- Inform the child when the procedure is near completion.
- Praise the child for cooperation.

Topical medications may be applied directly to the wound with a tongue blade or gloved hand as well as using impregnated fine-mesh gauze. Dressings are then applied to assist in exudate absorption, wound débridement, and increased patient comfort. All dressings applied circumferentially should be wrapped in a distal-to-proximal manner. The dressing is applied with sufficient tension to remain in place but not so tightly as to impair circulation or limit motion. An elastic net is then applied to secure the dressing in place. A stable dressing is especially important when the child is ambulatory.

Standard Precautions, including the use of protective garb and barrier techniques, should be followed when caring for patients with burns. Frequent hand and forearm washing is the single most important element of the infection control program. Strict policies for cleaning the environment and patient care equipment should be implemented to minimize the risk for cross-contamination. All visitors and members of other departments should be oriented to the infection control policies, including the importance of hand and forearm washing and use of protective garb. Visitors should be screened for infection and contagious diseases before patient contact.

Prevention of Complications

Acute Care. The maintenance of body temperature is important to children with burns. Core body temperature is supported when energy is conserved with an environmental temperature of 28° to 33°C (82.4° to 91.4°F). Large areas of the body should not be exposed simultaneously during dressing changes. Warmed solutions, linens, occlusive dressings, heat shields, a radiant warmer, and warming blankets assist in preventing hypothermia.

The chief danger during acute care is infection—wound infection, generalized sepsis, or bacterial pneumonia. Accurate and ongoing assessments of all parameters that provide clues to the early diagnosis and treatment of infection are essential. Symptoms of sepsis include a decreased level of consciousness, a rising or falling white blood cell count, hyperthermia progressing to hypothermia, increasing fluid requirements, hypoactive or absent bowel sounds, a rising or falling blood glucose level, tachycardia, tachypnea, and thrombocytopenia. Infection delays the progress of wound healing.

Children are reluctant to move if movement causes pain, and they are likely to assume a position of comfort. Unfortunately, the most comfortable position often encourages the formation

FIG 47-20 Extensive scars from a flame burn. (Courtesy The Paul and Carol David Foundation Burn Institute, Akron, OH.)

FIG. 47-21 Child in an elasticized (Jobst) garment and "airplane" splints.

of contractures and loss of function. Ongoing efforts to prevent contractures include maintaining proper body alignment, positioning and splinting involved extremities in extension, providing active and passive physical therapy, and encouraging spontaneous movement when feasible. Frequent position changes are important to promote adequate bronchopulmonary hygiene and capillary perfusion to common pressure areas. Low–air loss beds are beneficial for morbidly obese children or children with posterior grafts. Special attention should be given to areas at risk for increased pressure, such as the posterior scalp, heels, sacrum, and areas exposed to mechanical irritation from splints and dressings.

Long-Term Care. When the burn heals, the rehabilitative phase of care begins. Scar formation becomes a major problem as burn wounds heal (Fig. 47-20). Contractile properties of the scar tissue can result in disabling contractures, deformity, and disfigurement.

Uniform pressure applied to the scar decreases the blood supply. When pressure is removed, blood supply to the scar is immediately increased; therefore periods without pressure should be brief to avoid nourishment of the hypertrophic tissue. Continuous pressure to areas of scarring can be achieved by elastic bandages or commercially available pressure garments. Because these custom-made garments are often worn for months, revisions may be required as the child grows. It is much easier to prevent scarring and contracture of the wound than to resolve an existing problem. Splints and appliances may also be needed until wound maturation is achieved (Fig. 47-21).

Scar tissue has certain significant properties, particularly for growing children. Intense itching occurs in healing burn wounds and scar tissue until the scar is no longer active. Itching is usually treated with a combination of H_1 and H_2 antagonists such as cetirizine (Zyrtec) and cimetidine (Tagamet) (Baker, Zeller, Klein, et al., 2001); an H_1 antagonist alone; and frequent applications of a moisturizer, such as Vaseline Intensive Care Rescue, Aveeno Baby, Alpha Keri, or Eucerin. Massage therapy during the application of moisturizers is also beneficial to stretch scar tissue and aid in contracture prevention. Scar tissue has no sweat glands, and children with extensive scarring may experience difficulty during hot weather. Caregivers should be alerted to this possibility and be prepared to institute alternate methods of cooling when necessary.

Scar tissue does not grow and expand as does normal tissue, which may create difficulties, especially in functional areas such as on the hands and over joints. Additional surgery is sometimes required to allow independent functioning in daily activities, to improve cosmetic appearance, or to restore anatomic integrity.

The nursing activities in the rehabilitative phase of treatment focus on the child's and family's adaptation to the burn injury and their ability to reintegrate into the community. The psychologic pain and sequelae of severe burn injury are as intense as the physical trauma. The impact of severe burns taxes the coping mechanisms at all ages. Very young children, who suffer acutely from separation anxiety, and adolescents, who are developing an identity, are probably the most affected psychologically. Toddlers cannot understand why the parents they love and who have protected them can leave them in such a frightening and unfamiliar place. Adolescents, in the process of achieving independence from the family, find themselves in a dependent role with a damaged body. Being different from others at a time when conformity with peers is so important is difficult to accept.

Anticipation of the return to school can be overwhelming and frightening. It is essential that health care professionals recognize the importance of preparing teachers and classmates for the child's return. Teachers need to be provided with information to assist the child and family and to promote the child's optimal adjustment. Hospital-sponsored school reentry programs use a variety of methods to provide education and information about the implications of the injury, the garments and appliances, and the need for support and acceptance. Telephone calls, videotapes, information packets, and visits by members of the health care team offer opportunities to help with reintegration into the school environment—a focal point of the child's life.

Psychosocial Support of the Child. Children should begin early to do as much for themselves as possible and to be active participants in their care. Loss of control and perceived helplessness may result in acting-out behaviors. During illness, children can regress to a previous developmental level that allows them to deal with stress. As children begin to participate in their care, they gain confidence and self-esteem. Fears and anxieties diminish with accomplishment and self-confidence. If the child demonstrates nonadherence in the

rehabilitative phase, a behavior modification program can be initiated to promote or reward the child's accomplishment in care.

Children need to know that their injury and the treatments are not punishment for real or imagined transgressions and that the nurse understands their fear, anger, and discomfort. They also need body contact. This is often difficult to arrange for the child with massive burns. Stroking areas of unburned skin is comforting. Even older children enjoy sitting on the parent's lap and being cuddled and hugged. This can be a reward or a comfort in times of stress, but most of all it should be kept in mind that it is a natural part of childhood.

Psychosocial Support of the Family. Recognizing and respecting each family's strengths, differences, and methods of coping allow the nurse to respond to their unique needs by implementing a family-centered approach to care. In the acute phase, all attention is focused on the child and the parents feel powerless and ineffectual. Most parents feel overwhelming guilt, whether or not the guilt is justified. They feel responsible for the injury. These feelings may impede the child's rehabilitation. Parents may indulge the child and allow nonadherent behaviors that affect physical and emotional recovery. Parents need to be informed of the child's progress and helped to cope with their feelings while providing support to their child. The nurse can help them understand that it is not selfish to look after themselves and their own needs to meet their child's needs. It is important to recognize the parents' need to grieve the change in their child's normal appearance as part of the grieving process. Definitive professional help may be needed for parents whose response to the injury is severe or whose response to stress is manifested in destructive behavior.

The parents are members of the multidisciplinary team and participate in the development of the care plan. It is important to facilitate their input; to consider all aspects of the physical, emotional, social, and cultural factors affecting the child and family; and to establish a realistic home therapy program. The family's willingness to assume responsibility for care and their ability to implement the therapeutic regimen are assessed. Home, school, and other environmental factors are explored; financial concerns and available community resources are discussed; and a specific care plan for the child, with an anticipated follow-up program, is developed.

Prevention of Burn Injury. The best intervention is to prevent burns from occurring. Hot liquids in the kitchen and bathroom most commonly injure infants and toddlers. Hot liquids should be kept out of reach; tablecloths and dangling appliance cords are often pulled by toddlers, who spill hot grease and liquids on themselves. Electrical cords and outlets represent a potential risk to small children, who may chew on accessible cords and insert objects into outlets.

The Consumer Product Safety Commission recommends a reduction of water heater thermostats to a maximum of 48.9°C (120°F). The "dial-down" recommendation has been suggested by utility companies, burn treatment centers, medical personnel, and others interested in public safety. However, many water heaters continue to remain set at levels well above the safe level. Small children are especially at risk for scald injuries from hot tap water because of their decreased reaction time and agility, their curiosity, and the thermal sensitivity of their skin. Caregivers should never leave a child unattended in a bath and without adult supervision. Water should always be tested before a child is placed in the tub or shower.

The increased use of microwave ovens has resulted in burn injuries from the extremely hot internal temperatures generated in heated items. Baby formula, jelly-filled pastries, and hot liquids and dishes may result in cutaneous scalds or the ingestion of overheated liquids. Parents should use caution when removing items from the microwave oven and should always test the food before giving it to children.

As children mature, risk-taking behaviors increase. Matches and lighters are dangerous in the hands of children. Adults must remember to keep potentially hazardous items out of the reach of children; a lighter, like a match, is a tool for adult use.

Education related to fire safety and survival should begin with very young children. They can practice "stop, drop, and roll" to extinguish a fire. The fire escape route, including a safe meeting place away from the home in case of fire, also should be practiced. Additional information on burn care and prevention can be obtained from the American Burn Association* and the National Safety Council†.

Community activities are also helpful in supporting burn survivors and preventing burns. The Aluminum Cans for Burned Children (ACBC) is an exemplary effort based at the Paul and Carol David Foundation Burn Institute in Akron, Ohio‡. Activities funded by ACBC include a Burn Survivors Support Group, Burn Camp, and meetings of Juvenile Firestoppers (for children with fire-setting behavior). Adult weekend retreats and school and family education sessions are a part of this program. The burn center and fire department provide the personnel to present programs.

Sunburn

Sunburn is a common skin injury caused by overexposure to ultraviolet radiation (UVR). The sun emits a continuous spectrum of visible and nonvisible light rays that range in length from very short to very long. The shorter, higher-frequency waves are more damaging than longer wavelengths, but much of the light is filtered out as it travels through the atmosphere. Of the light that does filter through, ultraviolet A (UVA) waves are the longest and cause only minimum burning, but they play a significant role in photosensitive and photoallergic reactions. They are also responsible for premature aging of the skin and potentiate the effects of ultraviolet B (UVB) waves. UVB waves are shorter and are responsible for tanning, burning, and most of the harmful effects attributed to sunlight, especially skin cancer.

Numerous factors influence the amount of UVR exposure. Maximum exposure occurs at midday (10 AM–4 PM), when the distance from the sun to a given spot on the earth is shortest. There is more exposure at higher altitudes and near the equator and less when the sky is hazy (although the amount of UVR that does penetrate is easily underestimated). Window glass effectively screens out UVB but not UVA rays. Fresh snow, water, and sand reflect UVR, especially when the sun is directly overhead.

Sunburn is usually an epidermal burn, although severe sunburn can be a partial-thickness burn with blister formation. Treatment of sunburn involves stopping the burning process, decreasing the inflammatory response, and rehydrating the skin. Local application of cool tap water soaks or immersion in a tepid-water bath (temperature slightly below 36.7°C [98°F]) for 20 minutes or until the skin is cool limits tissue destruction and relieves the discomfort. After the cool applications, a bland oil-in-water moisturizing lotion

can be applied. Partial-thickness burns are treated the same as those from any heat source (see earlier discussion on burns).

CARE MANAGEMENT

Protection from sunburn is the major goal of management, and the harmful effects of the sun on the delicate skin of infants and children are currently receiving increased attention. To protect skin exposed to the sun for extended periods, skin should be covered with clothing and FDA-approved sun protection agents should be applied.

Two types of products are available for sun protection: topical sunscreens, which partially absorb UVR; and sun blockers, which block out UVR by reflecting sunlight. The most frequently recommended sun blockers are zinc oxide and titanium dioxide ointments. Sunscreens are products containing a sun protection factor (SPF) based on evaluation of effectiveness against UVR. For example, if individuals normally burn in 10 minutes without a sunscreen, use of a sunscreen with SPF 15 allows them to remain in the sun 15 times 10, or 150, minutes (2½ hours), before acquiring the same degree of burns. The most effective sunscreens against UVB are *p*-aminobenzoic acid (PABA) and PABA-esters. However, many individuals are allergic to PABA, and sunscreens without PABA are encouraged to prevent these reactions in children.

Sunscreens are applied evenly to all exposed areas, with special attention to skinfolds and areas that might become exposed as clothing shifts. Avoid eye contact. Parents are directed to read labels of sunscreen products carefully for the SPF and follow the manufacturer's directions for application.

! NURSING ALERT

Sunscreens are not recommended for infants younger than 6 months. However, infants younger than 6 months may have sunscreen applied over small areas of skin such as the back of hands that may not be adequately covered by clothing when they are in the sun. Infants should be kept out of the sun or physically shaded from it. Fabric with a tight weave, such as cotton, offers good protection.

Individuals who work in the community, such as teachers, day-care workers, coaches, and youth group leaders, as well as relatives, should all be made aware of sun safety for children. Sunscreens must be applied *liberally and frequently.*

Cold Injury

In cold injuries the nature of the heat-regulating mechanisms of the body are such that the inner portion of the body, or core, produces heat and the periphery, or outer area, conserves or dissipates heat. When the body attempts to conserve heat, the outer tissues are subjected to low temperatures and local trauma may result.

Chilblain (redness and swelling of the skin) occurs when extremities, usually the hands, are exposed to cold temperatures and moisture. The response may vary but is characterized by intense vasodilation that increases the temperature of involved tissues above that of unaffected tissue and produces edematous, reddish blue patches that itch and burn. As warming takes place, the sensations become more intense, but ordinarily they subside in a few days.

Frostbite is the term used to describe tissue damage caused when excessive heat loss to local tissues allows ice crystals to form in tissues. The frostbitten part appears white or blanched, feels solid, and is without sensation. Rapid rewarming is associated with less tissue necrosis than slow thawing. It restores blood flow and shortens the period of cellular damage. Rewarming produces a flush (sometimes deep purple) and a return of sensation, which is extremely painful. Large blisters may appear in 24 to 48 hours after rewarming and begin to reabsorb within 5 to 10 days followed by the formation of a hard black eschar. Superficial injury often heals without incident. Rewarming is accomplished by immersing the part in well-agitated water at 37.8° to 42.2°C (100° to 108°F). Discomfort is managed with analgesics and sedatives. Care of blistered skin is similar to that described for burns. It is seldom possible to estimate the extent of tissue loss until new skin layers are revealed after the eschar layer separates.

KEY POINTS

- A variety of factors can produce lesions of the skin.
- It is important for nurses to be able to describe skin lesions accurately.
- The process of wound healing consists of hemostasis, inflammation, proliferation, and remodeling.
- A moist environment promotes wound healing.
- Bacterial, viral, and fungal infections are common in childhood.
- Some skin diseases are transmitted by arthropod vectors, especially ticks.
- The most common skin infestations of childhood—scabies and pediculosis capitis—affect children of any age and from any social class.
- Contact dermatitis may involve a primary irritant or a sensitizing agent.
- Adverse reactions to drugs are manifested more often in the skin than in any other body organ.
- The most common skin disorders of infancy are diaper dermatitis, seborrheic dermatitis, and AD.
- Acne, a disorder affecting many adolescents, is related to hormonal fluctuation, stimulation of the sebaceous glands, excessive sebum production, the formation of comedones, and the overgrowth of the *P. acnes* organism.
- Medication and gentle facial cleansing are the treatments of choice for acne.
- Burns are caused by thermal, chemical, electric, or radioactive agents.
- Burns are assessed on the extent, depth, and severity of the wound.
- Essentials of emergency care of burn injury include stopping the burning process, covering the burn, transporting the injured child to medical aid, and providing reassurance to the child and family.
- Management of minor burns consists of facilitating wound healing, relieving discomfort, and preventing complications.
- Management of major burns consists of facilitating wound healing, relieving discomfort, replacing destroyed skin, preventing or treating complications, and providing rehabilitation.
- Sunscreen is recommended for use when the skin is exposed to the damaging effects of the sun's rays.
- Thermal injuries to the skin can result from exposure to extreme cold.

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Outline a care plan for a child immobilized with an injury or a debilitating condition.
- Formulate a teaching plan for the parents of a child in a cast.
- Explain the functions of the various types of traction.
- Differentiate among the various congenital skeletal defects.
- Design a teaching plan for the parents of a child with a congenital skeletal deformity.
- Describe the therapies and nursing care of a child with scoliosis.
- Outline a plan of care for a child with osteomyelitis.
- Differentiate between osteosarcoma and Ewing sarcoma.
- Describe the nursing care of a child with juvenile arthritis.
- Demonstrate an understanding of the management of systemic lupus erythematosus.

THE IMMOBILIZED CHILD

One of the most difficult aspects of illness in children is the immobility it imposes. Children by nature are usually active; and immobility, however temporary, may have lasting effects on the child's developmental progress. The most frequent reasons for immobility are congenital defects (e.g., spina bifida); degenerative disorders (e.g., muscular dystrophy); and infections or injuries that impair the integumentary system (severe burns), the musculoskeletal system (e.g., multiple fractures, osteomyelitis), or the neurologic system (e.g., spinal cord injury, Guillain-Barré syndrome, traumatic brain injury). At times therapies such as traction and spinal fusion are responsible for prolonged immobilization, although the increasing trends in health care are early mobilization and discharge and outpatient treatment.

Physiologic Effects of Immobilization

Many clinical studies, including space program research, have documented predictable consequences that occur after immobilization and the absence of gravitational force. Functional and metabolic responses to restricted movement can be noted in most of the body systems. Each has a direct influence on the child's growth and development because homeostatic mechanisms thrive on normal use and need feedback to maintain dynamic equilibrium. Inactivity leads to a decrease in the functional capabilities of the whole body as dramatically as the lack of physical exercise leads to muscle weakness.

Disuse from illness, injury, or a sedentary lifestyle can limit function and potentially delay age-appropriate milestones. Most of the pathologic changes that occur during immobilization arise from decreased muscle strength and mass, decreased metabolism, and bone demineralization, which are closely interrelated, with one change leading to or affecting the other. Some results of immobilization are primary and produce a direct effect; other pathophysiologic consequences occur frequently but seem to be more indirect and therefore are secondary effects. Many pathophysiologic changes affect more than one body system, with the primary or secondary effect being demonstrated in both systems.

The major effects of immobilization are outlined briefly in Table 48-1 and are related directly or indirectly to decreased muscle activity, which produces numerous primary changes in the musculoskeletal system with secondary alterations in the cardiovascular, respiratory, metabolic, and renal systems. The musculoskeletal changes that occur during disuse are a result of alterations in gravity and stress on the muscles, joints, and bones. Muscle disuse leads to tissue breakdown and loss of muscle mass **(atrophy).** Muscle atrophy causes decreased strength and endurance, which may take weeks or months to restore.

During immobilization a joint contracture begins when the arrangement of collagen, the main structural protein of connective tissues, is altered, resulting in a denser tissue that does not glide as easily. Eventually muscles, tendons, and ligaments can shorten and reduce joint movement, ultimately producing contractures that

TABLE 48-1 SUMMARY OF PHYSICAL EFFECTS OF IMMOBILIZATION WITH NURSING INTERVENTIONS*

PRIMARY EFFECTS	SECONDARY EFFECTS	NURSING CONSIDERATIONS
Muscular System		
Decreased muscle strength, tone, and endurance	Decreased venous return and decreased cardiac output	Use antiembolism stockings or intermittent compression devices to promote venous return (monitor circulatory and neurovascular status of extremities when such devices are used).
	Decreased metabolism and need for oxygen Decreased exercise tolerance Bone demineralization	Plan play activities to use uninvolved extremities. Place in upright posture when possible. Perform passive range-of-motion exercises.
Disuse atrophy and loss of muscle mass	Catabolism Loss of strength	Have patient perform range-of-motion, active, passive, and stretching exercises.
Loss of joint mobility	Contractures, ankylosis of joints	Maintain correct body alignment. Use joint splints as indicated to prevent further deformity. Maintain range of motion.
Weak back muscles	Secondary spinal deformities	Maintain body alignment.
Weak abdominal muscles	Impaired respiration	See nursing considerations for respiratory system.
Skeletal System		
Bone demineralization—osteoporosis, hypercalcemia	Negative bone calcium uptake Pathologic fractures Calcium deposits Extraosseous bone formation, especially at hip, knee, elbow, and shoulder Renal calculi	With paralysis use upright posture on tilt table. Handle extremities carefully when turning and positioning. Administer calcium-mobilizing drugs (diphosphonates) and normal saline infusions as ordered. Ensure adequate intake of fluid; monitor output. Acidify urine. Promptly treat urinary tract infections.
Negative bone calcium uptake	Life-threatening electrolyte imbalance	Monitor serum calcium levels. Provide electrolyte replacement as indicated.
Metabolism		
Decreased metabolic rate	Slowing of all systems Decreased food intake	Mobilize as soon as possible. Have patient perform active and passive resistance and deep-breathing exercises. Ensure adequate food intake. Provide a high-protein diet.
Negative nitrogen balance	Decline in nutritional state	Encourage small, frequent feedings with protein and preferred foods.
	Impaired healing	Monitor for and prevent pressure areas.
Hypercalcemia	Electrolyte imbalance	See nursing consideration for skeletal system.
Decreased production of stress hormones	Decreased physical and emotional coping capacity	Identify causes of stress. Implement appropriate interventions to lower physical and psychosocial stresses.
Cardiovascular System		
Decreased efficiency of orthostatic neurovascular reflexes	Inability to adapt readily to upright position **(orthostatic intolerance)** Pooling of blood in extremities in upright posture	Monitor peripheral pulses and skin temperature changes. Use antiembolism stockings or intermittent compression devices to decrease pooling when upright.
Diminished vasopressor mechanism	Orthostatic intolerance with syncope, hypertension, deceased cerebral blood flow, tachycardia	Provide abdominal support. In severe cases use antigravitational pants. Position horizontally.
Altered distribution of blood volume	Increased cardiac workload Decreased exercise tolerance	Monitor hydration, blood pressure, and urinary output.

TABLE 48-1 SUMMARY OF PHYSICAL EFFECTS OF IMMOBILIZATION WITH NURSING INTERVENTIONS—cont'd

PRIMARY EFFECTS	SECONDARY EFFECTS	NURSING CONSIDERATIONS
Venous stasis	Pulmonary emboli or thrombi	Encourage and assist with frequent position changes. Elevate extremities without knee flexion. Ensure adequate fluid intake. Have patient perform active or passive exercises or movement as needed. Prescribe routine wearing of antiembolism stockings or intermittent compression devices. Monitor for signs of *pulmonary embolism*—sudden dyspnea, chest pain, respiratory arrest. Promptly intervene to maintain adequate oxygenation if signs and symptoms of pulmonary emboli are noted. Measure circumference of extremities periodically. Give anticoagulant drugs as prescribed.
Dependent edema	Tissue breakdown and susceptibility to infection	Administer skin care. Turn every 2-4 hr. Monitor skin color, temperature, and integrity. Use pressure-reduction surface as necessary to prevent skin breakdown. (See Chapter 47.)
Respiratory System		
Decreased need for oxygen	Altered oxygen–carbon dioxide exchange and metabolism	Promote exercise as tolerated. Encourage deep-breathing exercises.
Decreased chest expansion and diminished vital capacity	Diminished oxygen intake Dyspnea and inadequate arterial oxygen saturation; acidosis	Position for optimum chest expansion. Semi-Fowler position may assist in lung expansion if patient can tolerate. Use prone positioning without pressure on abdomen to allow gravity to aid in diaphragmatic excursion. Ensure that patient maintains proper alignment when sitting to prevent pressure on respiratory mechanism.
Poor abdominal tone and distention	Interference with diaphragmatic excursion	Avoid restriction of chest and abdominal musculature. Supply torso support to promote chest expansion.
Mechanical or biochemical secretion retention	Hypostatic pneumonia Bacterial and viral pneumonia Atelectasis	Change position frequently. Carry out percussion, vibration, and drainage (or suctioning) as necessary. Use incentive spirometer. Monitor breath sounds.
Loss of respiratory muscle strength	Poor cough	Encourage coughing and deep breathing. Support chest wall by splinting with pillow when patient coughs. Use incentive spirometer. Observe for signs of respiratory distress with pulse oximetry or blood gas measurement as necessary.
	Upper respiratory tract infection	Prevent contact with infected persons. Provide adequate hydration. Administer immunizations as necessary (pneumococcal, meningococcal).
Gastrointestinal System		
Distention caused by poor abdominal muscle tone	Interference with respiratory movements	Monitor bowel sounds. Encourage small, frequent feedings.
	Difficulty in feeding in prone position	Have patient sit in upright position in bedside chair if possible.
No specific primary effect	Possible constipation caused by gravitational effect on feces through ascending colon or weakened smooth muscle tone	Carry out bowel training program with hydration, stool softeners, increased fiber intake, and mild laxatives if necessary.
	Anorexia	Stimulate appetite with favored foods.

Continued

TABLE 48-1 SUMMARY OF PHYSICAL EFFECTS OF IMMOBILIZATION WITH NURSING INTERVENTIONS—cont'd

PRIMARY EFFECTS	SECONDARY EFFECTS	NURSING CONSIDERATIONS
Urinary System		
Alteration of gravitational force	Difficulty in voiding in prone or supine position	Position as upright as possible to void.
Impaired ureteral peristalsis	Urinary retention in calyces and bladder	Hydrate to ensure adequate urinary output for age.
	Infection	Stimulate bladder emptying with warm running water as necessary.
	Renal calculi	Catheterize only for severe urinary retention.
		Administer antibiotics as indicated.
Integumentary System		
Altered tissue integrity	Decreased circulation and pressure leading to tissue injury	Turn and reposition at least every 2-4 hr.
		Frequently inspect total skin surface.
		Eliminate mechanical factors causing pressure, friction, moisture, or irritation.
		Place on pressure-relief mattress.
	Difficulty with personal hygiene	Assess ability to perform self-care and assist with bathing, grooming, and toileting as needed.
		Encourage self-care to potential ability.
		Ensure adequate intake of protein, vitamins, and minerals.

*Individualize care according to child's needs; interventions may vary in different institutions.

restrict function. The daily stresses on bone created by motion and weight bearing maintain the balance between bone formation (osteoblastic activity) and bone resorption (osteoclastic activity). During immobilization increased calcium leaves the bone, causing **osteopenia** (demineralization of the bones), which may predispose bone to pathologic fractures.

The major musculoskeletal consequences of immobilization are as follows:

- Significant decrease in muscle size, strength, and endurance
- Bone demineralization leading to osteoporosis
- Contractures and decreased joint mobility.

Circulatory stasis combined with hypercoagulability of the blood, which results from factors such as damage to the endothelium of blood vessels (Virchow triad), can lead to thrombus and embolus formation. *Deep vein thrombosis (DVT)* involves the formation of a thrombus in a deep vein such as the iliac and femoral veins and can cause significant morbidity if it remains undetected and untreated. The larger the portion of the body immobilized and the longer the immobilization, the greater the risks of consequences of immobility.

Psychologic Effects of Immobilization

For children one of the most difficult aspects of illness is immobilization. Throughout childhood physical activity is an integral part of daily life and is essential for physical growth and development. The activity helps children deal with a variety of feelings and impulses and provides a mechanism by which they can exert control over inner tensions. Children respond to anxiety with increased activity. Removal of this power deprives them of necessary input and a natural outlet for their feelings and fantasies.

When children are immobilized by disease or as part of a treatment regimen, they experience diminished environmental stimuli with a loss of tactile input and an altered perception of themselves and their environment. Sudden or gradual immobilization narrows the amount and variety of environmental stimuli that children receive by means of all of their senses: touch; sight; hearing; taste; smell; and proprioception, or the feeling of where they are in their environment. This sensory deprivation commonly leads to feelings of isolation and boredom and of being forgotten, especially by peers.

Physical interference with the activity of young children makes them feel frustrated and helpless. Even speech and language skills require sensorimotor activity and experience. For the toddler exploration and imitative behaviors are essential to developing a sense of autonomy; the preschooler's expression of initiative is evidenced by the need for vigorous physical activity; the school-age child's development is strongly influenced by physical achievement and competition; and the adolescent relies on mobility to achieve independence and self-identity. The quest for mastery at every stage of development is related to mobility.

The monotony of immobilization may lead to sluggish intellectual and psychomotor responses, decreased communication skills, increased fantasizing, and rarely hallucinations and disorientation. Children are likely to become depressed over loss of ability to function or the marked changes in body image. They may regress to earlier developmental behaviors such as wanting to be fed, bedwetting, and baby talk.

Children may react to immobility by active protest, anger, and aggressive behavior; or they may become quiet, passive, and submissive. They may believe that the immobilization is a justified punishment for misbehavior. Children should be allowed to display their anger, but it should be within the limits of safety to their self-esteem and not damaging to the integrity of others. When children are unable to express anger, aggression is often displayed inappropriately through regressive behavior and outbursts of crying or temper tantrums.

Effect on Families

Even brief periods of immobilization may disrupt family function, and sudden catastrophic illness or chronic disability may severely tax their resources and coping abilities.

The family's needs often must be met by the services of a multidisciplinary team, and nurses play a key role in anticipating the

services they will need and coordinating conferences to plan care. In preparation for discharge home visits are advisable, and home management is commonly planned weeks in advance of the actual discharge. Such planning includes special considerations for cultural, economic, physical, and psychologic needs. A child with a severe disability is very dependent, and caregivers need rest periods to revitalize themselves (respite). Individual and group counseling is beneficial for solving problems in advance and provides an emotional support system. Parent groups may also be helpful and often allow nonthreatening social contact. The families of children with permanent disabilities need long-term resources because some of the most difficult problems arise as they try to sustain high-quality care for many years (see Chapter 36).

CARE MANAGEMENT

Physical assessment of the child who is immobilized for any number of reasons (e.g., injury or illness) includes a focus not only on the injured part (e.g., fracture) but also on the functioning of other systems that may be affected secondarily (i.e., the circulatory, renal, respiratory, muscular, and gastrointestinal systems). With long-term immobilization there may also be neurologic impairment and changes in electrolytes (especially calcium), nitrogen balance, and the general metabolic rate. The psychologic impact of immobilization should also be assessed.

Children who require prolonged total immobility and are unable to move themselves in bed should be placed on a pressure-reduction mattress to prevent skin breakdown. Frequent position changes also help prevent dependent edema and stimulate circulation, respiratory function, gastrointestinal motility, and neurologic sensation. Children at greater risk for skin breakdown include those with prolonged immobilization; mechanical ventilation; orthotic and prosthetic devices, including wheelchairs; and casts. Additional risk factors include poor nutrition, friction (from bed linen with traction), and moist skin (from urine or perspiration). Nursing care of children at risk includes strategies for preventing skin breakdown when such conditions are present. The Braden Q Scale is a reliable, objective tool that may be used in the assessment for pressure ulcer development in children who are acutely ill or at risk for skin breakdown from neurologic conditions and immobilization (Noonan, Quigley, and Curley, 2011) (see also Maintaining Healthy Skin, Chapter 39).

The use of antiembolism stockings or intermittent compression devices prevents circulatory stasis and dependent edema in the lower extremities and the development of DVT. Anticoagulant therapy may also be implemented with low-molecular-weight heparin, vitamin K antagonists, or unfractionated heparin. The child should be allowed as much activity as possible within the limitations of the illness or treatment. Any functional mobility, however minimal, is preferred to total immobility. High-protein, high-calorie foods are encouraged to prevent negative nitrogen balance, which may be difficult to correct by diet, especially if there is anorexia as a result of immobility and decreased gastrointestinal function (decreased motility and possibly constipation). Stimulating the appetite with small servings of attractively arranged, preferred foods may be sufficient. Sometimes supplementary nasogastric or gastrostomy feedings or intravenous (IV) fluids may be needed, but these are reserved for serious disability in which oral intake is impossible.

Adequate hydration and, when possible, an upright position and remobilization promote bowel and kidney function and help prevent complications in these systems. Children are encouraged to be as active as their condition and restrictive devices allow. This poses few problems for children, whose innate ingenuity and natural inclination toward mobility provide them with the impetus for physical activity. They need the opportunity, the materials or objects to stimulate activity, and the encouragement and participation of others. Those who are unable to move benefit from passive exercise and movement in consultation with a physical therapist.

Whenever possible, transporting the child outside the confines of the room increases environmental stimuli and allows social contact with others. Specially designed wheelchairs for increased mobility and independence are available. While hospitalized, children benefit from same-age visitors, computers, books, interactive video games, and other items brought from their own room at home, all of which help them to function in a more normal way. They also benefit from frequent visitors, accessibility of clocks and calendars, and a program of diversional therapy to help them function more normally. A child life specialist should be consulted for recreational planning. An activity center or slanting tray can be helpful for the child with limited mobility to use for drawing, coloring, writing, and playing with small toys such as trucks and cars. Children are able to express frustration, displeasure, and anger through play activities (see Chapter 38), which are helpful in the child's recovery. Hospitalized children should be allowed to wear their own clothes (street clothes, especially for preadolescent and adolescent girls) and resume school and preinjury activities. A parent or siblings should be allowed to stay overnight and room in with the hospitalized child to prevent the effects of family disruption caused by hospitalization. All efforts should be made to minimize this disruption. Although most of the suggestions discussed relate to hospital care, the same consultations (physical therapist, occupational therapist, child life specialist, speech therapist) and environment may also be considered in the home to help the child and family achieve independence and normalization.

Using dolls, stuffed animals, or puppets to illustrate and explain the immobilization method (e.g., traction, cast) is a valuable tool for small children. Placing a cast, tubing, or other restraining equipment on the doll offers the child a nonthreatening opportunity to express, through the doll, feelings about the restrictions, the nurse, and other health care providers. The doll or puppet may also be used for teaching the child and family procedures such as IV therapy, procedural sedation, and general anesthesia.

One of the most useful interventions to help children cope with immobility is participation in their own care. Self-care to the maximum extent is usually well received by children. They can help plan their daily routine; select their diet; and choose "street clothes," including innovative adornment such as a baseball cap or brightly colored socks to express their autonomy and individuality. They are encouraged to do as much for themselves as they are able to keep their muscles active and their interest alive.

Visits from significant people such as family members and friends offer occasions for emotional support and also provide opportunities for learning how to care for the child. Privacy is necessary, especially for adolescents.

For a child with greatly restricted movement (e.g., child with a large bilateral hip spica cast), nursing care is often a challenge. These situations require long-term care either in the hospital or at home; but, wherever the care occurs, consistent planning and coordination of activities with other health care workers and significant others are vital nursing functions.

With the increased trend toward early mobilization, early discharge, and home health care, many children are discharged home within a few days of hospitalization. Follow-up treatment may take place in the home setting or an outpatient ambulatory facility.

Family Support and Home Care

The needs of a child with severe disabilities can be complex, and family members require time to assimilate the teachings and demonstrations needed to understand the child's situation and care. Even a child who is confined on a short-term basis can be a challenge for the family, who are usually unprepared for the problems imposed by the child's special needs. Home modification is usually needed for facilitating care, especially when it involves traction, a large cast, or extended confinement. Suitable child care may be needed for times when all family members work.

Just as in the hospital, the child at home is encouraged to be as independent as possible and follow a schedule that approximates his or her normal lifestyle as nearly as possible such as continuing school lessons, regular bedtime, and suitable recreational activities.

TRAUMATIC INJURY

Soft-Tissue Injury

Injuries to the muscles, ligaments, and tendons are common in children (Fig. 48-1). In young children soft-tissue injury usually results from mishaps during play. In older children and adolescents, participation in sports is the more common cause.

Contusions

A *contusion* is damage to the soft tissue, subcutaneous structures, and muscle. The tearing of these tissues and small blood vessels and the inflammatory response lead to hemorrhage, edema, and associated pain when the child attempts to move the injured part. The escape of blood into the tissues is observed as *ecchymosis,* a black-and-blue discoloration.

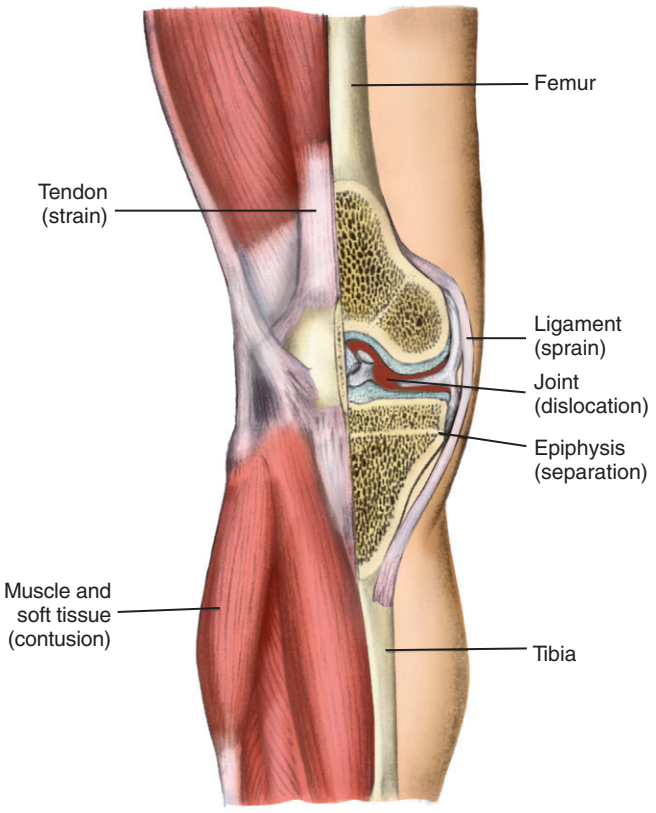

FIG 48-1 Sites of injuries to bones, joints, and soft tissues.

Large contusions cause gross swelling, pain, and disability; those sustained while the child is participating in sports usually receive immediate attention from health personnel. The less spectacular, smaller injuries may go unnoticed, allowing continued participation; however, they can become disabling after rest because of pain and muscle spasm. The young athlete is commonly instructed to "walk it off" or disregard the pain. Instead of this approach, first a qualified health care worker or certified athletic trainer should carry out an assessment of the affected area because further damage to the site may result if the area is severely traumatized. Immediate treatment consists of cold application, as described in the section on sprains. Return to participation is allowed when the strength and range of motion of the affected extremity are equal to those of the opposite extremity. *Myositis ossificans* may occur from deep contusions to the biceps or quadriceps muscles; this condition may result in a restriction of flexibility of the affected limb.

Contusions are crush injuries that occur in children when they slam their fingers (in doors, folding chairs, or equipment) or hit them (as when hammering a nail). A severe crush injury involves the bone, with swelling and bleeding beneath the nail (subungual) and sometimes laceration of the pulp of the distal phalanx. The *subungual hematoma* can be released by creating a hole at the proximal end of the nail with a battery-operated microcautery device or a heated sterile 18-gauge needle.

Dislocations

Long bones are held in approximation to one another at the joint by ligaments. A dislocation occurs when the force of stress on the ligament is so great as to displace the normal position of the opposing bone ends or the bone end from its socket. The predominant symptom is pain that increases with attempted passive or active movement of the extremity. In dislocations there may be an obvious deformity and inability to move the joint. Dislocation of the phalanges is the most common type seen in children, followed by elbow dislocation. One of the most common injuries in young children is subluxation of the annular ligament, also called *pulled elbow* or *nursemaid elbow.* With this injury the annular ligament slips proximally off the radial head into the joint between the radial head and ulna, causing immediate pain and limited supination (Carrigan, 2011). In the majority of cases the injury occurs in a child younger than 5 years who receives a sudden longitudinal pull or traction at the wrist while the arm is fully extended and the forearm pronated. It usually occurs when an adult or older sibling who is holding the child by the hand or wrist gives a sudden pull or jerk to prevent a fall or attempts to lift the child by pulling the wrist or when the child pulls away by dropping to the floor or ground. The child often cries, appears anxious, and refuses to use the affected limb; there is an absence of swelling. The practitioner manipulates the arm by applying firm finger pressure to the head of the radius, then supinates and flexes the forearm to return the ligament to its place. A click or clunk may be heard or felt, and functional use of the arm returns within minutes. However, the longer the subluxation is present, the longer it takes for the child to recover mobility after treatment. Usually no anesthetic is required, but a mild pain reliever such as acetaminophen may be given. In an older child severe elbow injury or dislocation should be carefully evaluated by a practitioner immediately; likewise a traumatic elbow injury in the younger child that is not a subluxation should be evaluated carefully.

In children younger than 5 years of age the hip can be dislocated by a fall. The greatest risk after this injury is the potential loss of blood supply to the head of the femur. Relocation of the hip within

60 minutes after the injury provides the best chance for preventing damage to the femoral head.

Shoulder dislocations occur most often in older adolescents and are often sports related. Temporary restriction of the joint with a sling or bandage that secures the arm to the chest in a shoulder dislocation can provide sufficient comfort and immobilization until medical attention is received.

Simple dislocations should be reduced as soon as possible with the child under mild (procedural) sedation and often local anesthesia. Anesthetics such as IV ketamine (Ketalar), midazolam (Versed), IV propofol (Diprivan), or fentanyl (Sublimaze) can be used to produce partial or complete analgesia. Nitrous oxide in concentrations of 50% to 70% has been shown to be safe for relatively short periods (15 to 20 minutes) in children ages 1 year and above (Babl, Oakley, Seaman, et al., 2008; Zier and Liu, 2011) An unreduced dislocation is complicated by increased swelling, making reduction difficult and increasing the risk of neurovascular problems. Treatment depends on the severity of the injury.

Sprains

A sprain occurs when trauma to a joint is so severe that a ligament is partially or completely torn or stretched by the force created as a joint is twisted or wrenched, often accompanied by damage to associated blood vessels, muscles, tendons, and nerves.

The presence of joint laxity is the most valid indicator of the severity of a sprain. In a severe injury the child complains of the joint "feeling loose" or as if "something is coming apart," and may describe hearing a "snap," "pop," or "tearing." Pain is seldom the principal subjective symptom. There is a rapid onset with swelling (often diffuse), accompanied by immediate disability and appreciable reluctance to use the injured joint.

Strains

A strain is a microscopic tear to the musculotendinous unit and has features in common with sprains. The area is painful to touch and swollen. Most strains are incurred over time rather than suddenly, and the rapidity of the appearance provides clues regarding severity. In general the more rapidly the strain occurs, the more severe the injury. When the strain involves the muscular portion, there is more bleeding, often palpable soon after injury and before edema obscures the hematoma.

Therapeutic Management

The first minutes to 12 hours are the most critical period for virtually all soft-tissue injuries. Basic principles of managing sprains and other soft-tissue injuries are summarized in the acronyms *RICE* and *ICES:*

R—Rest
I—Ice
C—Compression
E—Elevation

I—Ice
C—Compression
E—Elevation
S—Support

Soft-tissue injuries should be iced immediately. This is best accomplished with crushed ice wrapped in a towel or encased in a screw-top ice bag or resealable storage bag. A wet elastic wrap, which transfers cold better than dry wrap, is applied to provide compression and keep the ice pack in place. Chemical-activated ice packs are also effective for immediate treatment but are not reusable and must be monitored closely for leakage. A cloth barrier should be used between the ice container and the skin to prevent trauma to the tissues. Ice has a rapid cooling effect on tissues and reduces the pain threshold. However, it should never be applied for more than 30 minutes at a time because of the homeostatic response of the body to cold, which may trigger a decrease in vascularization at the injury site. A plastic bag of frozen vegetables such as peas serves as a convenient ice pack for soft-tissue injuries. It is clean, watertight, and easily molded to the injured part. When available, snow placed in a plastic bag may serve as an ice bag.

Elevating the extremity uses gravity to facilitate venous return and reduce edema formation in the damaged area. The point of injury should be kept several inches above the level of the heart for therapy to be effective. Several pillows can be used for elevation. Allowing the extremity to be dependent causes excessive fluid accumulation in the area of injury, delaying healing and causing painful swelling.

Torn ligaments, especially those in the knee, are usually treated by immobilization with a knee immobilizer or range-of-motion brace until the child is able to walk without a limp. Crutches are used for mobility to rest the affected extremity. Passive leg exercises, gradually increased to active ones, are begun as soon as sufficient healing has taken place. Parents and children are cautioned against using any form of liniment or other heat-producing preparation before examination. If the injury requires casting or splinting, the heat generated in the enclosed space can cause extreme discomfort and even tissue damage. In many cases torn knee ligaments are managed with arthroscopy and ligament repair or reconstruction as necessary, depending on the extent of the tear, the ligaments involved, and the child's age. Surgical reconstruction of the anterior cruciate ligament may be performed in young athletes who wish to continue in active sports (Sarwark, 2010).

Fractures

Bone fractures occur when the resistance of bone against the stress being exerted yields to the stress force. Fractures are a common injury at any age but are more likely to occur in children and older adults. Because childhood is a time of rapid bone growth, the pattern of fractures, problems of diagnosis, and methods of treatment differ in the child and the adult. In children fractures heal much faster than in adults. Consequently children may not require as long a period of immobilization of the affected extremity as an adult with a fracture.

Fracture injuries in children are most often a result of traumatic incidents at home, at school, in a motor vehicle, or in association with recreational activities. Children's everyday activities include vigorous play that predisposes them to injury (i.e., climbing, falling down, running into immovable objects, skateboarding, and receiving blows to any part of their bodies).

Aside from automobile accidents or falls from heights, true injuries that cause fractures rarely occur in infancy; therefore bone injury in children of that age-group warrants further investigation. In any small child, especially under the age of 12 months, radiographic evidence of fractures at various stages of healing is, with few exceptions, a result of *nonaccidental trauma* (child abuse). Any investigation of fractures in infants, particularly multiple fractures, should include consideration of *osteogenesis imperfecta.*

Fractures in school-age children are often a result of playground falls or bicycle-automobile or skateboard injuries. Adolescents are vulnerable to multiple and severe trauma because they are mobile on bicycles, all-terrain vehicles, skateboards, skis, snowboards, trampolines, and motorcycles and are active in sports.

A distal forearm (radius, ulna, or both) injury is the most common fracture in children. The clavicle is also a common fracture sustained in childhood, with approximately half of clavicle fractures occurring in children younger than 10 years of age. Common

mechanisms of injury include a fall with an outstretched hand or direct trauma to the bone. In neonates a fractured clavicle may occur with a large newborn and a small maternal pelvis. This may be noted in the first few days after birth by a unilateral Moro reflex or at the 2-week well-child check, when a fracture callus is palpated on the infant's healing clavicle.

Types of Fractures

A fractured bone consists of fragments—the fragment closer to the midline, or the proximal fragment; and the fragment farther from the midline, or the distal fragment. When fracture fragments are separated the fracture is complete; when fragments remain attached the fracture is incomplete. The fracture line can be any of the following:

- Transverse—Crosswise at right angles to the long axis of the bone
- Oblique—Slanting but straight between a horizontal and perpendicular direction
- Spiral—Slanting and circular, twisting around the bone shaft

The twisting of an extremity while the bone is breaking results in a spiral break. If the fracture does not produce a break in the skin, it is a simple, or closed, fracture. Open, or compound, fractures are those with an open wound through which the bone protrudes. If the bone fragments cause damage to other organs or tissues (e.g., the lung, liver), the injury is said to be a complicated fracture. When small fragments of bone are broken from the fractured shaft and lie in the surrounding tissue, the injury is a comminuted fracture. This type of fracture is rare in children. The types of fractures that are seen most often in children are described in Box 48-1 and Fig. 48-2.

Growth Plate (Physeal) Injuries

The weakest point of long bones is the cartilage growth plate, or the physis. Consequently this is a frequent site of damage of childhood trauma. Growth plate fractures are classified with the Salter-Harris classification system (Fig. 48-3). Detection of physeal injuries is sometimes difficult but critical. Close monitoring and early treatment, if indicated, are essential to prevent longitudinal or angular growth deformities (or both). Treatment of these fractures may include surgical open reduction and internal fixation to prevent or reduce growth disturbances.

Immediately after a fracture occurs, the muscles contract and physiologically splint the injured area. This phenomenon accounts for the muscle tightness observed over a fracture site and the deformity that is produced as the muscles pull the bone ends out of alignment. This muscle response must be overcome by traction or complete muscle relaxation (e.g., anesthesia) to realign the distal bone fragment to the proximal bone fragment.

Bone Healing and Remodeling

Bone healing is rapid in growing children because of the thickened periosteum and generous blood supply. When there is a break in the continuity of bone, the osteoblasts are stimulated to maximal

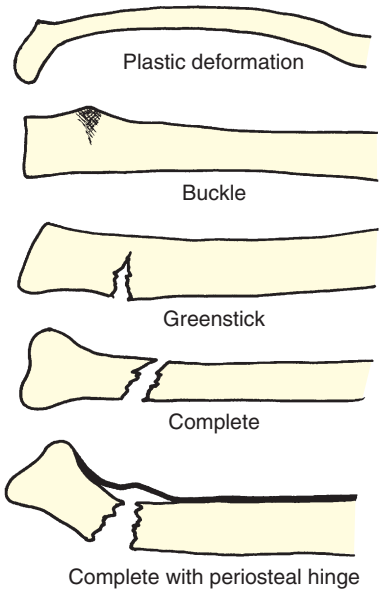

FIG 48-2 Types of fractures in children.

BOX 48-1 TYPES OF FRACTURES IN CHILDREN

Plastic deformation—Occurs when the bone is bent but not broken. A child's flexible bone can be bent 45 degrees or more before breaking. However, if bent, the bone will straighten slowly, but not completely, to produce some deformity but without the angulation seen when the bone breaks. Bends occur most commonly in the ulna and fibula, often in association with fractures of the radius and tibia.

Buckle, or torus, fracture—Produced by compression of the porous bone; appears as a raised or bulging projection at the fracture site. These fractures occur in the most porous portion of the bone near the metaphysis (the portion of the bone shaft adjacent to the epiphysis) and are more common in young children.

Greenstick fracture—Occurs when a bone is angulated beyond the limits of bending. The compressed side bends, and the tension side fails, causing an incomplete fracture similar to the break observed when a green stick is broken.

Complete fracture—Divides the bone fragments. These fragments often remain attached by a periosteal hinge, which can aid or hinder reduction.

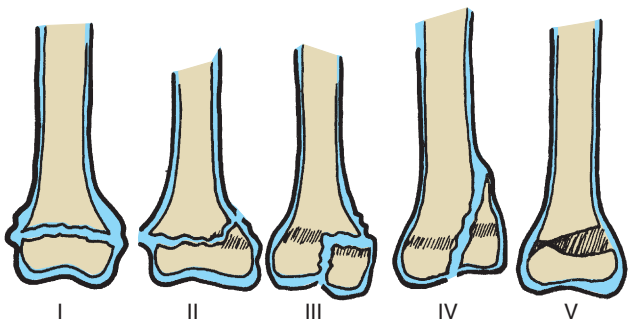

FIG 48-3 Salter Harris fracture classification. Types of epiphyseal injury in order of increasing risk. The injuries are classified as follows: type I, separation or slip of growth plate without fracture of the bone; type II, separation of growth plate and breaking off of section of metaphysis; type III, fracture of epiphysis extending through joint surface; type IV, fracture of growth plate, epiphysis, and metaphysis; and type V, crushing injury of epiphysis (can be diagnosed only in retrospect). This classification of epiphyseal injuries was developed by orthopedists RB Salter and WR Harris. (First published in Salter RB, Harris WR: Injuries involving the physeal plate, *J Bone Joint Surg Am* 45[3]:587-622, 1963.)

activity. New bone cells are formed in immense numbers almost immediately after the injury and in time are evidenced by a bulging growth of new bone tissue between the fractured bone fragments. This is followed by deposition of calcium salts to form a *callus.* Remodeling is a process that occurs in the healing of long bone fractures in growing children. The irregularities produced by the fracture become indistinct as the angles and bone overgrowth are smoothed out, giving the bone a straighter appearance. A general rule of thumb is that an angulated fracture in a growing child remodels by one degree per month (Green and Swiontkowski, 2008).

Fractures heal in less time in children than in adults. The approximate healing times for a femoral shaft are as follows:

- Neonatal period—2 to 3 weeks
- Early childhood—4 weeks
- Later childhood—6 to 8 weeks
- Adolescence—8 to 12 weeks

Diagnostic Evaluation

A history of the injury may be lacking in some childhood injuries. Infants and toddlers are unable to communicate, and older children may not volunteer information (even under direct questioning) when the injury occurred during forbidden activities. Whenever possible it is helpful to obtain information from someone who witnessed the injury. In cases of nonaccidental trauma providers may give false information to protect themselves or family members.

The child may exhibit the same manifestations seen in adults (Box 48-2). However, often a fracture is remarkably stable because of intact periosteum. The child may even be able to use an affected arm or walk on a fractured leg. Because bones are highly vascular, a soft, pliable hematoma may be felt around the fracture site.

Radiographic examination is the most useful diagnostic tool for assessing skeletal trauma. The calcium deposits in bone make the entire structure radiopaque. Radiographic films are taken after fracture reduction and in some cases during the healing process to determine satisfactory progress.

! NURSING ALERT

A fracture should be strongly suspected in a mobile small child who refuses to walk or crawl.

Therapeutic Management

The goals of fracture management are as follows:

- To regain alignment and length of the bony fragments (reduction)
- To retain alignment and length (immobilization)
- To restore function to the injured parts
- To prevent further injury and deformity

BOX 48-2 CLINICAL MANIFESTATIONS OF A FRACTURE

- Signs of injury:
  - Generalized swelling
  - Pain or tenderness
  - Diminished functional use of affected part
- May be:
  - Bruising
  - Severe muscular rigidity
  - **Crepitus** (grating sensation at fracture site)

Most children's fractures heal well, and nonunion is rare. Fractures are splinted or casted to immobilize and protect the injured extremity. Children with displaced fractures may have immediate surgical reduction and fixation (internal or external) rather than being immobilized by traction. This practice is more common and holds true for all types of fractures, including femur fractures, although there is variation based on provider preference and institutional practice. Some conditions, including open fractures, compartment syndrome, fractures associated with vascular or nerve injury, and joint dislocations that are unresponsive to reduction maneuvers, require immediate medical attention.

In children immobilization is used until adequate callus is formed. The position of the bone fragments in relation to one another influences the rapidity of healing and residual deformity. Weight bearing and active movement for the purpose of regaining function may begin after the fracture site is determined to be stable by the medical provider. The child's natural tendency to be active is usually sufficient to restore normal mobility, and physical or occupational therapy is rarely indicated.

Children are most frequently hospitalized for fractures of the femur and supracondylar area of the distal humerus. If simple reduction cannot be achieved or a neurovascular problem is detected after the injury, observation in a hospital setting may be indicated. The trend is to avoid hospitalization. The major methods for immobilizing a fracture (i.e., casting and traction) are described later.

CARE MANAGEMENT

Nurses are frequently the people who make the initial assessment of a child with a suspected fracture (see Emergency box). The child and parents may be frightened and upset, and the child is often in pain. Therefore, if the child is alert and there is no evidence of hemorrhage, the initial nursing interventions are directed toward calming and reassuring the child and parents so a more extensive assessment can be more easily accomplished.

EMERGENCY

Fracture

- Assess the extent of injury—Six *P*s:
  1. *P*ain and point of tenderness
  2. *P*ulses—Distal to fracture site
  3. *P*allor
  4. *P*aresthesia—Sensation distal to fracture site
  5. *P*aralysis—Movement distal to fracture site
  6. *P*ressure
- Determine the mechanism of injury.
- Move the injured part as little as possible.
- Cover open wounds with a sterile or clean dressing.
- Immobilize the limb, including joints above and below the fracture site; do not attempt to reduce the fracture or push protruding bone under the skin.
  - Soft splint (pillow or folded towel)
  - Rigid splint (rolled newspaper or magazine)
  - Uninjured leg can serve as a splint for a leg fracture if no splint available
- Reassess neurovascular status.
- Apply traction if circulatory compromise is present.
- Elevate the injured limb if possible.
- Apply cold to the injured area.
- Call emergency medical services or transport to medical facility.

While remaining calm and speaking in a quiet voice, the nurse can ask the parents and older child to describe what happened. The child may arrive with the limb supported in some manner; if not, careful support or immobilization may be provided to the affected site. In the event that the limb is supported or immobilized, it may be best not to touch the child but to ask him or her to point to the painful area and wiggle the fingers or toes. By this time the child may feel relatively safe and will allow someone to gently touch the area just enough to feel the pulses and test for sensation. A child's anxiety is greatly influenced by previous experiences with injury and with health care providers. However, he or she needs to be told what will happen and what to do to help. The affected limb need not be palpated, and it should not be moved unless properly splinted. If the child is at home or the practitioner is not present to examine her or him, some type of splint is applied carefully for transport to the medical facility. Parental anxiety may be heightened by the child's pain reaction and fear and possibly by other events surrounding the accident. It is important to communicate to the parent that the child will receive the necessary care, including pain management.

! NURSING ALERT

Compartment syndrome is a serious complication that results from compression of nerves, blood vessels, and muscle inside a closed space. This injury may be devastating, resulting in tissue death, and thus requires emergency treatment (fasciotomy). The six *P*s of ischemia from a vascular, soft tissue, nerve, or bone injury should be included in an assessment of any injury (Box 48-3):

1. *P*ain
2. *P*allor
3. *P*ulselessness
4. *P*aresthesia
5. *P*aralysis
6. *P*ressure

The Child in a Cast

The completeness of the fracture, the type of bone involved, and the amount of weight bearing influence how much of the extremity must be included in the cast to immobilize the fracture site completely. In most cases the joints above and below the fracture are immobilized to eliminate the possibility of movement that might cause displacement at the fracture site. Four major categories of casts are used for fractures: *upper extremity* to immobilize the wrist or elbow, *lower extremity* to immobilize the ankle or knee, *spinal* and *cervical* for immobilization of the spine, and *spica* to immobilize the hip and knee.

BOX 48-3 COMPARTMENT SYNDROME EVALUATION

Assess the extent of injury—6 *P*s:

1. **Pain:** Severe pain that is not relieved by analgesics or elevation of the limb; movement that increases pain
2. **Pulse:** Inability to palpate a pulse distal to the fracture or compartment
3. **Pallor:** Pale-appearing skin, poor perfusion, capillary refill greater than 3 seconds
4. **Paresthesia:** Tingling or burning sensations
5. **Paralysis:** Inability to move extremity or digits
6. **Pressure:** Involved limb or digits may feel tense and warm; skin tight, shiny; pressure within the compartment elevated

The Cast

Casts are constructed from gauze strips and bandages impregnated with plaster of Paris or more commonly from synthetic lighter-weight and water-resistant materials (e.g., waterproof liners, fiberglass and polyurethane resin).

Both types of casting produce heat from chemical reaction activated by water immediately after application. Plaster casts mold closely to the body part, take 10 to 72 hours to dry, have a smooth exterior, and are inexpensive. The newer synthetic casting material is lightweight, dries in 5 to 20 minutes, permits earlier weight bearing, and is water resistant when applied with a waterproof liner. It is always desirable to give children choices, and synthetic casting materials come in a variety of colors. The disadvantages of synthetic casting are its inability to mold closely to body parts; rough exterior, which may scratch surfaces; and increased cost. It is also difficult to write on synthetic casts; a waterproof marker or color markers may be used.

Cast Application. The child's developmental age should be considered before the cast is applied. For preschoolers who fear bodily harm and fantasize about the loss of an extremity, it may be helpful to use a plastic doll or stuffed animal to explain the procedure beforehand. Toddlers and preschoolers do not have easily defined body boundaries; if an extremity is wrapped in a bandage, cast, or splint, to the young child the extremity ceases to function or exist. It is also helpful to explain that some synthetic cast material will become warm during application but will not burn. During the application of the cast various distraction methods can be used, including discussing favorite pets or activities at school and blowing bubbles. In this age-group explanations such as, "This will help your arm get better" are futile because the child has no concept of causality.

Before the cast is applied, the extremities are checked for any abrasions, cuts, or other alterations in the skin surface and for the presence of rings or other items that might cause constriction from swelling; such objects are removed. A tube of cloth stockinette or Gore-Tex liner is stretched over the area to be casted, and bony prominences are padded with soft cotton sheeting. Dry rolls of casting material are immersed in a pail of water. The wet rolls are put on in a bandage fashion and molded to the extremity. During application of the cast the underlying stockinette is pulled over the rough edges of the cast and secured with casting material to form a padded edge to protect the skin.

CARE MANAGEMENT

The complete evaporation of the water from a hip spica cast can take 24 to 48 hours when older types of plaster materials are used. Drying occurs within minutes with fiberglass cast material. The cast must remain uncovered to allow it to dry from the inside out. Turning the child in a plaster cast at least every 2 hours helps to dry a body cast evenly and prevents complications related to immobility. A regular fan or cool-air hair dryer to circulate air may be helpful when the humidity is high.

! NURSING ALERT

Heated fans or dryers are not used because they cause the cast to dry on the outside and remain wet beneath or cause burns from heat conduction by way of the cast to the underlying tissue.

A wet plaster cast should be supported by a pillow that is covered with plastic. The cast should be handled by the palms of the hands instead of the fingertips to prevent indenting the cast, which can create pressure areas. A dry plaster-of-Paris cast produces a hollow sound when it is tapped with the finger. After it has dried "hot spots" felt on the cast surface or a foul-smelling odor may indicate an infection. This should be reported for further evaluation; if concern continues, an opening, or a "window," could be exposed over the area of concern to evaluate the site.

During the first few hours after a cast is applied, the chief concern is that the extremity may continue to swell to the extent that the cast becomes a tourniquet, shutting off circulation and producing neurovascular complications (compartment syndrome) (see Box 48-3). To reduce the likelihood of this potential problem, the body part should be elevated, thereby increasing venous return. If edema is excessive, casts are *bivalved* (i.e., cut to make anterior and posterior halves that are held together with an elastic bandage). The cast and the involved extremity are observed frequently for neurovascular integrity and any signs of compromise. Permanent muscle and tissue damage can occur within a few hours.

! NURSING ALERT

Observations such as pain (unrelieved by pain medication 1 hour after administration, especially with passive range of motion), swelling, discoloration (pallor or cyanosis) of the exposed portions, decreased pulses, decreased temperature, paresthesia, or the inability to move the distal exposed part(s) should be reported immediately. Pallor, paralysis, and pulselessness are late signs (see Box 48-3).

When an extremity that has sustained an open fracture is casted, a window is often left over the wound area to allow for observation and dressing of the wound. For the first few hours after surgery substantial bleeding may soak through the cast. Periodically the circumscribed bloodstained area should be outlined with a waterproof marker, and the time indicated to provide a guide for assessing the amount of bleeding.

Appropriate cast care guidelines for the child's caregiver are necessary before discharge. Instructions are also given for checking for signs and symptoms that indicate that the cast is too tight (see Patient Teaching box). Parents should also be told to take the child to the health care provider for attention if the cast becomes too loose because a loose cast no longer serves its purpose.

Nurses can help families adapt the child's home environment to meet the temporary encumbrance of a large cast or one that restricts the child's mobility (e.g., a long-leg or spica cast [Fig. 48-4]). Commonplace situations become problematic (e.g., transporting a child safely and comfortably in a car). Standard seat belts and car seats may not be readily adapted for use by children in some casts. Specially designed car seats and restraints are available that meet safety requirements.* Alterations to standard car seats to accommodate the cast are not recommended because the structure may be adversely altered and fail to properly restrain the child. A bedside commode or rental wheelchair may be necessary equipment for a child who is nonambulatory.

Parents are taught the proper care of the cast or brace and helped to devise means for maintaining cleanliness. A superabsorbent

PATIENT TEACHING

Cast Care

- Keep the casted extremity elevated on pillows or similar support for the first day or as directed by the health care provider.
- Avoid denting the plaster cast with fingertips (use palms of hand to handle) while it is still wet to avoid creating pressure points.
- Observe the extremities (fingers or toes) for any evidence of swelling or discoloration (darker or lighter than a comparable extremity) and contact the health care provider if noted.
- Check movement and sensation of the visible extremities frequently.
- Follow health care provider's orders regarding any restriction of activities.
- Restrict strenuous activities for the first few days.
  - Engage in quiet activities but encourage use of muscles.
  - Move the joints above and below the cast on the affected extremity.
- Encourage frequent rest for a few days, keeping the injured extremity elevated while resting.
- Avoid allowing the affected limb to hang in a dependent position for any length of time.
  - Keep an injured upper extremity elevated (e.g., in a sling) while upright.
  - Elevate a lower limb when sitting and avoid standing for too long.
- Do not allow the child to put anything inside the cast. Keep small items that might be placed inside the cast away from small children.
- Keep a clear path for ambulation. Remove toys, hazardous floor rugs, pets, or other items over which the child might stumble.
- Use crutches appropriately if lower-limb fracture requires nonweight bearing on affected extremity.
- The crutches should fit properly, have a soft rubber tip to prevent slipping, and be well padded at the axilla.
- With crutch walking the child's body weight is supported on the hand grips, not the axilla.

FIG 48-4 Spica cast with hip abductor. Note casts on doll as well.

*For information on specially adapted molded-plastic chairs for children who have spica casts, contact Snug Seat at 800-336-7684, www.snugseat.com/en-US/Welcome-to-Snug-Seat.aspx. The E-Z-On vest is a special safety harness for larger children with poor trunk control. Additional safety restraints and a listing of distributors are available from SafetyBeltSafe USA, www.carseat.org. Another resource is the National Center for the Safe Transportation of Children with Special Health Care Needs, 800-543-6227, www.preventinjury.org/specNeeds.asp.

disposable diaper is tucked beneath the entire perineal opening of the cast. A larger diaper can be applied and fastened over the small diaper and cast to hold the smaller diaper in place. In the event that the larger diaper becomes wet or soiled, it is likely that the cast is as well.

For tightly fitting casts transparent film dressings can be cut into strips as for petaling, with one edge applied to the cast edge and the other directly to the perineum; this forms a continuous waterproof bridge between the perineum and the cast to prevent leakage. An additional advantage to the use of this transparent dressing is that it keeps both the skin and the cast dry while allowing for observation of skin beneath the dressing.

Older infants and small children may stuff bits of food, small toys, or other items under the cast; parents should be alerted to this possibility so they can initiate suitable preventive measures.

Feeding an infant in a hip spica cast offers problems in positioning. Very young infants can be fed in the supine position with the head elevated. With the infant's hips and legs supported on a pillow at the side, the parent can cuddle the infant in his or her arms during feeding. A somewhat similar position can be used for breastfeeding (i.e., with the infant supported on pillows or held in a "football" hold facing the mother with the legs behind her). An alternate position is to hold the infant upright on the caregiver's lap with the legs of the infant astride the adult's leg.

Children in spica casts usually find the prone position easier for self-feeding from a small table placed next to the dining table; alternatively they may manage a semisitting position in bed or a wheelchair (see Fig. 48-4). The use of a conventional toilet is almost impossible. A bedside toilet can be adapted for use. Small bedpans or other containers offer alternatives for elimination. The nurse may suggest waterproofing methods by devising plastic wraps for elimination and showers. Baths are possible only if the plaster cast is kept out of the water and covered to prevent it from becoming wet.

Cast Removal. Cutting the cast to remove it or relieve tightness is frequently a frightening experience for children. They fear the sound of the cast cutter and are terrified that both their flesh and the cast will be cut. The oscillating blade vibrates rapidly back and forth and will not cut when placed *lightly* on the skin. Children have described it as producing a "tickly" sensation. The vibration also generates heat that the child may feel. Both of these feelings should be explained.

Preparation for the procedure helps reduce anxiety, especially if a trusting relationship has been established between the child and the nurse. Many young children come to regard the cast as part of themselves, which intensifies their fear of removal (Fig. 48-5). They need continual reassurance that all is going well and that their behavior is accepted. After the cast is removed, the parents and child should be given the option of keeping it. If the cast has been in place for a lengthy period, decreased muscle mass will be noted. The child should be reassured that resuming exercise and routine activities will return function and appearance (provided there was no significant trauma beforehand).

After the cast is removed, the skin surface will be caked with desquamated skin and sebaceous secretions. Application of mineral oil (e.g., baby oil) or lotion may remove the particles and provide comfort. Soaking the extremity in a bathtub is usually sufficient for their removal, but it may take several days to eliminate the accumulation completely. The parents and child should be instructed not to pull or forcibly remove this material with vigorous scrubbing because it may cause excoriation and bleeding.

FIG 48-5 Young children usually adapt well to a cast but often fear the removal.

The Child in Traction

The ever-changing health care arena has witnessed the demise of many long-term treatments involving lengthy hospitalization; one such change is in the area of traction. Most balanced skeletal traction is applied in children after a severe or complex injury to allow physiologic stability, align bone fragments, and permit closer evaluation of the injured site. Newer technology has produced orthopedic fixation devices that allow partial or full mobility, thus preventing long-term immobilization and its consequences. In many situations surgical intervention may be carried out within a matter of days; therefore skeletal traction devices described herein may be used infrequently in pediatrics.

Purposes of Traction

The six primary purposes of traction areas are

1. To fatigue the involved muscles and reduce muscle spasm so bones can be realigned.
2. To position the distal and proximal bone ends in desired realignment to promote satisfactory bone healing.
3. To immobilize the fracture site until realignment has been achieved and sufficient healing has taken place to permit casting or splinting.
4. To help prevent or improve contracture deformity.
5. To provide immobilization of specific areas of the body.
6. To reduce muscle spasms (rare in children).

The three essential components of traction management are traction, counter traction, and friction (Fig. 48-6). To reduce or realign a fracture site, traction (forward force) is produced by attaching weight to the distal bone fragment. Body weight provides counter traction (backward force), and the patient's contact with the bed constitutes the frictional force. These forces are used to align the distal and proximal bone fragments by adjusting the line of pull upward or downward and adducting or abducting the extremity.

To attain equilibrium the amount of forward force is adjusted by adding weight to or subtracting weight from the traction; or counter traction can be increased by elevating the foot of the bed to create a greater gravitational pull to the backward force.

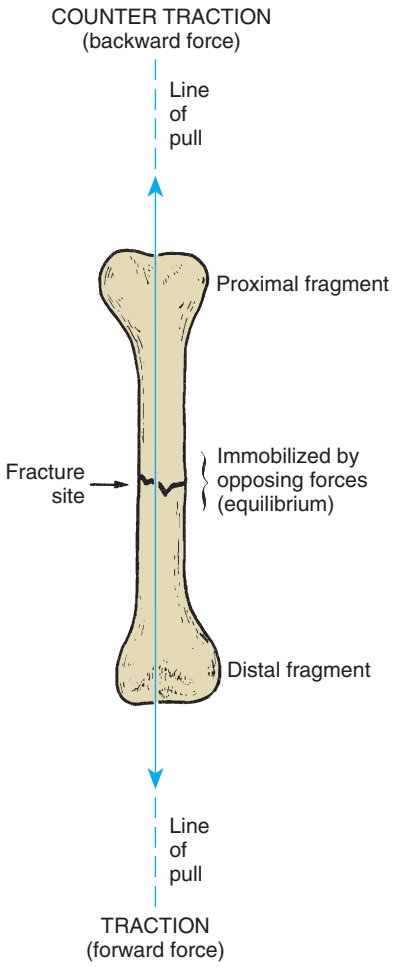

FIG 48-6 Application of traction to maintain bone alignment.

The all-or-none law, characteristic of muscle contractibility, influences the complete relaxation. When muscles are stretched, muscle spasm ceases, which permits the realignment of the bone ends. The continuous maintenance of traction is important during this phase because releasing the traction allows the normal contracting ability of the muscle to again cause a malpositioning of the bone ends.

The realignment of the fragments is a gradual process that is achieved more rapidly in infants, who have limited muscle tone, than in muscular teenagers. The desired vector force and callus formation are checked periodically by radiographic examination. The traction pull to some degree immobilizes the fracture site; however, adjunctive immobilizing devices such as splints or casts are sometimes used with skeletal traction. Immobilization with traction is maintained until the bone ends are in satisfactory realignment or muscle fatigue is achieved, after which a less confining type of immobilization (i.e., a cast, pins, or external stabilization device) is applied.

Types of Traction (General)

The pull needed for traction can be applied to the distal bone fragment in several ways (Box 48-4). The type of traction applied is determined primarily by the child's age, the condition of the soft tissues, and the type and degree of displacement of the fracture. Fractures most commonly treated by application of traction are those involving the femur and vertebrae. The major types of traction for specific fractures are discussed briefly in the following sections.

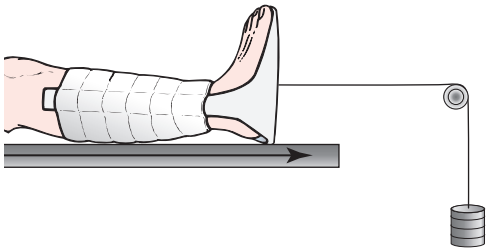

FIG 48-7 Buck extension traction. (From Lewis SL, Heitkemper MM, Dirksen S, et al, editors: *Medical-surgical nursing: assessment and management of clinical problems*, ed 8, St Louis, 2011, Mosby.)

BOX 48-4 TYPES OF TRACTION

Manual traction—Applied to the body part by the hands placed distal to the fracture site. Manual traction may be provided during application of a cast but more commonly when a closed reduction is performed.

Skin traction—Applied directly to the skin surface and indirectly to the skeletal structures. The pulling mechanism is attached to the skin with adhesive material or an elastic bandage. Both types are applied over soft, foam-backed traction straps to distribute the traction pull.

Skeletal traction—Applied directly to the skeletal structure by a pin, wire, or tongs inserted into or through the diameter of the bone distal to the fracture.

The use of upper-extremity traction in children is uncommon. Newer surgical techniques allow for early mobilization and optimal results without traction. Nursing care of the child with upper-extremity traction is the same as that for lower-extremity traction, which is discussed in the following paragraphs.

The frequent site for a femoral fracture is in the middle third of the shaft. With this fracture there may be significant overriding but minimal displacement. In a fracture in the lower third of the shaft, the pull of the gastrocnemius muscle causes the distal fragment to become downwardly displaced.

Fractures of the femur can often be reduced with immediate application of a hip spica cast in young children. When traction is required, several types may be used based on the initial assessment.

Bryant traction is a type of running traction in which the pull is in only one direction. Skin traction is applied to the legs, which are flexed at a 90-degree angle at the hips. The child's trunk (with the buttocks raised slightly off the bed) provides counter traction. Bryant traction may be used to treat a femoral shaft fracture in young children.

Buck extension traction (Fig. 48-7) is a type of traction with the legs in an extended position. Except for fracture cases turning from side to side with care is permitted to maintain the involved leg in alignment. Buck extension traction is used primarily for short-term immobilization such as preoperative management of a child with a dislocated hip or correction of contractures or bone deformities such as in Legg-Calvé-Perthes disease. Buck traction may be accomplished with either skin straps or a special foam boot designed for traction.

Russell traction uses skin traction on the lower leg and a padded sling under the knee. Two lines of pull, one along the longitudinal

FIG 48-8 Halo vest. (From Herring JA: *Tachdjian's pediatric orthopaedics*, ed 4, Philadelphia, 2008, Saunders.)

line of the lower leg and one perpendicular to the leg, are produced. This combination of pulls allows realignment of the lower extremity and immobilizes the hip and knee in a flexed position. The hip flexion must be kept at the prescribed angle to prevent fracture malalignment because there is no direct support under the fracture and the skin traction may slip. Special nursing measures include carefully checking the position of the traction so the amount of desired hip flexion is maintained and damage to the common peroneal nerve under the knee does not produce footdrop.

A common skeletal traction is 90-degree–90-degree traction (90-90 traction). The lower leg is supported by a boot cast or calf sling, and a skeletal Steinmann pin or Kirschner wire is placed in the distal fragment of the femur, resulting in a 90-degree angle at both the hip and the knee. From a nursing standpoint this traction facilitates position changes, toileting, and prevention of complications related to traction.

Balanced suspension traction may be used with or without skin or skeletal traction. Unless used with another traction, the balanced suspension merely suspends the leg in a desired flexed position to relax the hip and hamstring muscles and does not exert any traction directly on a body part. A Thomas splint extends from the groin to midair above the foot, and a Pearson attachment supports the lower leg. Towels or pieces of felt covered with stockinette are clipped or pinned to the splints for leg support. When the child is lifted off the bed, the traction lifts with the child without loss of alignment. This traction requires careful checking of splints and ropes to make certain that no slippage or fraying has occurred. The traction is of great value in an older and heavier child when it is essential to lift the patient for care.

The cervical area is a vulnerable site for flexion or extension injuries to muscle, vertebrae, or the spinal cord. Cervical muscle trauma without other complications is treated with a cervical hard collar to relieve the weight of the head from the fracture site. When a child displaces or fractures a cervical vertebra, it may be necessary to reduce and immobilize the site with cervical skeletal traction. The spinal cord runs through the intravertebral canal, and dislocation or fracture of the vertebrae can also cause spinal cord injury. Nursing assessment of neurologic function is essential to prevent further injury during the application and use of cervical skeletal traction. Most cervical traction is accomplished with the use of a halo brace or halo vest (Fig. 48-8). This device consists of a steel halo attached to the head by four screws (or pins) inserted into the outer skull; several rigid bars connect the halo to a vest that is worn around the chest, thus providing greater mobility of the rest of the body while avoiding cervical spinal motion altogether. If the injury has been limited to a vertebral fracture without neurologic deficit, a halo brace can be applied to permit earlier ambulation. Gardner-Wells tongs may be used with the halo vest (Fisher, Williams, and Levine, 2008). Gardner-Wells tongs are spring loaded; thus making burr holes and shaving hair are not required; a local anesthetic may be used during application. In-line cervical traction may also be accomplished by attaching Gardner-Wells tongs to the child's head, with a 3- to 4-pound weight (depending on the child's weight) exerting traction on the cervical vertebrae.

As the neck muscles fatigue with constant traction pull, the vertebral bodies gradually separate so the cord is no longer pinched between the vertebrae. Immobilization until fracture healing or surgical fixation can occur is an essential goal of cervical traction. If immobilization is required in an infant or young child, a special cervical spine cast (Minerva cast) is applied.

CARE MANAGEMENT

To assess the child in traction, it is essential to know the purpose for which the traction is applied and understand the basic principles of traction. Regular assessment of both the child and the traction apparatus is required (see Guidelines box). Many of the nursing problems associated with a child in traction are related to immobility. Modifying the child's diet, encouraging fluids, increasing fiber, and offering a mild stool softener may be necessary to prevent constipation.

When indicated by the attending practitioner, the nurse may remove nonadhesive skin traction. In these cases intermittent traction is released periodically and reapplied as ordered. A child may have several types of traction at one time; each one must be assessed separately to avoid problems.

! NURSING ALERT

Skeletal traction is never released by the nurse (except under direct supervision by the practitioner). This precaution includes not lifting the weights that are applying traction (e.g., for moving the child in bed, for repositioning).

In addition to routine skin observation and care, the child in skeletal traction needs special skin care at the pin site according to hospital policy or practitioner preference. Pin sites should be frequently assessed and cleaned to prevent infection; after the first 48 to 72 hours pin site care may be performed once daily or weekly for mechanically stable pins (Holmes, Brown, and Pin Site Care Expert Panel, 2005). Use of a 2-mg/mL chlorhexidine solution has been proposed as best practice care for skeletal pin sites by the National Association of Orthopaedic Nurses (Holmes, Brown, and Pin Site Care Expert Panel, 2005). A pressure-reduction device such as a special air mattress decreases the chance of skin breakdown. A small hand mirror facilitates visualization of inaccessible skin areas.

When the child is first placed in traction, increased discomfort is common as a result of the traction pull fatiguing the muscle. It has been determined that orthopedic conditions are associated with a higher-than-average number of painful events and a higher percentage of bodily symptoms than other common conditions. Analgesics, including IV opioids and muscle relaxants, help during this phase of care and should be administered liberally.

GUIDELINES

Traction Care

Understand Therapy
- Understand purposes of traction.
- Understand function of traction in each specific situation.

Maintain Traction
- Check desired line of pull and relationship of distal fragment to proximal fragment. Check whether fragment is being directed upward, adducted, or abducted.
- Check function of each component.
  - Position of bandages, frames, splints, specialized boot
  - Ropes—In center track of pulley, taut, no fraying, knots tied securely
  - Pulleys—In original position on attachment bar; have not been displaced from original site
  - Wheels freely moveable
  - Weights—Correct amount of weight, hanging freely, in safe location
- Check bed position; head or foot should be elevated as directed for desired amount of pull and counter traction.
- Do not remove skeletal traction or adhesive traction straps on skin traction.

Maintain Alignment
- Observe for correct body alignment with emphasis on alignment of shoulder, hip, and leg.
- Check after child has moved.
- Maintain correct angles at joints.

Skin Traction
- Replace nonadhesive straps and/or elastic bandage on skin traction *when permitted* and/or absolutely necessary, but make certain that traction on limb is maintained by someone during procedure.
- Assess straps or bandages to ascertain whether they are applied correctly (diagonal or spiral), not too loose or too tight, which could cause slippage and malalignment of traction.
- Assess traction boot to ensure that it has not slipped and is not causing compression of the foot, thus impairing the circulation.

Skeletal Traction
- Check pin sites frequently for signs of bleeding, inflammation, or infection.
- Cleanse and dress pin sites per evidence-based guidelines or institution protocol.
- Apply topical antiseptic or antibiotic to pin sites daily as ordered.
- Cover ends of pins with protective rubber or padding to prevent child's being scratched by pin.
- Note pull of traction on pin; pull should be even.
- Check pin screws to be certain that screws are tight in metal clamp that attaches traction apparatus to pin.

Prevent Skin Breakdown
- Provide foam overlay or alternating-pressure mattress underneath hips and back.
- Make total-body skin checks for redness or breakdown, especially over areas that receive greatest pressure.
- Wash and dry skin at least daily.
- Inspect pressure points daily or more often if risk of breakdown is observed.
- Use a skin breakdown assessment scale such as Modified Braden Q.
- Stimulate circulation with gentle massage over pressure areas.
- Change position at least every 2 hours to relieve pressure.
- Encourage increased intake of oral fluids.
- Provide and encourage patient to eat a balanced diet, including vegetables and fruits.

Prevent Complications
- Check pulses in affected area and compare with pulses in contralateral site.
- Assess circular dressings for excessive tightness.
- Assess restrictive bandages or devices used to maintain traction on affected limb.
  - Make certain that they are not too loose or too tight.
  - Remove periodically and check for pressure areas.
- Encourage deep breathing exercises. Note any neurovascular changes such as the following:
  - Changes in color in skin and nail beds
  - Alterations in sensation, increased pain
  - Alterations in motor ability
- Take immediate action to correct problem or report to practitioner if neurovascular changes are found.
- Record findings of neurovascular changes.
- Carry out passive, active, or active-with-resistance exercises of uninvolved joints.
- Note if any tightness, weakness, edema, or contractures are developing in uninvolved joints and muscles.
- Take measures to correct or prevent further development of weakness such as applying footboard or foot orthoses to prevent footdrop.

NURSING ALERT

For skeletal traction to be effective, ensure that the weights are hanging freely at all times. The specific nursing responsibilities for the patient in traction are outlined in the Guidelines box above.

Distraction

Unlike traction, which helps bones realign and fuse properly, distraction is the process of separating opposing bone to encourage regeneration of new bone in the created space. Distraction can also be used when limbs are of unequal lengths and new bone is needed to elongate the shorter limb.

External Fixation

Monolateral, Taylor Spatial Frame, and Ilizarov external fixators (IEFs) are common external fixation devices. The IEF uses a system of wires, rings, and telescoping rods that permits limb lengthening to occur by manual distraction (Fig. 48-9). In addition to lengthening bones, the device can be used to correct angular or rotational defects or immobilize fractures. It is attached surgically by securing a series of external full or half rings to the bone with wires. External telescoping rods connect the rings to one another. Manual distraction is accomplished by manipulating the rods to increase the distance between the rings. A percutaneous **osteotomy** is performed when the device is applied to create a "false" growth plate. A special osteotomy or corticotomy involves cutting only the cortex of the

FIG 48-9 Child with Ilizarov external fixator (right leg) during physical therapy on parallel bars.

bone while preserving its blood supply, bone marrow, endosteum, and periosteum. Capillary blood flow to the transected area is essential for proper bone growth. Cut bone ends typically grow at a rate of 1 cm (0.4 inches) per month. The IEF can result in up to a 15-cm (6-inch) gain in length.

CARE MANAGEMENT

Success of the external fixation devices depends on the child's and family's cooperation; therefore before surgery they must be fully informed of the appearance of the device and how it accomplishes bone growth and limits bone mobility, alterations in activities, and home and follow-up care. Children are involved in learning to adjust the device to accomplish distraction. Children and parents should be instructed in pin care, including observation for infection and loosening of the pins. Cleaning routines for the pin sites vary among practitioners but should not traumatize the skin.

Children who participate actively in their care report less discomfort. Because the device is external, the child and family need to be prepared for the reactions of others and helped to camouflage it with appropriate apparel such as wide-legged pants that close with self-adhering fasteners around it. A loose sock or stockinette may also be used over the device to decrease public awareness. Partial weight bearing is allowed, and the child learns to walk with crutches. Alterations in activity include modifications at school and in physical education. Full weight bearing is not allowed until the distraction is completed and bone consolidation has occurred. Follow-up care is essential to maintain appropriate distraction until the desired limb length is achieved. The device is removed surgically after the bone has consolidated, and the child may need to use crutches or have a cast for 4 to 6 weeks after removal to reduce the risk of fracture.

Amputation

A child may be born with the congenital absence of an extremity, have a traumatic loss of an extremity, or need a surgical amputation for a pathologic condition such as osteosarcoma (see p. 1561). With today's surgical technology and the quick thinking of bystanders who save a traumatically amputated body part, some children have had fingers and arms sewn back on with variable degrees of functional use regained.

Surgical amputation or the surgical repair of a permanently severed limb focuses on constructing an adequately nourished residual limb. A smooth, healthy, padded stump, free of nerve endings, is important in prosthesis fitting and subsequent ambulation. In some situations in which there is no vascular or neurologic deficit, a cast is applied to the stump immediately after the procedure; and a pylon, metal extension, and artificial foot are attached so the patient can walk on the temporary prosthesis within a few hours.

CARE MANAGEMENT

Stump shaping is done after surgery with special elastic bandaging using a figure-eight bandage, which applies pressure in a cone-shaped fashion. This technique decreases stump edema, controls hemorrhage, and aids in developing desired contours so the child will bear weight on the posterior aspect of the skin flap rather than on the end of the stump. Stump elevation may be used during the first 24 hours, but after this time the extremity should not be left in this position because contractures in the proximal joint will develop and seriously hamper ambulation.

! NURSING ALERT

For an amputated limb or body part that may be reattached, do the following:

1. Rinse limb gently with normal saline.
2. Loosely wrap limb in sterile gauze.
3. Place wrapped limb in a watertight bag.
4. Cool (without freezing) bag in ice water (do not pack in ice because this may harm tissue).
5. Label with child's name, date, and time and transport with the child to the hospital.

For older children and adolescents, arm exercises, bed pushups, and prosthesis-training programs using parallel bars help build up the arm muscles necessary for walking with crutches. Full range-of-motion exercises of joints above the amputation must be performed several times daily using active and isotonic exercises. Young children are often spontaneously active and require little encouragement.

Depending on the child's age, children or their parents will need to learn hygiene, including carefully washing with soap and water every day and checking for skin irritation, breakdown, and infection. A tube of stockinette or powder is used to slide the prosthesis on more easily. Skin must be checked carefully every time the prosthesis is removed, and prosthesis tolerance time must be adjusted to prevent skin breakdown.

For children who have had an amputation, *phantom limb sensation* is an expected experience because the nerve-brain connections are still present. Gradually these sensations fade, although in many people who have had amputations they persist for years. Preoperative discussion of this phenomenon helps a child understand these "unusual feelings" and not to hide the experiences from others. Limb pain, especially pain that increases with ambulation, should be evaluated for the possibility of a neuroma at the free nerve endings in the stump or other problems such as a poorly fitting prosthesis or joint instability.

SPORTS PARTICIPATION AND INJURY

Every sport has the potential for injury to participants, whether an adolescent engages in serious competition or participates for enjoyment. Serious injury occurs most often during rough contact sports or to people who are not physically prepared for the activity. Injuries also occur when the children's or adolescents' bodies are not suited to the sport, when their muscles and body systems (respiratory and cardiovascular) are not conditioned to endure physical stress, or when they lack the insight and judgment to recognize that an activity exceeds their physical abilities. Rapidly growing bones, muscles, joints, and tendons are especially vulnerable to unusual strain. In general more injuries occur during recreational sports participation than during organized athletic competition.

The environment and the sports or recreational equipment can also present risks. Children and adolescents who participate in physical activity or sports do so in many different environments, including indoors and outdoors, on floors, on the ground and snow, on or beneath water surfaces, and sometimes in free air space. Most of these activities also involve equipment, which children and adolescents may not be physically mature enough to manage safely. A common example is skateboarding when the child or adolescent does not take safety precautions and perceives increased risk taking as a part of the sport.

Acute overload injuries are those that occur suddenly during an activity and produce immediate symptoms. A blow or overstretching, twisting, or sudden stress to tissues can cause these injuries. For descriptions and management of traumatic injuries see p. 1536.

Overuse Injury

To excel in sports young athletes are forced to train longer, harder, and earlier in life than previously. The rewards are an increased level of fitness, better performance, faster times, and the satisfaction of attaining a personal goal. However, risks are associated when young people overtrain; these risks include recurrent upper-respiratory infections, sleep and mood disturbances, loss of appetite, decreased interest in training and competition, and inability to concentrate (Winsley and Matos, 2011). Growing numbers of young people participate in organized sports, resulting in an increase in overuse injuries. Nearly half of all injuries evaluated in pediatric sports medicine are overuse injuries (Biber and Gregory, 2010). Evidence-based recommendations for prevention and identification of risk factors for overuse injuries in older children and adolescents have been published elsewhere (Valovich McLeod, Decoster, Loud, et al., 2012).

The risk of overuse injury is always present and can be related to several factors, including training errors, muscle-tendon imbalance, anatomic malalignment (e.g., femoral anteversion, excessive lumbar lordosis, tibial torsion), incorrect footwear or playing surface, an associated disease state, and growth (growth cartilage is less resistant to microtrauma). Chronic pain in athletes is often associated with overuse injury, which can occur at any level of athletic participation. The common feature in overuse injuries is the *repetitive microtrauma* that occurs to a particular anatomic structure. Performing the same movements repeatedly can cause several types of injury:

- Frictional, or rubbing of one structure against another
- Tractional, or repeated pull on a ligament or tendon
- Cyclic, or repetitive loading of impact forces (stress fractures)

The end result is inflammation of the involved structure with complaints of pain, tenderness, swelling, and disability.

Stress Fractures

Stress fractures are a consequence of repetitive, excessive stress on the bone that causes microfractures within the bone. Continued stress to the bone can lead to spread of the microfracture and eventual macrofracture. The pathogenesis of stress injury to the bone is multifactorial and includes everything from the footwear to the fitness level of the athlete. Stress fractures occur most commonly in the lower extremities, particularly the tibia. Track and field athletes have the highest incidence of stress fractures (Patel, 2010).

The most common symptom of stress fracture is a sharp, persistent, progressive pain or a deep, persistent dull ache located over the bone. Sometimes there is pain on impact (heel strike), but the most important clinical sign is pain over the involved bony surface. Diagnosis is based on clinical observation and history. Plain radiographs are rarely diagnostic of stress fractures during the initial few weeks because callus formation is not yet evident. Magnetic resonance imaging (MRI) is used when other causes of pain must be excluded.

Therapeutic Management

Development of inflammation is common to all overuse injuries; therefore management involves rest or alteration of activities, physical therapy, and medication. Rest is the primary therapy, usually interpreted as reduced activity and the use of alternative exercise—not bed rest or immobilization with casting. The main purpose is to alleviate the repetitive stress that initiated the symptoms. It is important to keep the adolescent mobile, and training can be continued. Alternative exercise is selected that maintains conditioning without aggravating the injury. For example, pool running (treading water in the deep end of a pool) can use the same movements as running but without the weight bearing; bicycling, swimming, and rowing are viable alternatives.

Other modalities include cryotherapy and cold whirlpool baths. Sometimes taping, bracing, splinting, and other orthoses are used, depending on the injury. Nonsteroidal antiinflammatory drugs (NSAIDs) are often prescribed to reduce inflammation and pain. Topical medications are of questionable value.

Nurse's Role in Sports for Children and Adolescents

Nurses are often involved in sports activities in the areas of preparation and evaluation for activities, prevention of injury, treatment of injuries, and rehabilitation after injury. Selecting an appropriate sport for both recreation and competition is a joint effort of the adolescent, parents, and health care providers. The best approach to counseling children, adolescents, and parents regarding sports participation is to encourage activities that are most likely to provide pleasure and physical benefits throughout childhood and into adulthood. Exposure to a variety of activities is better for young children than limiting them to one sport. Parents should be cautioned against overcommitting children to sports activities so they have time for other activities.

When children sustain athletic injuries, nurses are often responsible for instructions regarding care. Instructions (e.g., schedule for appointments, application of ice, any restrictions in activity) should be clear and accompanied by written directions. Nurses should emphasize the importance of taking medications as prescribed, especially if they are needed for an extended period and if adherence is an issue. Antiinflammatory medications given an hour before practice or competition may help children continue their activities.

Prevention of sports injuries is the most important aspect of athletic programs. Children should be suited to the activity, and the

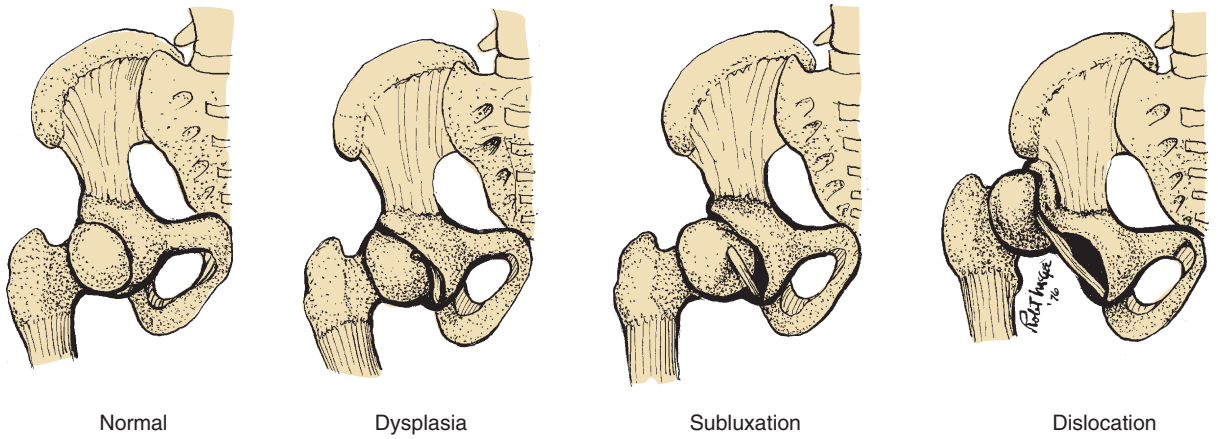

FIG 48-10 Configuration and relationship of structures in developmental dysplasia of the hip.

environment and the equipment must be safe. Children should be prepared for the sport, especially if it requires strenuous or continuous physical exertion. Nurses, coaches, and athletic trainers must collaborate to ensure that safety measures are implemented. Stretching exercises, warm-up and cool-down activities, and appropriate training are requirements for safe participation. Protective measures such as pads, taping, and wrapping are also important to prevent injury. Finally nurses must be aware of environmental safety risks.

BIRTH AND DEVELOPMENTAL DEFECTS

Some skeletal defects may be diagnosed at birth or within days, weeks, or months after birth. In other cases the deviation may be difficult to detect without careful inspection Therefore it is imperative that nurses become acquainted with signs of these defects and understand the principles of therapy to direct others in the care and management of these children.

Developmental Dysplasia of the Hip

The broad term developmental dysplasia of the hip (DDH) describes a spectrum of disorders related to abnormal development of the hip that may occur at any time during fetal life, infancy, or childhood. A change in terminology from *congenital hip dysplasia* and *congenital dislocation of the hip* to DDH more properly reflects a variety of hip abnormalities in which there is a shallow acetabulum, subluxation, or dislocation.

The incidence of hip instability is approximately 1.5 per 1000 live births, and approximately 15% to 50% of infants with DDH are born breech. Girls are affected more commonly (80%), and there is a positive family history in approximately 12% to 33% of affected individuals (Sankar, Horn, Wells, et al., 2011a). Two published meta-analyses have identified the following risk factors: breech birth, female gender, family history of DDH, left hip, first-born child, and positive clicking hips with clinical examination (de Hundt, Vlemmix, Bais, et al., 2012; Ortiz-Neira, Paolucci and Donnon, 2012).

Pathophysiology

The cause of DDH is unknown, but certain factors such as gender, birth order, family history, intrauterine position, delivery type, joint laxity, and postnatal positioning are believed to affect the risk of DDH. Predisposing factors associated with it may be divided into three broad categories: (1) physiologic factors, which include maternal hormone secretion and intrauterine positioning; (2) mechanical factors, which involve breech presentation, multiple fetus, oligohydramnios, and large infant size (other mechanical factors may include continued maintenance of the hips in adduction and extension that will in time cause a dislocation); and (3) genetic factors, which entail a higher incidence of DDH in siblings of affected infants and an even greater incidence of recurrence if a sibling and one parent were affected.

Some experts categorize DDH into two major groups: (1) idiopathic, in which the infant is neurologically intact; and (2) teratologic, which involves a neuromuscular defect such as arthrogryposis or spina bifida. The teratologic forms usually occur in utero and are much less common.

Three degrees of DDH are illustrated in Fig. 48-10:

1. *Acetabular dysplasia*—This is the mildest form of DDH, in which there is neither subluxation nor dislocation. There is a delay in acetabular development evidenced by osseous hypoplasia of the acetabular roof that is oblique and shallow, although the cartilaginous roof is comparatively intact. The femoral head remains in the acetabulum.
2. *Subluxation*—The largest percentage of DDH, subluxation, implies incomplete dislocation of the hip and is sometimes regarded as an intermediate state in the development from primary dysplasia to complete dislocation. The femoral head remains in contact with the acetabulum, but a stretched capsule and ligamentum teres cause the head of the femur to be partially displaced. Pressure on the cartilaginous roof inhibits ossification and produces a flattening of the socket.
3. *Dislocation*—The femoral head loses contact with the acetabulum and is displaced posteriorly and superiorly over the fibrocartilaginous rim. The ligamentum teres is elongated and taut.

Factors related to infant handling are indicated in the Cultural Competence box.

Recently several prominent orthopedic specialty organizations recommended that infants' hips be placed in slight flexion and abduction during swaddling. It was further recommended that their knees be maintained in slight flexion and that forced or sustained passive hip extension in the first few months should be avoided (Price and Schwend, 2011). These recommendations were supported by evidence that demonstrated a significant relationship between tight swaddling and hip dysplasia and are aimed at decreasing the incidence of hip dysplasia in infants.

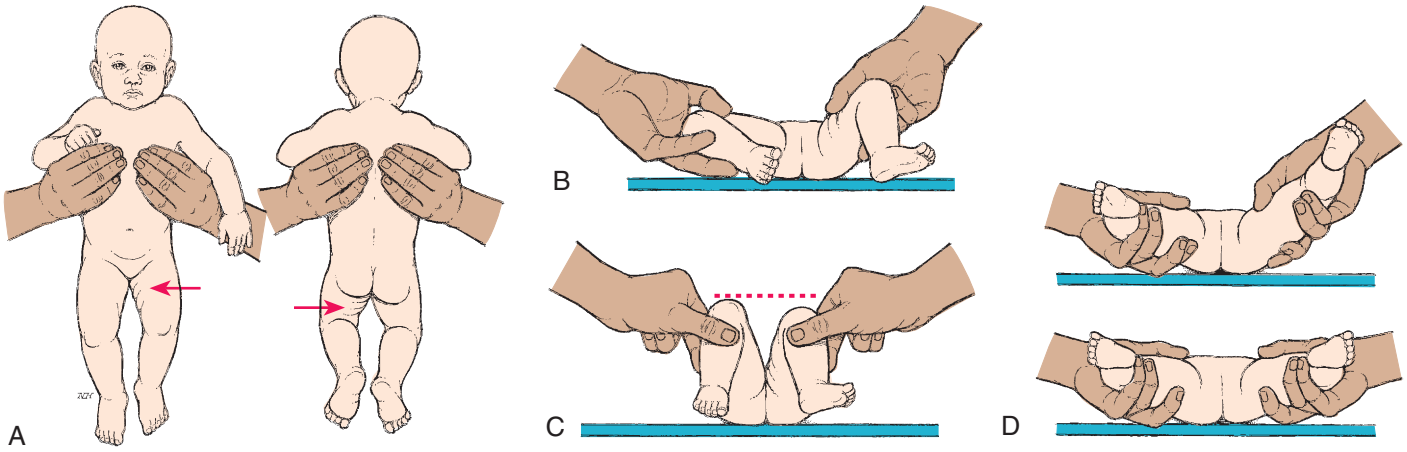

FIG 48-11 Signs of developmental dysplasia of the hip. **A,** Asymmetry of gluteal and thigh folds. **B,** Limited hip abduction as seen in flexion. **C,** Apparent shortening of the femur as indicated by the level of the knees in flexion. **D,** Ortolani maneuver clunk elicited (in infants <4 weeks of age).

CULTURAL COMPETENCE

Developmental Dysplasia of the Hip

A striking relationship exists between the development of the dislocation and methods of handling infants. Among the cultures with the highest incidence of dislocation, newly born infants are tightly wrapped in blankets or other swaddling material or strapped to cradle boards. In cultures such as the Far East, where mothers traditionally carry infants on their backs or hips in the widely abducted straddle position, the disorder is virtually unknown.

Diagnostic Evaluation

DDH is often not detected at the initial examination after birth; thus all infants should be carefully monitored for hip dysplasia at follow-up visits throughout the first year of life and routine well-child checks. In the newborn period hip dysplasia usually appears as hip joint laxity rather than outright dislocation (Fig. 48-11). Subluxation and the tendency to dislocate can be demonstrated by the Ortolani or Barlow tests (see Fig. 48-11, *B* to *D*). The Ortolani and Barlow tests are most reliable from birth to 4 weeks of age. With the Barlow test the thighs are adducted; the Ortolani test involves abducting the thighs to test for hip subluxation or dislocation (Seidel, Ball, Dains, et al., 2006). Other signs of DDH are shortening of the limb on the affected side (see Fig. 48-11, *C*), asymmetric thigh and gluteal folds (see Fig. 48-11, *A*), broadening of the perineum (in bilateral dislocation) (Box 48-5), and decreased hip abduction on the affected side.

Radiographic examination in early infancy is not reliable because ossification of the femoral head does not normally take place until the fourth to sixth month of life. However, the cartilaginous head can be visualized directly by ultrasonography. Universal newborn screening with ultrasonography has been proposed in the United States; however, numerous studies reveal that this approach has a high rate of false-positive results and subsequent overtreatment. Therefore ultrasonography is recommended as an adjunct to other diagnostic procedures (AAP Committee on Quality Improvement, 2000; Sankar, Horn, Wells, et al., 2011a). Radiographic examination is useful in confirming the diagnosis in infants older than age 4 months and children. An upward slope in the roof of the acetabulum (the acetabular angle) greater than 30 degrees with upward and outward displacement of the femoral head is a frequent finding in older children. Computed tomography (CT) may be useful to assess the position of the femoral head relative to the acetabulum after closed reduction and casting. The AAP (2000) has published extensive clinical guidelines for screening and early detection of DDH.

BOX 48-5 CLINICAL MANIFESTATIONS OF DEVELOPMENTAL DYSPLASIA OF THE HIP

Infants

- Shortening of limb on affected side (Galeazzi sign)
- Restricted abduction of hip on affected side
- Unequal gluteal folds (best visualized with infant prone)
- Positive Ortolani test (hip reduced by abduction)
- Positive Barlow test (hip dislocated by adduction)

Older Infants and Children

- Affected leg appears shorter than the other
- Telescoping or piston mobility of joint—Head of femur felt to move up and down in buttock when extended thigh is pushed first toward child's head and then pulled distally
- Trendelenburg sign—When child stands first on one foot and then on the other (holding onto a chair, rail, or someone's hands) bearing weight on affected hip, pelvis tilts downward on normal side instead of upward, as it would with normal stability
- Greater trochanter prominent and appearing above a line from anterosuperior iliac spine to tuberosity of ischium
- Marked lordosis and waddling gait (bilateral hip dislocation)

Therapeutic Management

Treatment is begun as soon as the condition is recognized because early intervention is more favorable to the restoration of normal bony architecture and function. The longer treatment is delayed, the more severe the deformity, the more difficult the treatment, and the less favorable the prognosis. The treatment varies with the child's age and the extent of the dysplasia. The goal of treatment is to obtain and maintain a safe, congruent position of the hip joint to promote normal hip joint development.

Newborns to Age 6 Months. The hip joint is maintained by dynamic splinting in a safe position with the proximal femur centered in the acetabulum in an attitude of flexion. Of the numerous devices available, the Pavlik harness is the most widely used; and with time, motion, and gravity, the hip works into a more abducted, reduced position (Fig. 48-12). The harness is worn continuously until the hip is proved stable on clinical and ultrasound examination, usually in 6 to 12 weeks.

When adduction contracture is present, other devices such as Bryant traction (see p. 1543) are used to slowly and gently stretch the hip to full abduction, after which wide abduction is maintained until stability is attained. When there is difficulty in maintaining stable reduction, a hip spica cast is applied and changed periodically to accommodate the child's growth. After 3 to 6 months sufficient stability is acquired to allow transfer to a removable protective abduction brace. The duration of treatment depends on development of the acetabulum but is usually accomplished within the first year.

Ages 6 to 24 Months. In this age-group the dislocation may not be recognized until the child begins to stand and walk, when attendant shortening of the limb and contractures of hip adductor and flexor muscles become apparent (DDH hip radiograph). A surgical closed reduction is performed, and the child is placed in a spica cast for approximately 12 weeks. An abduction orthosis may be used instead of a hip spica cast. In the event that the hip remains unstable, an open reduction is performed (Sankar, Horn, Wells, et al., 2011a).

Older Children. Correction of the hip deformity in older children is inherently more difficult than in the preceding age-groups because secondary adaptive changes and other etiologic factors (e.g., juvenile arthritis or nonambulatory cerebral palsy) complicate the condition. Operative reduction, which may involve preoperative traction, tenotomy of contracted muscles, and any one of several innominate osteotomy procedures designed to construct an acetabular roof, often combined with proximal femoral osteotomy, is usually required. After cast removal range-of-motion exercises help restore movement. Successful reduction and reconstruction become increasingly difficult after the age of 4 years and are usually impossible or inadvisable in children older than 6 years of age because of severe shortening and contracture of muscles and deformity of the femoral and acetabular structures.

CARE MANAGEMENT

Nurses are in a unique position to detect DDH in early infancy. During the infant assessment process and routine nursing activities, the hips and extremities are inspected for any deviations from normal. These observations are reported to the attending practitioner, and an ambulatory child who displays a limp or an unusual gait should be referred for evaluation. This may indicate an orthopedic or neurologic problem. Nonambulatory children with cerebral palsy should also be assessed for evidence of hip problems.

! NURSING ALERT

The Ortolani and Barlow tests must be performed by an experienced clinician to prevent an injury to the infant's hip.

The major nursing problems in the care of an infant or child in a cast or other device are related to maintenance of the device and adaptation of nurturing activities to meet the patient's needs. Generally treatment and follow-up care of these children are carried out in an outpatient setting.

The primary nursing goal is teaching parents to apply and maintain the reduction device. The Pavlik harness allows for easy handling of the infant and usually produces less apprehension in the parent than heavy braces and casts. Because of infants' rapid growth, the straps should be checked in the beginning of therapy and every 1 to 2 weeks for adjustments (Hart, Albright, Rebello, et al., 2006). It is important that parents understand the correct use of the appliance, which may or may not allow for its removal during bathing. Removing the harness is determined individually on the basis of the provider's recommendation, the family's level of understanding, and the degree of hip deformity. Parents are instructed to not adjust the harness. The child should be examined by the practitioner before any adjustment is attempted to make certain that the hips are in correct placement.

! NURSING ALERT

The former practice of double or triple diapering for DDH is not recommended because there is no evidence to support its efficacy.

Skin care is an important aspect of the care of an infant in a harness. The following instructions for preventing skin breakdown are stressed:

- Always put an undershirt (or a shirt with extensions that close at the crotch) under the chest straps and put knee socks under the foot and leg pieces to prevent the straps from rubbing the skin.
- Check frequently (at least 2 or 3 times a day) for red areas under the straps and clothing.
- Gently massage healthy skin under the straps once a day to stimulate circulation. In general avoid lotions and powders because they can cake and irritate the skin.
- Always place the diaper under the straps.

Parents are encouraged to hold the infant with a harness and continue care and nurturing activities. The nurse can assist by being available for parents' questions about the necessary adaptations to daily care to decrease their anxiety and possible feelings about the child being hurt by routine caring.

Casts and orthotic devices (braces) offer more challenging nursing and caregiver problems because they cannot be removed for routine care, although sometimes a brace may be removed for

bathing. Care of an infant or a small child with a cast requires nursing innovation to reduce irritation and maintain cleanliness of both the child and the cast, particularly in the diaper area. (See p. 1540 for care of the child in a cast.)

It is important for nurses, parents, and other caregivers to understand that children in corrective devices need to be involved in all of the activities of any child in the same age-group. Confinement in a cast or appliance should not exclude children from family (or unit) activities. They can be held astride the lap for comfort and transported to areas of activity. The child may be allowed to walk in a cast or orthotic device. An adapted wheelchair, stroller, or scooter can offer mobility to an older infant or child.

Clubfoot

Clubfoot is a complex deformity of the ankle and foot that includes forefoot adduction, midfoot supination, hindfoot varus, and ankle equinus. Deformities of the foot and ankle are described according to the position of the ankle and foot. The more common positions involve the following variations:

- *Talipes varus*—An inversion, or bending inward
- *Talipes valgus*—An eversion, or bending outward
- *Talipes equinus*—Plantar flexion, in which the toes are lower than the heel
- *Talipes calcaneus*—Dorsiflexion, in which the toes are higher than the heel
- *Talipes equinovarus*—Toes lower than the heel and facing inward

Most cases of clubfoot are a combination of these positions, and the most frequently occurring type of clubfoot (≈95% of cases) is the composite deformity talipes equinovarus (TEV), in which the foot is pointed downward (plantar flexed) and inward in varying degrees of severity (Fig. 48-13). Clubfoot may occur as an isolated deformity or in association with other disorders or syndromes such as chromosome abnormalities, arthrogryposis, cerebral palsy, or spina bifida.

The incidence of clubfoot in the general population is approximately one per 1000 live births, with boys affected twice as often as girls. Bilateral clubfeet occur in 50% of the cases (Hosalkar, Spiegel, and Davidson, 2011). The precise cause of clubfoot is unknown. Some authorities attribute the defect to abnormal positioning and restricted movement in utero, although the evidence is not conclusive. Other experts implicate arrested or abnormal embryonic development. Arrested development during this early stage tends to result in a rigid deformity; however, mechanical pressures from intrauterine positioning are likely causes of more flexible deformities (Shyy, Wang, Sheffield, et al., 2010).

FIG 48-13 Bilateral congenital talipes equinovarus (congenital clubfoot) in 2-month-old infant. (From Zitelli BJ, Davis HW: *Atlas of pediatric physical diagnosis,* ed 4, St Louis, 2002, Mosby.)

Classification

Clubfoot may be further divided into three categories: (1) positional clubfoot (also called *transitional, mild,* or *postural clubfoot*), which is believed to occur primarily from intrauterine crowding and responds to simple stretching and casting; (2) *syndromic* (or teratologic) clubfoot, which is associated with other congenital anomalies such as myelomeningocele or arthrogryposis and is a more severe form of clubfoot that is often resistant to treatment; and (3) *congenital* clubfoot, also referred to as *idiopathic,* which may occur in an otherwise normal child and has a wide range of rigidity and prognosis.

The mild, or postural, clubfoot may correct spontaneously or may require passive exercise or serial casting. There is no bony abnormality, but there may be tightness and shortening of the soft tissues medially and posteriorly. The teratologic clubfoot usually requires surgical correction and has a high incidence of recurrence. The congenital idiopathic clubfoot, or "true clubfoot," almost always requires surgical intervention because there is bony abnormality.

Diagnostic Evaluation

The deformity is readily apparent and easily detected prenatally through ultrasonography or at birth. However, it must be differentiated from some positional deformities that can be corrected passively or overcorrected. Paralytic changes in the lower extremity of children with neuromuscular involvement often produce equinovarus deformity. An increased risk of hip dysplasia is associated with clubfoot deformities.

Therapeutic Management

The goal of treatment for clubfoot is to achieve a painless, plantigrade, and stable foot. Treatment of clubfoot involves three stages: (1) correction of the deformity, (2) maintenance of the correction until normal muscle balance is regained, and (3) follow-up observation to avert possible recurrence of the deformity. Some feet respond to treatment readily; some respond only to prolonged, vigorous, and sustained efforts; and the improvement in others remains disappointing even with maximal effort on the part of all concerned.

A common approach to clubfoot management is the Ponseti method (Ponseti, 1996). Serial casting is begun shortly after birth. Weekly gentle manipulation and serial long-leg casts allow for gradual repositioning of the foot (Fig. 48-14). The extremity or extremities are casted until maximum correction is achieved, usually within 6 to 10 weeks. Most of the time a percutaneous heel cord tenotomy is performed at the end of the serial casting to correct the equinus. After the tenotomy, a long-leg cast is applied and left in place for 3 weeks. A Denis Browne bar with Ponseti sandals or straight-laced shoes placed in abduction is then fitted to prevent recurrence. Inability to achieve normal foot alignment after casting and tenotomy indicates the need for surgical intervention.

CARE MANAGEMENT

Nursing care of the child with clubfoot is the same as for any child who has a cast (see p. 1540). Because the child will spend considerable time in a corrective device, nursing care plans include both long- and short-term goals. Conscientious observation of the skin and circulation is particularly important in young infants because

FIG 48-14 Feet casted for correction of bilateral congenital talipes equinovarus.

of their rapid growth rate. Because treatment and follow-up care are handled in the orthopedist's office, clinic, or outpatient department, parent education and support are important in nursing care of these children.

It is important for parents to understand the overall treatment program, the importance of regular cast changes, and the role they play in the long-term effectiveness of the therapy. Reinforcing and clarifying the orthopedist's explanations and instructions, teaching parents about care of the cast or appliance (including vigilant observation for potential problems), and encouraging parents to facilitate normal development within the limitations imposed by the deformity or therapy are all part of nursing responsibilities.

Metatarsus Adductus (Varus)

Metatarsus adductus, or metatarsus varus, is probably the most common congenital foot deformity. In most instances, it is a result of abnormal intrauterine positioning, particularly in a firstborn child, and is usually detected at birth. The deformity is characterized by medial adduction of the toes and forefoot, frequently in association with inversion, and by convexity of the lateral border of the foot. Metatarsus adductus may be divided into three categories: type I, in which the forefoot is flexible and corrects easily with manipulation; type II, in which there is only partial flexibility in the forefoot, and it corrects passively past neutral position but only to neutral position with active manipulation; and type III, in which the forefoot is rigid and will not stretch to neutral position with manipulation. Unlike TEV, with which it is often confused, the angulation occurs at the tarsometatarsal joint, but the heel and ankle remain in a neutral position. Ankle range of motion is normal. This deformity often causes a pigeon-toed gait in the child.

Management depends on the rigidity and type of the deformity. With types I and II correction can usually be accomplished by gentle manipulation and passive stretching of the foot, which the parent is taught to perform. Repeated and consistent stretching is continued for the first 6 weeks, after which the treatment is based on the flexibility of the foot. With type III the child usually requires serial manipulation and casting to correct the defect. Casting is performed every 1 to 2 weeks for 6 to 8 weeks, after which a corrective shoe or orthosis may be used. Surgical correction is rarely required for the condition but may be performed in children 4 to 6 years of age who have considerable pain on ambulation or are unable to wear certain kinds of shoes as a result of the defect (Hosalkar, Spiegel, and Davidson, 2011).

CARE MANAGEMENT

The nursing role primarily involves identifying the defect so early therapy and instruction of the parents can be initiated. The nurse teaches the parents how to hold the heel firmly and stretch only the forefoot; otherwise undue force on the heel may produce a valgus deformity. If casting or an orthosis is required, the nurse instructs the parents in cast care and observation of the corrective device (see p. 1540).

Skeletal Limb Deficiency

Congenital limb deficiencies, or reduction malformations, are manifested by a variety of degrees of loss of functional capacity. They are characterized by underdevelopment of skeletal elements of the extremities. The range of malformation can extend from minor defects of the digits to serious abnormalities such as *amelia,* absence of an entire extremity; or *meromelia,* partial absence of an extremity, which includes *phocomelia* (seal limbs), the interposed deficiency of long bones with relatively good development of hands and feet attached at or near the shoulder or the hips. Most reduction defects are primary defects of development of the limb, but prenatal destruction of the limb such as full or partial amputation of a limb in utero from constriction of an *amniotic band* (amniotic band syndrome) can occur. Neonates with congenital limb deficiencies often have associated malformations and should be thoroughly investigated for cardiovascular, central nervous system (CNS), renal, and digestive abnormalities (Stoll, Alembik, Dott, et al., 2010).

Pathophysiology

Limb deficiencies can be attributed to both heredity and environment and can originate at any stage of limb development. Formation of limbs may be suppressed at the time of limb bud formation, or there may be interference in later stages of differentiation and growth. Heredity appears to play a prominent role, and prenatal environmental insults have been implicated in a number of cases such as the well-publicized thalidomide tragedy of the 1950s and early 1960s, which demonstrated a clear relationship between the time of exposure of the pregnant woman to the antiemetic drug and the presence and type of limb deformity in the newborn. There still are many drugs that may have similar teratogenic effects in the first trimester of pregnancy; therefore medication administration during this period should be evaluated carefully by the practitioner. Deletion or shortening of digits or limbs may also be associated with chorionic villus sampling, especially before 10 to 12 weeks of gestation; however, the incidence and relationship remain uncertain.

Therapeutic Management

Children with congenital limb deficiencies should be fitted with prosthetic devices whenever possible, and the devices should be applied at the earliest possible stage of development in an attempt to match the infant's motor readiness. This favors natural progression of prosthetic use. For example, an infant with an upper-extremity deficiency is fitted with a simple passive device such as a mitten prosthesis to encourage limb exploration, sitting (with the extremities needed for support), and bilateral hand activities.

Lower-limb prostheses are applied when the infant begins sitting up and can maintain balance. In preparation for prosthetic devices, surgical modification may be necessary to ensure the most favorable use of the device because severe deformity can interfere with its

effective use. Phocomelic digits are preserved for controlling switches of externally powered appliances in the upper extremities. Digits (in both the upper and lower extremities) provide the child with surfaces for tactile exploration and stimulation. Prostheses are replaced to accommodate the child's growth and increasing capabilities.

CARE MANAGEMENT

Prosthetic application training and habilitation are most successfully carried out in a center that specializes in meeting the special needs of these children, especially very young children and those with amputations or missing limbs. Management involves a prosthetist who specializes in the development, fitting, and maintenance of prosthetic limbs and other health care workers such as physical and occupational therapists. Parents need special attention and support and are encouraged to help the child make age-commensurate adjustments to the environment. Although these children need assistance, overprotection may produce overdependence, with later maladjustment to school and other situations.

Osteogenesis Imperfecta

Osteogenesis imperfecta (OI) is the most common osteoporosis syndrome in childhood. However, it is very rare. OI is a heterogeneous, autosomal dominant disorder characterized by fractures and bone deformity. There are at least eight described types of OI, which accounts for significant disease variability. Clinical features may include varying degrees of bone fragility, deformity, and fracture; blue sclerae; hearing loss; and *dentinogenesis imperfecta* (hypoplastic discolored teeth). Although inheritance follows an autosomal dominant pattern in most cases, rare autosomal recessive inheritance exists primarily in populations with consanguineous marriages (Marini, 2011).

Most types of OI have defects in the *COL1A1* or *COL1A2* genes, which code for polypeptide chains in type 1 procollagen, a precursor of type 1 collagen, a major structural component of bone. The error results in faulty bone mineralization, abnormal bone architecture, and increased susceptibility to fracture. Additional autosomal recessive genes linked to OI have been identified and help explain bone biology and pathogenetic mechanisms in OI (Aglan, Hosny, El-Houssini, et al., 2012).

OI has several classifications based on clinical features and patterns of inheritance (Box 48-6). Clinically type I is the most common, with wide variability of bone fragility; some affected family members have significant deformity and disability, but others lead agile, active lives. Type II variants are the most severe and are considered lethal in infancy. Type III OI is characterized by multiple fractures; bone deformity; and severe disability, including scoliosis and vertebral compression; affected individuals rarely live to 30 years of age. Growth failure and short stature are common. Type IV is similar to type I with blue or white sclerae. Another variant, or type V, has been described in which those affected have a hyperplastic callus, a radiodense metaphyseal band, and calcification of the interosseous membrane of the forearm; no collagen mutations are noted in this group (Marini, 2011). A type VI has been described with a characteristic mineralization defect, which does not respond to pamidronate therapy as do types I to V (Land, Rauch, Travers, et al., 2007). However, a small group of children with type VI responded favorably to denosumab, a RANK ligand inhibitor (Semler, Netzer, Hoyer-Kuhn, et al., 2012). Children affected with this type have no dental involvement and normal sclerae; a bone biopsy is the only way to establish a diagnosis because of the similarities to other types. Types VII and VIII overlap types II and III in relation to clinical features; but these types who survive have white sclerae, a normal-to-small head circumference, short stature, and rhizomelia (Marini, 2011).

Therapeutic Management

The treatment for OI is primarily supportive, although patients and families are optimistic about new research advances. The use of bisphosphonate therapy with IV pamidronate to promote increased bone density and prevent fractures has become standard therapy for many children with OI; however, long bones are weakened by prolonged treatment. One of the advantages of bisphosphonate therapy is the decrease in vertebral compression and scoliosis (Marini, 2011).

The goals of a rehabilitative approach to management are directed toward preventing (1) positional contractures and deformities, (2) muscle weakness and osteoporosis, and (3) malalignment of lower-extremity joints prohibiting weight bearing.

Lightweight braces and splints help support limbs, prevent fractures, and aid in ambulation. Physical therapy helps prevent disuse osteoporosis and strengthens muscles, which in turn improve bone density.

Surgery is sometimes used to help treat the manifestations of the disease. Surgical techniques are used to correct deformities that interfere with bracing, standing, or walking. For a child with

BOX 48-6 CLASSIFICATION OF OSTEOGENESIS IMPERFECTA†

Type I*
- **A**—Mild bone fragility; blue sclerae; normal teeth; hearing loss (occurs between ages 20 and 30 years); autosomal dominant inheritance
- **B**—Same as A except dentinogenesis imperfecta instead of normal teeth
- **C**—Same as B but no bone fragility

Type II—Lethal; stillborn or die in early infancy; severe bone fragility, multiple fractures at birth; 10% of cases of OI; autosomal recessive inheritance

Type III—Severe bone fragility leading to severe progressive deformities; normal sclerae; marked growth failure; most autosomal recessive inheritance; few autosomal dominant inheritance

Type IV
- **A**—Mild-to-moderate bone fragility; normal sclerae; normal teeth; short stature; variable deformity; autosomal dominant inheritance
- **B**—Same as A except dentinogenesis imperfecta instead of normal teeth; approximately 6% of cases of OI

Type V—Clinically similar to type IV; hyperplastic callus; collagen mutation negative

Type VI—Sclerae and dentition normal; moderate-to-severe bone fragility; diagnosis by bone biopsy because of similarities to other types (Land, Rauch, Travers, et al., 2007)

Types VII and VIII (recessive form)—Clinically overlap types II and III but have white sclerae, rhizomelia, and small-to-normal head circumference; severe osteochondroplasia and short stature in survivors (Marini, 2011)

OI, Osteogenesis imperfecta.
*Two thirds of cases are type I.
†This classification is based on that proposed by Sillence DO, Senn A, Danks DM: Genetic heterogeneity in osteogenesis imperfecta, *J Med Genet* 16(2):101-116, 1979; which originally included OI type I-IV. Additional types have been described but are not included herein.

recurrent fractures, inserting an intramedullary rod provides stability to bones.

CARE MANAGEMENT

Infants and children with this disorder require careful handling to prevent fractures. They must be supported when they are being turned, positioned, moved, and held. Even changing a diaper may cause a fracture in severely affected infants. These children should never be held by the ankles when being diapered but should be gently lifted by the buttocks or supported with pillows.

Both parents and the affected child need education regarding the child's limitations and guidelines in planning suitable activities that promote optimal development and protect the child from harm. Realistic occupational planning and genetic counseling are part of the long-term goals of care. Educational materials and information can be obtained from the Osteogenesis Imperfecta Foundation,* which also has a network that can put a family in contact with other families with a similar problem.

OI is a differential diagnosis that must be ruled out in the event of multiple fractures that could be attributed to nonaccidental injury (child abuse). A detailed history, no evidence of associated soft-tissue injury, and the presence of other symptoms related to OI help to determine the diagnosis.

! NURSING ALERT

Children with multiple fractures should be screened for OI. The possibility that nonaccidental trauma is the cause of fractures in children must be evaluated carefully by a multidisciplinary team.

ACQUIRED DEFECTS

Legg-Calvé-Perthes Disease

Legg-Calvé-Perthes disease, sometimes called *coxa plana* or *osteochondritis deformans juvenilis*, is a self-limiting disorder in which there is aseptic necrosis of the femoral head. The disease affects children ages 2 to 12 years, but most cases occur in boys between 4 and 8 years of age as an isolated event. In approximately 10% of cases the involvement is bilateral; most of the affected children have a skeletal age significantly below their chronologic age (Sankar, Horn, Wells, et al., 2011b). The male-to-female ratio is 4:1 or 5:1. Caucasian children are affected 10 times more frequently than African-American children.

Pathophysiology

The cause of the disease is unknown, but a disturbance of circulation to the femoral capital epiphysis produces an ischemic aseptic necrosis of the femoral head. During middle childhood circulation to the femoral epiphysis is more tenuous than at other ages and can become obstructed by trauma, inflammation, coagulation defects, and a variety of other causes. The pathologic events seem to take place in four stages (Box 48-7). The entire process may encompass as little as 18 months or continue for several years. The reformed femoral head may be severely altered or appear entirely normal.

Clinical Manifestations and Diagnostic Evaluation

The onset of Legg-Calvé-Perthes disease is usually insidious, and the history may reveal only intermittent appearance of a limp on the affected side or a symptom complex, including hip soreness, ache, or stiffness, which can be constant or intermittent. The parents may report seeing the child limping, and the limp becomes more pronounced with increased activity. The pain may be experienced in the hip, along the entire thigh, or in the vicinity of the knee joint. The pain and limp are usually most evident on arising and at the end of a long day of activities. The pain is usually accompanied by joint dysfunction and limited range of motion. There may be a vague history of trauma. The diagnosis is established by history, examination, radiographs, and rarely MRI.

Therapeutic Management

Because deformity occurs early in the disease process, the aims of treatment are to eliminate hip instability; restore and maintain adequate range of hip motion; prevent capital femoral epiphyseal collapse, extrusion, or subluxation; and ensure a well-rounded femoral head at the time of healing. Treatment varies according to the child's age at the time of diagnosis and the appearance of the femoral head vasculature and position within the acetabulum. Nonsurgical containment of the femoral head may be accomplished with abduction casts, immobilization, and NSAIDs; and a pelvic or proximal femoral osteotomy may be used to contain the femoral head. Activity causes microfractures of the soft ischemic epiphysis, which tend to induce synovitis, stiffness, and adductor contracture. The initial therapy is rest and nonweight bearing, which helps reduce inflammation and restore motion. Later active motion is encouraged. In some cases traction is applied to stretch tight adductor muscles.

Containment can be accomplished in several ways. One is the use of nonweight-bearing devices such as an abduction brace (e.g., Atlanta Scottish Rite orthosis), leg casts, or a leather harness sling, which prevent weight bearing on the affected limb. Another includes the use of various weight-bearing appliances such as abduction-ambulation braces or casts after a period of bed rest and traction. A third option consists of surgical reconstruction and containment procedures. Conservative therapy must be continued for 2 to 4 years, although braces constructed from lightweight materials allow the child to maintain a nearly normal activity level. Although surgical correction subjects the child to additional risks (e.g., from anesthesia, infection, blood transfusion), it returns him or her to normal activities in 3 to 4 months. The use of home traction has also been explored.

BOX 48-7 RADIOGRAPHIC STAGES OF LEGG-CALVÉ-PERTHES DISEASE

Stage I: initial or **avascular stage**—Aseptic necrosis or infarction of the capital femoral epiphysis with degenerative changes producing flattening of the upper surface of the femoral head

Stage II: fragmentation or **revascularization stage**—Capital bone resorption and revascularization with fragmentation (vascular resorption of the epiphysis) that gives a mottled appearance on radiographs

Stage III: reossification or **reparative stage**—New bone formation, which is represented on radiographs as calcification and ossification or increased density in the areas of radiolucency. This filling-in process appears to take place from the periphery of the head centrally

Stage IV: residual or **regenerative stage**—Gradual reformation of the head of the femur without radiolucency and, it is hoped, to a spherical form

*804 W. Diamond Ave., Suite 210, Gaithersburg, MD 20878, 800-981-2663, www.oif.org.

Another surgical option is hip resurfacing; in this procedure the hip joint is replaced with a metal cup in the acetabulum that interfaces with a capped bearing located on the femoral head. Hip resurfacing decreases the risk of dislocation and is more bone conserving than hip arthroplasty (Costa, Johnson, Naziri, et al., 2011). Total hip arthroplasty may be offered to adolescents and young adults with Legg-Calvé-Perthes when other surgical methods have failed to provide a stable hip joint or when conditions such as femoral acetabular impingement or avascular necrosis are present (Shrader, 2012).

The disease is self-limiting, but the ultimate outcome of therapy depends on early and efficient treatment and the child's age at the onset of the disorder. Younger children (5 years and younger) whose epiphyses are more cartilaginous have the best prognosis for complete recovery. Children 10 years and older have a significant risk for degenerative arthritis, especially with femoral head deformity at the time of diagnosis. The later the diagnosis is made, the more femoral damage will have occurred before treatment is implemented. In most cases, with good patient compliance with the prescribed regimen, the prognosis is excellent.

CARE MANAGEMENT

Nurses may be the first health care providers to identify affected children and refer them for medical evaluation. They are also people on whom the child and the family can rely to help them understand and adjust to the therapeutic measures. Because most of the child's care is conducted on an outpatient basis, the major emphasis of nursing care is teaching the family the care and management of the corrective appliance selected for therapy. The family must learn the purpose, function, application, and care of the corrective device and the importance of compliance to achieve the desired outcome (see Family-Centered Care).

One of the most difficult aspects associated with the disorder is coping with a normally active child who feels well but must remain relatively inactive during periods when nonweight bearing is required. Suitable activities must be devised to meet the needs of a child in the process of developing a sense of initiative or industry. Activities that meet the creative urges are well received.

FAMILY-CENTERED CARE

Legg-Calvé–Perthes Disease

A family with five healthy children was one day startled to learn that their 2-year-old son could no longer walk. He was diagnosed with Legg-Calvé-Perthes disease. Through several years of prosthetic devices and numerous physician visits, hospitalizations, and surgeries, this family turned a potentially devastating experience into one with cherished memories.

Today the parents reflect on how their family coped with the reality of a debilitating disease. It was difficult for the parents to observe an eager, energetic child watch other children riding bicycles, running, or playing outdoor games. But they are warmed by memories of watching their other children make the difference for their sibling. They all developed a strong bond through caring and sharing with one another. Coping as a family was an easy adjustment and, most of all, therapeutic. Today, more than 20 years later, the parents believe that each family member has grown with feelings of faith and trust. The experience proved to them that life will go on and that life is what you make it!

–Shona Swenson Lenss, MS, RN, FNP
Cheyenne, WY

Slipped Capital Femoral Epiphysis

Slipped capital femoral epiphysis (SCFE) refers to the spontaneous displacement of the proximal femoral epiphysis in a posterior and inferior direction. It develops most frequently shortly before or during accelerated growth and the onset of puberty (children between the ages of 9 and 16 years; median age 13 years for boys and 12 years for girls) and is most frequently observed in boys and obese children. The incidence is 11 cases per 100,000 children. Bilateral involvement occurs in up to 40% to 60% of cases (Lehmann, Aarons, Loder, et al., 2006; Sankar, Horn, Wells, et al., 2011c).

Pathophysiology

Most cases of SCFE are idiopathic, although it can be associated with endocrine disorders, growth hormone therapy, renal osteodystrophy, and radiotherapy. The cause of idiopathic SCFE is multifactorial and includes obesity, physeal architecture and orientation, and pubertal hormone changes that affect physeal strength. Although obesity stresses the physeal plate, SCFE can also occur in children who are not obese. Radiographs show medial displacement of the epiphysis and uncovered upper portion of the femoral neck adjacent to the physis. There is a widened growth plate and irregular metaphysis. The capital femoral epiphysis remains in the acetabulum, but the femoral neck slips, deforming the femoral head and stretching blood vessels to the epiphysis.

Diagnostic Evaluation

The disorder is suspected when an adolescent or preadolescent displays clinical signs or complains of hip, groin, thigh, or knee pain (Box 48-8). The diagnosis is confirmed by anteroposterior and frog-leg radiographic examination that reflects a change in position of the proximal femoral epiphysis.

Therapeutic Management

The treatment goals of SCFE are to (1) prevent further slipping until physeal closure, (2) avoid further complication such as avascular necrosis, and (3) maintain adequate hip function (Loder, 2006; Sankar, Horn, Wells, et al., 2011c). After the diagnosis has been established, the child should be nonweight bearing to prevent further slippage. Some surgeons prefer to take the child to surgery within 24 hours of the onset of acute symptoms and avoid further risk for avascular necrosis (Loder, 2006). Surgical treatment varies with the degree of displacement. Surgical pinning in situ involves the placement of a single pin or multiple pins and screws through the femoral neck into the proximal femoral epiphysis to prevent further slippage. An osteotomy for deformity is seldom needed in the acute setting. Hip arthroscopy performed before in situ pinning has been shown to be effective in decreasing hip pain and allowing

BOX 48-8 CLINICAL MANIFESTATIONS OF SLIPPED CAPITAL FEMORAL EPIPHYSIS

- Limp on affected side
- Pain in hip
  - Continuous or intermittent
  - Frequently referred to groin, anteromedial aspect of thigh, or knee
- Restricted internal rotation on adduction with external rotation deformity
- Loss of abduction and internal rotation as severity increases
- Shortening of lower extremity

early hip movement in some children with SCFE (Jayakumar, Ramachandran, Youm, et al., 2012). Total hip arthroplasty may also be used in adolescents and young adults (Shrader, 2012). Postsurgical care includes nonweight bearing with crutch ambulation until acceptable, painless range of motion is achieved. SCFE is an emergency and requires early diagnosis and treatment to increase the likelihood of an acceptable outcome.

CARE MANAGEMENT

Nursing care is the same as that for a child in a cast or in traction, as discussed earlier in this chapter. Postoperative care involves hemodynamic stabilization and assessment for complications.

! NURSING ALERT

Children with hip issues such as Legg-Calvé-Perthes or SCFE often present with groin, thigh, or knee pain. This is often because of referred pain and is anatomically related to the obturator nerve. Any time a child presents with groin, thigh, or knee pain, a complete hip examination is paramount to rule out underlying hip pathology.

Kyphosis and Lordosis

The spine, consisting of numerous segments, can acquire deformity curves of three types, kyphosis, lordosis, and scoliosis (Fig. 48-15). **Kyphosis** is an abnormally increased lateral angulation in the convex curvature of the spine (see Fig. 48-15, *B*). It can occur secondary to disease processes such as tuberculosis (TB), chronic arthritis, osteodystrophy, or compression fractures of the thoracic spine. The most common form of kyphosis is postural. Children are prone to exaggeration of a normal kyphosis, especially when skeletal growth outpaces growth of muscle. They assume abnormal sitting and standing positions. *Scheuermann kyphosis* is a thoracic curve greater than 45 degrees with wedging greater than 5 degrees of at least three adjacent vertebral bodies and vertebral irregularity.

Postural (flexible) kyphosis is almost always accompanied by a compensatory postural lordosis (i.e., an abnormally exaggerated concave lumbar curvature). Treatment of kyphosis consists of exercises to strengthen shoulder and abdominal muscles and bracing for more marked deformity. With adolescents who are self-conscious about their appearance, the best approach is to emphasize the cosmetic value of corrective therapy and place the responsibility on the adolescent for carrying out an exercise program at home with regular visits to and assessments by a therapist. Treatment with a brace may be indicated until skeletal maturity, and surgical fusion may be considered for severe, painful, or progressive thoracic curves such as Scheuermann kyphosis.

Lordosis is an accentuation of the cervical or lumbar curvature beyond physiologic limits (see Fig. 48-15, *C*). It may be a secondary complication of a disease process, a result of trauma, or idiopathic. It is often seen in association with flexion contractures of the hip, scoliosis, obesity, DDH, and SCFE. During the pubertal growth spurt lordosis of varying degrees is observed in teenagers, especially girls. In obese children the weight of the abdominal fat alters the center of gravity, causing a compensatory lordosis. Unlike kyphosis, severe lordosis is usually accompanied by pain.

Treatment involves management of the predisposing cause (e.g., weight loss and correction of deformities) when possible. Postural exercises or support garments are helpful in relieving symptoms in some cases; however, these do not usually effect a permanent cure.

Idiopathic Scoliosis

Idiopathic *scoliosis* is a complex spinal deformity in three planes, usually involving lateral curvature, spinal rotation causing rib asymmetry, and thoracic hypokyphosis. It is the most common spinal deformity and can be further classified according to age of onset: infantile, at birth or up to 3 years of age; childhood or juvenile, which develops during childhood (4 to 10 years); or most commonly adolescent (diagnosed at age 10 years or later), which develops during the growth spurt of early adolescence.

Scoliosis can be caused by a number of conditions and may occur alone or in association with other diseases, particularly neuromuscular conditions. However, in most cases there is no apparent cause; hence the name *idiopathic scoliosis*. There appears to be a genetic component to the etiology of idiopathic scoliosis;

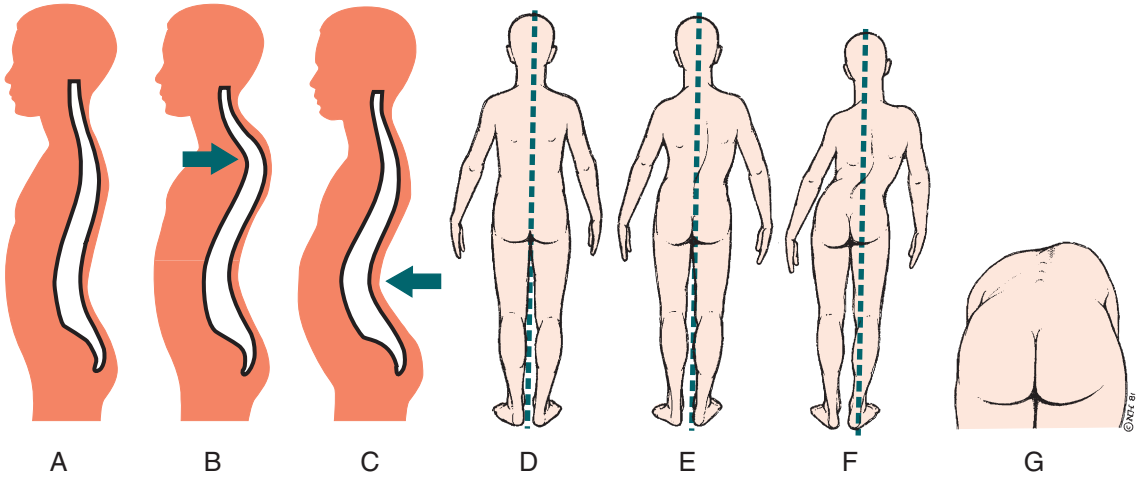

FIG 48-15 Spinal column curvatures. **A,** Normal spine. **B,** Kyphosis. **C,** Lordosis. **D,** Normal spine in balance. **E,** Mild scoliosis in balance. **F,** Severe scoliosis not in balance. **G,** Rib hump and flank asymmetry seen in flexion caused by rotary component. (Redrawn from Hilt NE, Schmitt EW: *Pediatric orthopedic nursing,* St Louis, 1975, Mosby.)

however, the exact relationship has yet to be established. The following section is limited to a discussion of adolescent idiopathic scoliosis.

Idiopathic scoliosis is most noticeable during the preadolescent growth spurt. Parents frequently bring a child for follow-up on an abnormal school scoliosis screening or because of ill-fitting clothes such as poorly fitting slacks. School screening is somewhat controversial because no controlled studies have demonstrated improved outcomes, and a reported number of false-positive results lead to referrals. The American Academy of Orthopaedic Surgeons and the AAP published a joint statement favoring scoliosis screening for preadolescents and adolescents either in the school, health care provider's office, or nurses' clinic (Richards and Vitale, 2008). According to the American Academy of Orthopaedic Surgeons (Richards and Vitale, 2008), girls should be screened at ages 10 and 12 years, and boys should be screened once at either age 13 or 14 years. The benefits of early detection, referral, and medical treatment are considered to be significant, but the people performing the screenings must be educated in the detection of spinal deformity.

Diagnostic Evaluation

Observation is performed behind an undressed (in undergarments), standing child, noting shoulder height, scapular or flank shape, and hip height and alignment. When the child bends forward at the waist (the Adams forward bend test) with hanging arms, asymmetry of the ribs and flanks may be noted. A scoliometer is also used in the initial screening to measure the angle of truncal rotation. Often a primary and a compensatory curve place the head in alignment with the gluteal cleft. However, in the uncompensated curve the head and hips are not aligned (see Fig. 48-15, *E* and *F*). (See Spine, Chapter 29, for additional information.) Definitive diagnosis is made by radiographs of the child in the standing position and use of the Cobb technique that establishes the degree of curvature. The Risser scale is used to evaluate skeletal maturity on the radiographs; the scale helps to make a determination of the likely progression of the spinal angulature based on growth potential. Radiographic curves need to measure at least 10 degrees for diagnosis. Curves of less than 25 degrees are mild and require observation during growth.

! NURSING ALERT

Intraspinal conditions or other disease processes that can cause scoliosis must be ruled out. The presence of pain, sacral dimpling or hairy patches, cutaneous vascular changes, absent or abnormal reflexes, bowel or bladder incontinence, or left thoracic curve may indicate an intraspinal abnormality such as syringomyelia, diastematomyelia, or tethered cord syndrome. An MRI scan should be obtained for evaluation.

Therapeutic Management

Current management options include observation with regular clinical and radiographic evaluation, orthotic intervention (bracing), and surgical spinal fusion. Treatment decisions are based on the magnitude, location, and type of curve; the child's age and skeletal maturity; and any underlying or contributing disease process.

Bracing and Exercise. For many curves in growing children and adolescents, bracing may be the treatment of choice. It is important to understand that *bracing is not curative* but that it may slow the progression of the curvature to allow skeletal growth and maturity. The two most common types of bracing are (1) the Boston and Wilmington braces, which are underarm orthoses customized from prefabricated plastic shells, with corrective forces for each patient using lateral pads and decreasing lumbar lordosis; and (2) a TLSO (thoracolumbosacral orthosis), which is an underarm orthosis made of plastic that is custom molded to the body and then shaped to correct or hold the deformity (Fig. 48-16). The Milwaukee brace, or CTLSO (cervical thoracolumbosacral orthosis), which is an individually adapted brace that includes a neck ring, is rarely used in scoliosis but is sometimes used in the treatment of kyphosis. The Charleston nighttime bending brace is worn only when the child is in bed because it prevents walking because of the severity of the trunk bend. Compliance in wearing the brace is difficult because of the child's age and preoccupation with body image and appearance. Bracing is the standard treatment for moderate curvatures in growing children (Sponseller, 2011).

Exercises, transcutaneous electrical stimulation, and chiropractic treatment are rarely of value for managing scoliosis. Exercises are beneficial when used in conjunction with bracing to maintain and strengthen spinal and abdominal muscles during treatment.

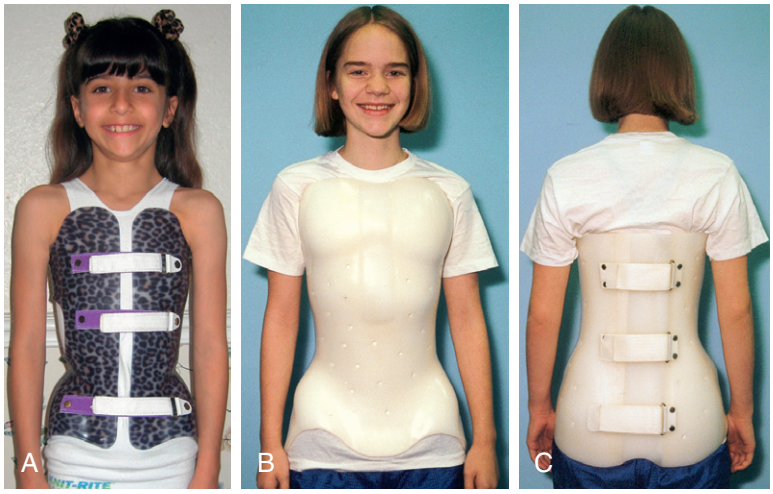

FIG 48-16 A, Standard thoracolumbosacral orthosis (TLSO) brace for idiopathic scoliosis. Note the color and design incorporated into the brace to make it more acceptable to children and adolescents. **B,** Variation of a standard TLSO that fastens in the back **(C)** to provide needed support for the spine curvature.

Surgical Management. Surgical intervention may be required for treatment of severe curves, which are typically greater than 45 degrees. The degree of curvature, its behavior, the etiology, and the symptoms guide the decision for surgery. Bracing is ineffective in managing curves greater than 45 degrees. Progressive curves that do not respond to bracing and progressive congenital and neuromuscular curves require surgical intervention.

The surgical technique of spinal fusion consists of realignment with internal fixation and instrumentation combined with bony fusion *(arthrodesis)* of the realigned spine. Bone from the iliac crest or donor bone is used to fuse the spine. The goals of surgical intervention are to improve the curvatures on the sagittal and coronal planes and have a solid, pain-free fusion in a well-balanced torso, with maximum mobility of the remaining spinal segments. Surgical approaches may be posterior, anterior, or both.

Many instrumentation systems are available, including Dwyer, Zielke, Luque, Cotrel-Dubousset, Isola, TSRH (Texas Scottish Rite Hospital), and Moss Miami. Selection of the system is individualized according to the patient's needs and surgeon's preference. Combinations of rods, hooks, wires, and pedicle screws may be used.

The Luque-rod segmental spinal instrumentation provides segmental stability with the use of wires and L-shaped rods. By way of a posterior approach, the wires are threaded beneath the lamina of each vertebra and tightened around the rods resting along the transverse processes to stabilize the spine. The advantage of this method is that the patient can be mobile within a few days and requires no postoperative immobilization. A higher risk of nerve damage has been reported.

The Cotrel-Dubousset instrumentation is a newer generation of spinal instrumentation and implements bilateral rods and hooks at many sites. Anterior approaches using the Dwyer or Zielke instrumentation involve screws into the vertebral bodies connected by a cable or rod. These systems require postoperative immobilization with a custom-fitted plastic jacket.

CARE MANAGEMENT

Treatment for scoliosis extends over a significant portion of the affected child's period of growth. In adolescents this period is the one in which their identity, both physical and psychologic, is formed. The identification of scoliosis as a "deformity," in combination with unattractive appliances and a significant surgical procedure, can have a negative effect on the already fragile adolescent body image. The adolescent and family require excellent nursing care not only for physical needs to be met but also for psychologic needs associated with the diagnosis, surgery, postoperative recovery, and eventual rehabilitation. Although adolescents with scoliosis are encouraged to participate in most peer activities, necessary therapeutic modifications are likely to make them feel different and apart. Nursing care of the adolescent who is facing scoliosis surgery, potential social isolation, pain, and uncertainty, in addition to misunderstood emotions and body image issues, must be evaluated from the adolescent's perspective to be successful in meeting the individual's needs (Napierkowski, 2007).

When a child or adolescent first faces the prospect of a prolonged period in a brace or other device, the therapy program and the nature of the device must be explained thoroughly to both the child and the parents so they understand the anticipated results, how the appliance corrects the defect, the freedoms and constraints imposed by the device, and what they can do to help achieve the desired goal. Management involves the skills and services of a team of specialists, including the orthopedist, neurosurgeon, physical therapist, orthotist (a specialist in fitting orthopedic braces), nurse, social worker, and sometimes a thoracic or pulmonary specialist.

It is difficult for a child or adolescent to be restricted at any phase of development; but adolescents need continual positive reinforcement, encouragement, and as much independence as can be safely assumed during this time. They appreciate guidance and assistance regarding anticipated problems such as selection of clothing and participation in social activities. Socialization with peers is strongly encouraged, and every effort is expended to help the adolescent feel attractive and worthwhile.

Preoperative Care. The preoperative workup usually involves a radiographic series, including bending and traction films, pulmonary function studies, and laboratory studies (including prothrombin, partial thromboplastin, and platelet function test; blood count; electrolyte levels; urinalysis and urine culture; and blood levels of any medications). Because spinal surgery usually involves considerable blood loss, several options are considered before surgery to maintain or replace blood volume. These options include autologous blood donations obtained from the patient before the surgery; intraoperative blood salvage; intraoperative hemodilution; erythropoietin administration; and controlled induced hypotension, which must be monitored carefully at all times to prevent physiologic instability (Newton and Wenger, 2005).

Surgery for spinal fusion is complex; and often adolescents who require the procedure because of idiopathic scoliosis are not familiar with medical terms, procedures, or experiences. Preoperative teaching is critical for the adolescent to be able to cooperate and participate in his or her treatment and recovery. Because the surgery is extensive, the patient is taught how to manage his or her own patient-controlled analgesia (PCA) pump, how to log roll, and the use and function of other equipment such as a chest tube (for anterior repair) and Foley catheter. It is recommended that the child or adolescent bring a favorite toy (age dependent) or personal items such as a favorite stuffed animal, laptop computer (with Internet access), cell phone or iPod, or movie player for postoperative use. Meeting with a peer who has undergone a similar surgery may also be valuable.

Postoperative Care. After surgery patients are monitored in an acute care setting and log rolled when changing position to prevent damage to the fusion and instrumentation. Skin care is important, and pressure-relieving mattresses or beds may be needed to prevent pressure wounds (see Maintaining Healthy Skin, Chapter 39).

In addition to the usual postoperative assessments of wound, circulation, and vital signs, the neurologic status of the patient's extremities requires special attention. Prompt recognition of any neurologic impairment is imperative because delayed paralysis may develop that requires surgical intervention. Common postoperative problems after spinal fusion include neurologic or spinal cord injury, hypotension from acute blood loss, wound infection, syndrome of inappropriate antidiuretic hormone, atelectasis, pneumothorax, ileus, delayed neurologic injury, and implanted hardware complications (Freeman, 2007; Newton and Wenger, 2005). *Superior mesenteric artery syndrome* may occur several days after spinal surgery; this involves duodenal compression by the aorta and superior mesenteric artery and may result in acute partial or complete duodenal obstruction. Clinical manifestations include epigastric pain, nausea, copious vomiting, and eructation; symptoms are aggravated in the supine position and often relieved with the patient in a left lateral decubitus or prone position.

The child usually has considerable pain for the first few days after surgery and requires frequent administration of pain medication, preferably IV opioids administered on a regular schedule. For

children able to understand the concept, PCA is recommended (see Pain Assessment; Pain Management, Chapter 30).

In most cases the patient begins ambulation as soon as possible, depending on the instrumentation used—generally by the second or third postoperative day. The patient is discharged by 1 week, depending on the surgical approach. In addition to pain management, she or he is evaluated for skin integrity, adequate urinary output, fluid and electrolyte balance, and ileus. Discharge planning should include a timetable for follow-up with the practitioner and resumption of regular activities.

The patient may start physical therapy as soon as he or she is able, beginning with range-of-motion exercises on the first postoperative day and many of the activities of daily living in the following days. Self-care such as washing and eating is always encouraged. Throughout the hospitalization age-appropriate activities and contact with family and friends are important parts of nursing care and planning (see The Immobilized Child, p. 1531).

The family is encouraged to become involved in the patient's care to facilitate the transition from hospital to home management. An organization that provides education and services to both families and professionals is the National Scoliosis Foundation.* The American Academy of Orthopaedic Surgeons† and Scoliosis Research Society,‡ an organization of physicians and scientists, have published an excellent book, *Scoliosis;* and the Scoliosis Research Society has educational information available on its website.

INFECTIONS OF BONES AND JOINTS

Osteomyelitis

Osteomyelitis, an infectious process in the bone, can occur at any age but most frequently is seen in children 10 years of age or younger. Boys are more commonly affected than girls, and the median age of diagnosis is 5 to 6 years of age. The limbs most commonly affected include the foot, femur, tibia, and pelvis. It is estimated that one in 5000 children younger than the age of 13 years is diagnosed each year with this condition (Zaoutis, Localio, Leckerman, et al., 2009). *Staphylococcus aureus* is the most common causative organism. Neonates are also likely to have osteomyelitis caused by group B streptococci. Children with sickle cell disease may develop osteomyelitis from *Salmonella* organisms and *S. aureus*. *Neisseria gonorrhoeae* is a potential causative organism in sexually active adolescents. *Kingella kingae* has been reported as one of the most causative organisms in children younger than age 5 years (Kaplan, 2011a).

Acute hematogenous osteomyelitis results when a bloodborne bacterium causes an infection in the bone. Common foci include infected lesions, upper respiratory tract infections, otitis media, tonsillitis, abscessed teeth, pyelonephritis, and infected burns. Exogenous osteomyelitis is acquired from direct inoculation of the bone from a puncture wound, open fracture, surgical contamination, or adjacent tissue infection. Subacute osteomyelitis has a longer course and may be caused by less virulent microbes with a walled-off abscess or Brodie abscess, typically in the proximal or distal tibia. Chronic osteomyelitis is a progression of acute osteomyelitis and is characterized by dead bone, bone loss, and drainage and sinus tracts.

Generally healthy bone is not likely to become infected. Factors that contribute to infection include inoculation with a large number of organisms, presence of a foreign body, bone injury, high virulence of an organism, immunosuppression, and malnutrition; certain types and locations of bone are also more vulnerable to infection.

BOX 48-9 CLINICAL MANIFESTATIONS OF ACUTE OSTEOMYELITIS

General Manifestations
- History of trauma to affected bone (frequent)
- Child appears very ill
- Irritability
- Elevated temperature
- Restlessness
- Rapid pulse
- Dehydration

Local Manifestations
- Tenderness
- Increased warmth
- Diffuse swelling over involved bone
- Involved extremity painful, especially on movement
- Involved extremity held in semiflexion
- Surrounding muscles tense and resistant to passive movement

Typically children with acute hematogenous osteomyelitis are seen with a 2- to 7-day history of pain, warmth, tenderness, and decreased range of motion in the affected limb along with systemic symptoms of fever, irritability, and lethargy (Box 48-9). Infants may have an adjacent joint effusion as well. Symptoms often resemble those observed in other diseases involving bones such as arthritis, leukemia, or sarcoma.

Pathophysiology

In acute osteomyelitis bacteria adhere to bone, causing a suppurative infection with inflammatory cells, edema, vascular congestion, and small-vessel thrombosis; the result is bone destruction, abscess formation, and dead bone (sequestra). Infection within the bone can rupture through the cortex into the subperiosteal space, stripping loose periosteum and forming an abscess. As dead bone is resorbed, new bone is formed along the live bone and infection borders. This surrounding sheath of live bone is called an *involucrum.* Sinus tracts from perforations in the involucrum may drain pus through soft tissue to the skin.

The pathology of osteomyelitis is different in infants, children older than 1 year of age, and adults. In infants blood vessels cross the growth plate into the epiphysis and joint space, which allows infection to spread into the joint. In children the infection is contained by the growth plate, and joint infection is less likely (unless the infection is intracapsular). In older adolescents (with a closed growth plate) the infection is poorly contained, and the joint is compromised. Adult periosteum is attached to bone; consequently rupture through the periosteum and sinus drainage are more common in adults.

Diagnostic Evaluation

Organism identification and antibiotic susceptibility testing are essential for effective therapy. Cultures of aspirated purulent drainage along with cultures of blood, joint fluid, and infected skin samples should be obtained. Bone biopsy is indicated if blood culture results and radiographic findings are not consistent with osteomyelitis. Supporting evidence for osteomyelitis includes leukocytosis and elevated erythrocyte sedimentation rate (ESR) and

*Five Cabot Place, Stoughton, MA 02072, 800-673-6922, www.scoliosis.org.

C-reactive protein (CRP). Radiographic signs, except for soft-tissue swelling, are evident only after 2 to 3 weeks. A three-phase technetium bone scan can show areas of increased blood flow such as occurs in early stages in infected bone and is useful in locating multiple sites; however, it is not a diagnostic test. CT can detect bone destruction, and MRI provides anatomic details useful in delineating the area of involvement, especially if surgical intervention is planned. MRI is reported to be the most sensitive diagnostic radiologic tool for diagnosing osteomyelitis (Kaplan, 2011a). Sometimes the osteomyelitis may be unrecognized if it occurs as a complication of a severe toxic and debilitating disease. Neonates may not present with clinical manifestations other than limited mobility of the affected extremity; fever may or may not be present, and the neonate may not appear to be sick (Kaplan, 2011a).

Therapeutic Management

After culture specimens are obtained, empiric therapy is started with IV antibiotics covering the mostly likely organisms. For *S. aureus* nafcillin or clindamycin is generally used. Consideration should be given to the increased rates of *community-acquired methicillin-resistant S. aureus (CA-MRSA)* in the selection of first-line antibiotic therapy; MRSA may require vancomycin, or in some cases clindamycin may be appropriate. In one study children with MRSA osteomyelitis had an increased length of hospitalization, longer antibiotic course, and a greater number of complications (Saavedra-Lozano, Mejías, Ahmad, et al., 2008). When the infectious agent is identified, administration of the appropriate antibiotic is initiated and continued for at least 3 to 4 weeks; but the length of therapy is determined by the duration of the symptoms, the response to treatment, and the sensitivity of the organism; 6 weeks to 4 months may be required in some cases (Kaplan, 2011a). In selected cases oral antibiotic therapy may follow the IV treatment. Because of the prolonged duration of high-dose antibiotic therapy, it is important to monitor for hematologic, renal, hepatic, ototoxic, and other potential side effects. To prevent antibiotic-associated diarrhea in some children, administration of a probiotic may be considered.

Surgery may be indicated if there is no response to specific antibiotic therapy, a penetrating injury, persistent soft-tissue abscess is seen, or the infection spreads to the joint. Opinions differ regarding surgical intervention, but many advocate sequestrectomy and surgical drainage to decompress the metaphyseal space before purulent fluid erupts and spreads to the subperiosteal space, forming abscesses that strip the periosteum from bone or form draining sinuses. When these complications occur, a chronic infection usually persists, which may require antibiotic therapy for several months.

CARE MANAGEMENT

During the acute phase of illness movement of the affected limb causes discomfort; therefore the child is positioned comfortably with the affected limb supported. A temporary splint or cast may be applied. Weight bearing is avoided in the acute phase, and moving and turning are carried out carefully to minimize pain. The child may require long-term pain medication to deal with the bone pain. After surgery pain medication should be considered as with any other surgical procedure.

Antibiotic therapy requires careful observation and monitoring of the IV equipment and site. A peripherally inserted central catheter (PICC) may be inserted for long-term antibiotic therapy. Antibiotic therapy is often continued at home or through an outpatient infusion clinic.

Standard Precautions are implemented for all children with osteomyelitis. If there is an open wound, it is managed according to standard wound care precautions. If a PICC line or central venous catheter (CVC) is inserted, meticulous care should be taken to prevent catheter-related infection.

Providing diversional and constructive activities becomes an important nursing intervention. Children are usually confined to bed for some time during the acute phase but may be allowed to move about on a stretcher or in a wheelchair if isolation is not necessary.

As the infection subsides, physical therapy is instituted to ensure restoration of optimum function. The child may eventually be transitioned to a regimen of oral antibiotics, and progress is followed closely for some time.

Septic Arthritis

Septic arthritis is a bacterial infection in the joint. It usually results from hematogenous spread or direct extension of an adjacent cellulitis or osteomyelitis. Direct inoculation from trauma accounts for 15% to 20% of septic arthritis cases. The most common causative organism is *S. aureus*. Community-acquired MRSA is commonly a cause of septic arthritis. In addition to *S. aureus*, pathogens seen in neonates include group B streptococci, *Escherichia coli*, and *Candida albicans*. In children 2 months to 5 years of age, *S. aureus*, *Streptococcus pyogenes*, *Streptococcus pneumoniae*, and *K. kingae* are the primary organisms causing infection. Children older than 5 years are more likely to be infected by *S. aureus* and *S. pyogenes*, and sexually active adolescents may be infected by *N. gonorrhoeae* (Gutierrez, 2005; Kaplan, 2011b).

The knees, hips, ankles, and elbows are the most common joints affected. Clinical manifestations include severe joint pain, swelling, warmth of overlying tissue, and occasionally erythema. However, an infection involving the hip is considered a surgical emergency to prevent compromised blood supply to the head of the femur (Kaplan, 2011b).

The child is resistant to any joint movement. Features of systemic illness such as fever, malaise, headache, nausea, vomiting, and irritability may also be present.

THERAPEUTIC MANAGEMENT AND CARE MANAGEMENT

The affected joint is aspirated; and the specimen evaluated by Gram stain, cultures (including separate cultures for *Haemophilus influenzae* and *N. gonorrhoeae*), and determination of leukocyte count. In addition, blood cultures are performed, and a complete blood count with differential and ESR or CRP level is obtained. Early radiographic findings are limited to soft-tissue swelling but may reveal a foreign body, and such films always provide a baseline for comparison. Technetium scans reveal areas of increased blood flow but do not differentiate between sites. MRI and CT scans provide more detailed images of cartilage loss, joint narrowing, erosions, and ankylosis of progressive disease. Ultrasonography is helpful in the detection of joint effusions and fluid in the soft tissue and subperiosteum (Kaplan, 2011b).

Treatment is IV antibiotic therapy based on Gram stain results and the clinical presentation. The benefits of serial aspirations to demonstrate sterility of synovium fluid and reduce pressure or pain are controversial. Pain management is an important aspect of nursing care, particularly with involvement of a large joint such as the hip. Surgical intervention may also be required if there was a penetrating wound or a foreign object was possibly involved.

Physical therapy may be initiated for the child who is immobilized to prevent flexion contractures. Additional nursing care is the same as for osteomyelitis.

Skeletal Tuberculosis

In children tubercular infection of the bones and joints is acquired by lymphohematogenous spread at the time of primary infection. Occasionally it is from chronic pulmonary TB. Skeletal tubercular infection is not common in the United States but should be considered in communities with high TB case rates. The condition is a late manifestation of TB and is most likely to involve the vertebrae, causing tubercular spondylitis. If the infection is progressive, it causes Pott disease with destruction of the vertebral bodies and results in kyphosis and spinal malalignment. Symptoms are insidious. The child may report persistent or intermittent pain. Other findings include joint swelling and stiffness; fever and weight loss are not common. Tubercular arthritis can also affect single joints such as a knee or hip and tends to cause severe destruction of adjacent bone. Infection in the fingers causes spina ventosa, a tuberculous dactylitis.

As with pulmonary TB, the index case should be located. A family and environmental history needs to be obtained, and tuberculin skin tests (TSTs) performed. Results of TSTs are positive for the majority of children with tuberculous arthritis; however, the results are not diagnostic, and the clinical and laboratory features do not differentiate tubercular arthritis from a nontubercular septic arthritis. Diagnosis requires isolation of *Mycobacterium tuberculosis* from the site. Patients with the susceptible organism start treatment with combined antituberculosis chemotherapy (isoniazid, rifampin, and pyrazinamide); directly observed therapy (DOT) is preferred. (See also Chapter 40.)

CARE MANAGEMENT

Nursing care depends on the site and extent of infection. Tuberculous spondylitis and hip infection may require immobilization, casting, and surgical fusion. Nursing care is individualized but is generally the same as for osteomyelitis and septic arthritis.

BONE AND SOFT-TISSUE TUMORS

General Concepts: Bone Tumors

Bone tumors account for approximately 6% of all malignant neoplasms in children. Approximately 90% of all primary malignant bone tumors in children are either osteogenic sarcoma or Ewing sarcoma; osteosarcoma, the most common, occurs in 56% of all cases. The peak age for pediatric bone tumors is 15 years, and they occur more often in boys.

Most malignant bone tumors produce localized pain in the affected site, which may be severe or dull and may be attributed to trauma or the vague complaint of "growing pains." The pain is often relieved by a flexed position, which relaxes the muscles overlying the stretched periosteum. Frequently it draws attention when the child limps, curtails physical activity, or is unable to hold heavy objects (Box 48-10). A palpable mass is also a common manifestation of bone tumors, but systemic symptoms such as fever and other clinical symptoms such as spinal cord compression and respiratory distress are more frequent in patients with Ewing sarcoma.

Diagnostic Evaluation

Diagnosis begins with a thorough history and physical examination. A primary objective is to rule out causes such as trauma or infection.

BOX 48-10 CLINICAL MANIFESTATIONS OF BONE TUMORS

- Pain localized at affected site
  - May be severe or dull
  - Often relieved by position of flexion
- Frequently brought to attention when child:
  - Limps
  - Curtails own physical activity
  - Is unable to hold heavy objects

Careful questioning regarding pain is essential in attempting to determine the duration and rate of tumor growth. Physical assessment focuses on functional status of the affected area; signs of inflammation; size of the mass; and any systemic indication of generalized malignancy such as anemia, weight loss, and frequent infection.

Definitive diagnosis is based on radiologic studies such as plain films and CT or MRI of the primary site, CT of the chest, and radioisotope bone scans to evaluate metastasis and bone marrow examination in patients with Ewing sarcoma. A needle or surgical biopsy is necessary to establish the diagnosis. Ewing sarcoma most commonly involves the pelvis, long bones of the lower extremities, and chest wall and radiographically involves the diaphysis with detachment of the periosteum from the bone (Codman triangle). In osteosarcoma lesions are most commonly located in the metaphyseal region of the bone, often involving the long bones. Radial ossification in the soft tissue gives the tumor a "sunburst" appearance on plain radiograph.

Osteosarcoma

Osteosarcoma (osteogenic sarcoma) is the most common bone cancer in children and most commonly affects patients in the second decade of life during their growth spurt. It presumably arises from bone-forming mesenchyme, which gives rise to malignant osteoid tissue. Most primary tumor sites are in the diametaphyseal region (wider part of the shaft, adjacent to the epiphyseal growth plate) of long bones, especially in the lower extremities. More than half occur in the femur, particularly the distal portion, with the rest involving the humerus, tibia, pelvis, jaw, and phalanges.

Therapeutic Management

Optimum treatment of osteosarcoma includes surgery and chemotherapy. The surgical approach consists of surgical biopsy followed by either *limb salvage* or amputation. To ensure local control, all gross and microscopic tumors must be resected. A limb salvage procedure involves en bloc resection of the primary tumor with prosthetic replacement of the involved bone. For example, with osteosarcoma of the distal femur, a total femur and joint replacement are performed. Frequently children undergoing a limb salvage procedure receive preoperative chemotherapy in an attempt to decrease the tumor size and make surgery more manageable (Gorlick, Bielack, Teot, et al., 2011; Lanzkowsky, 2010).

Chemotherapy plays a vital role in treatment of osteosarcoma. Antineoplastic drugs such as high-dose methotrexate with citrovorum factor rescue, doxorubicin, cisplatin, ifosfamide, and etoposide may be administered singly or in combination and may be used either before or after surgical resection of the tumor. The use of postoperative chemotherapy after amputation has comparable results to trials using preoperative chemotherapy followed by limb

salvage surgery. Preoperative chemotherapy allows for examination of the surgical specimen at the time of definitive surgery, which predicts clinical outcome. When pulmonary metastases are found, thoracotomy and chemotherapy have resulted in prolonged survival and potential cure. These combined-modality approaches have significantly improved the prognosis in osteosarcoma to approximately 78% for nonmetastatic patients (Lanzkowsky, 2010). Ongoing trials are evaluating the use of muramyl tripeptide phosphatidylethanolamine (Mifamurtide) to eradicate micrometastases by stimulating macrophages to kill tumor cells not eliminated by chemotherapy (Lanzkowsky, 2010). This drug has been used successfully in patients with nonmetastatic osteosarcoma (Anderson, Tomaras, and McConnell, 2010).

CARE MANAGEMENT

Nursing care depends on the type of surgical approach. Obviously the family may have more difficulty adjusting to an amputation than a limb salvage procedure. In either instance preparation of the child and family is critical. Straightforward honesty is essential in gaining the child's cooperation and trust. The diagnosis of cancer should not be disguised with falsehoods such as "infection." To accept the need for radical surgery, the child must be aware of the lack of alternatives for treatment. Although the responsibility of telling the child is generally left to the physician, the nurse should be present at the discussion or be aware of exactly what is said. The child should be told a few days before surgery to allow him or her time to think about the diagnosis and consequent treatment and ask questions. (See Nursing Care Plan: The Child with a Bone Tumor.*)

Sometimes children have many questions about the prosthesis, limitations on physical ability, and prognosis in terms of cure. At other times they react with silence or a calm manner that belies their concern and fear. Either response must be accepted because it is part of the grieving process of a loss. For those who desire information, it may be helpful to introduce them to another person who has had an amputation before surgery or to show them pictures of the prosthesis.† However, the nurse must be careful not to overwhelm children with information. A sound approach is to answer questions without offering additional information. For those who do not pursue additional information, the nurse expresses a willingness to talk.

The child is also informed of the need for chemotherapy and its side effects before surgery. Exercise caution about offering too much information at one time. When discussing hair loss, emphasize positive aspects such as wearing a wig. Because bone tumors affect adolescents and young adults, it is not unusual for them to become angry over all of the radical body alterations.

If an amputation is performed, the child is usually fitted with a temporary prosthesis immediately after surgery, which permits early functioning and fosters psychologic adjustment. If this is not done, the child requires stump care, which is the same as for any person with an amputation. A permanent prosthesis is usually fitted within 6 to 8 weeks. During hospitalization the child begins physical therapy to become proficient in the use and care of the device.

Phantom limb pain may develop after amputation. This symptom is characterized by sensations such as tingling, itching, and more frequently pain felt in the amputated limb. The child and family need to know that the sensations are real, not imagined. Amitriptyline (Elavil) has been used successfully in children to decrease the pain. In addition, an epidural is often used before surgery as a nerve block in an effort to decrease or eliminate the occurrence of phantom limb pain. Much research is needed to further delineate the best care for these patients (Ong, Arneja, and Ong, 2006).

Discharge planning must begin early in the postoperative period. After the child has begun physical therapy, the nurse should consult with the therapist and practitioner to evaluate his or her physical and emotional readiness to reenter school. It is an opportune time to involve a community nurse in the child's home care. Every effort is made to promote normalcy and gradual resumption of realistic preamputation activities.* Role-playing in anticipation of such experiences is beneficial in preparing the child for the inevitable confrontation by others. Environmental barriers such as stairs are assessed in terms of the accessibility in the school and home, especially because the child may need to use crutches or a wheelchair before complete healing and prosthetic competency are achieved.

The nurse encourages the child to select clothing that best camouflages the prosthesis such as pants or long-sleeved shirts. Well-fitted prostheses are so natural looking that girls can usually wear sheer stockings without revealing the device. Emphasizing feminine or masculine apparel helps the child regain a feeling of self-identity. Even during the postoperative period, encouraging the child to wear blue jeans and a T-shirt may distract attention from the deformity and focus it on familiar aspects of appearance.

The family and child need much support in adjusting not only to a life-threatening diagnosis but also to alteration in body form and function. Because loss of a limb entails a grieving process, those caring for the child need to recognize that the reactions of anger and depression are normal and necessary. Often parents view the anger as a direct affront to them for allowing the amputation to occur, or they see the depression as rejection. These are not personal attacks but the child's attempts to cope with a loss.

Ewing Sarcoma (Primitive Neuroectodermal Tumor)

Ewing sarcomas, or the Ewing sarcoma family of tumors, which includes primitive neuroectodermal tumor of the bone, are the second most common malignant bone tumor (after osteosarcoma) in childhood (Lanzkowsky, 2010). Ewing sarcoma arises in the marrow spaces of the bone rather than from osseous tissue. The tumor originates in the shaft of long and trunk bones, most often affecting the pelvis, femur, tibia, fibula, humerus, ulna, vertebra, scapula, ribs, and skull. It occurs almost exclusively in individuals younger than age 30 and affects Caucasians much more often than other races.

Therapeutic Management

Limb salvage procedures might be feasible in extremity lesions, and amputation may be considered if the results of radiotherapy render the extremity useless or deformed (e.g., from restricted growth in young children). The treatment of choice for the majority of lesions is involved field radiotherapy and chemotherapy. A widely used drug regimen includes vincristine, doxorubicin, cyclophosphamide alternating with ifosfamide, and etoposide. The addition of ifosfamide and etoposide has increased the 3-year survival rate to 78% for patients with localized disease (Lanzkowsky, 2010).

*In Wilson D, Hockenberry MJ: *Wong's clinical manual of pediatric nursing*, ed 8, St Louis, 2012, Mosby.

†Information about prostheses can be obtained from the National Amputation Foundation, 40 Church St, Malverne, NY 11565, 516-887-3600, www.nationalamputation.org.

*Information about special programs for children with amputations is available from the Candlelighters Childhood Cancer Foundation, 8323 Southwest Freeway, Suite 435, Houston, TX 77074, 713-270-4700, www.candle.org.

CARE MANAGEMENT

The psychologic adjustment to Ewing sarcoma is typically less traumatic than it is to osteosarcoma because of the preservation of the affected limb. Many families accept the diagnosis with a sense of relief in knowing that this type of bone cancer does not necessitate amputation, and initially they may not be aware of the damaging effects on the irradiated site. Consequently they need preparation for the various diagnostic tests, including bone marrow aspiration and surgical biopsy, and adequate explanation of the treatment regimen. High-dose radiotherapy often causes a skin reaction of dry or moist desquamation followed by hyperpigmentation. The child should wear loose-fitting clothes over the irradiated area to minimize additional skin irritation. Because of increased sensitivity, the area should be protected from sunlight and sudden changes in temperature such as from heating pads or ice packs. Encourage the child to use the extremity as tolerated. Occasionally the physical therapist may plan an active exercise program to preserve maximum function.

The child needs the same considerations for adjusting to the effects of chemotherapy as any other patient with cancer. The drug regimen usually results in hair loss, severe nausea and vomiting, peripheral neuropathy, and possibly cardiotoxicity. Make every effort to outline a treatment plan that allows the child maximum resumption of a normal lifestyle and activities. (See Nursing Care Plan: The Child with Cancer.*)

Rhabdomyosarcoma

Rhabdomyosarcoma (*rhabdo*, striated) is the most common soft-tissue sarcoma in children. Striated (skeletal) muscle is found almost anywhere in the body; thus these tumors occur in many sites, the most common of which are the head and neck, especially the orbit. The disease occurs in children in all age-groups but is most common in children younger than 5 years of age. Its incidence is approximately 8.5 per 1 million for Caucasian children but only 4 per 1 million for African-American children in the age-group from 2 to 19 years (Lanzkowsky, 2010).

Rhabdomyosarcoma arises from embryonic mesenchyme. Three subtypes are recognized: embryonal, alveolar, and pleomorphic. Soft-tissue sarcomas are the fourth most common type of solid tumors in children. These malignant neoplasms originate from undifferentiated mesenchymal cells in muscles, tendons, bursae, and fascia or in fibrous, connective, lymphatic, or vascular tissue. They derive their name from the specific tissue(s) of origin such as myosarcoma (*myo,* muscle).

The initial signs and symptoms are related to the site of the tumor and compression of adjacent organs (Table 48-2). Some tumor locations such as the orbit manifest early in the course of the illness. Other tumors such as those of the retroperitoneal area only produce symptoms when they are relatively large and compress adjacent organs. Unfortunately many of the signs and symptoms attributable to rhabdomyosarcoma are vague and frequently suggest a common childhood illness such as "earache" or "runny nose." In rare instances the site of the primary tumor site is never identified.

Diagnostic Evaluation

Diagnosis begins with a careful history and physical examination. Radiographic studies to delineate the primary tumor site should include CT or MRI. Metastatic evaluation should include a CT of the chest, bone scan, and bilateral bone marrow aspirates and biopsies. For patients with tumors in the parameningeal area, a lumbar puncture should be done to examine the spinal fluid. When possible, an excisional biopsy or surgical resection of the tumor is done to confirm the diagnosis.

Careful staging is extremely important for planning treatment and determining the prognosis. The Intergroup Rhabdomyosarcoma Study has developed a surgicopathologic staging system, shown in Box 48-11 (Helman, 2011; Lanzkowsky, 2010).

With the use of contemporary multimodal therapy, more than 80% of patients with nonmetastatic disease are expected to survive

TABLE 48-2 CLINICAL MANIFESTATIONS OF RHABDOMYOSARCOMA ACCORDING TO TUMOR SITE

LOCATION	SIGNS AND SYMPTOMS
Orbit	Rapidly developing unilateral proptosis Ecchymosis of conjunctiva Loss of extraocular movements (strabismus)
Nasopharynx	Stuffy nose (earliest sign) Nasal obstruction—dysphagia, nasal voice (obstruction of posterior nasal conches), otitis media with effusion (obstruction of eustachian tube) Pain (sore throat and ear) Epistaxis Palpable neck nodes Visible mass in oropharynx (late sign)
Paranasal sinuses	Nasal obstruction Local pain Discharge Sinusitis Swelling
Middle ear	Signs of chronic serous otitis media with effusion (OME) Pain Sanguinopurulent drainage Facial nerve palsy
Retroperitoneal area (usually a "silent" tumor)	Abdominal mass Pain Signs of intestinal or genitourinary obstruction
Perineum	Visible superficial mass Bowel or bladder dysfunction (from tumor compression)

BOX 48-11 STAGING OF RHABDOMYOSARCOMA

Group I—Localized disease; tumor completely resected, and regional nodes not involved
Group II—Localized disease with microscopic residual, or regional disease with no residual or with microscopic residual
Group III—Incomplete resection or biopsy with gross residual disease
Group IV—Metastatic disease present at diagnosis

*In Wilson D, Hockenberry MJ: *Wong's clinical manual of pediatric nursing*, ed 8, St Louis, 2012, Mosby.

(Helman, 2011; Lanzkowsky, 2010). If relapse occurs, the prognosis for long-term survival is poor.

Therapeutic Management

All rhabdomyosarcomas are high-grade tumors with the potential for metastases. Therefore multimodal therapy is recommended for all patients. Complete removal of the primary tumor is advocated whenever possible. However, because the tumor is chemosensitive, radical procedures with high morbidity should be avoided. In most cases a biopsy is followed by chemotherapy, irradiation, or both. Patients with embryonal tumors and group I disease can be treated with chemotherapy alone, but all others require chemotherapy and radiotherapy. Drugs that are used most often for the treatment of rhabdomyosarcoma include vincristine, actinomycin D, cyclophosphamide (VAC); ifosfamide; topotecan; irinotecan; and doxorubicin, which are administered for about 1 year (Lanzkowsky, 2010).

CARE MANAGEMENT

The nursing responsibilities are similar to those for other types of cancer, especially the solid tumors when surgery is used. Specific objectives include (1) careful assessment for signs of the tumor, especially during well-child examinations; (2) preparation of the child and family for the multiple diagnostic tests; and (3) supportive care during each stage of multimodal therapy (see also Chapter 43).

DISORDERS OF JOINTS

Juvenile Idiopathic Arthritis

Juvenile idiopathic arthritis (JIA) is a new name replacing *juvenile rheumatoid arthritis (JRA)* in the research literature and now in clinical practice. The JRA nomenclature revision to JIA was partly attributable to the minimally applicable reference to "rheumatoid" in JRA. Only a small percentage of children have a positive rheumatoid factor, yet the name burdens the family with images of adult disfiguring rheumatoid arthritis, a distinctly different disease. Furthermore the JRA classification system focused more on disease at onset versus disease progression, which is more important.

Semantics aside, JIA is a chronic autoimmune inflammatory disease causing inflammation of joints and other tissue with an unknown cause. It starts before age 16, with a peak onset between 1 and 3 years of age. Twice as many girls as boys are affected. The reported incidence of chronic childhood arthritis varies from one to 20 cases per 100,000 children with a prevalence of 10 to 400 per 100,000 (Cassidy and Petty, 2011). The cause is unknown, but two factors are hypothesized: immunogenic susceptibility and an environmental or external trigger such as a virus (e.g., rubella, Epstein-Barr virus, parvovirus B19). There are a few known genetic risk factors, including HLA class I and class II genes, the *PTPN22* gene, and the *IL2RA/CD 25* gene; however, the genetic contribution is complicated and still not well understood.

Pathophysiology

The disease process is characterized by chronic inflammation of the synovium with joint effusion and eventual erosion, destruction, and fibrosis of the articular cartilage. Adhesions between joint surfaces and ankylosis of joints occur if the inflammatory process persists.

Clinical Manifestations

The outcome of JIA is variable and unpredictable. Even in severe forms the disease is rarely life threatening but can cause significant disability. The arthritis tends to wax and wane; however, patterns of clinical remission indicate that approximately 25% will obtain clinical remission off medication for a follow-up duration of at least 4 years. Children with arthritis in four or fewer joints had the greatest likelihood for a sustained remission. Children with extensive arthritis and a positive rheumatoid factor were less likely to have a sustained remission (Wallace, Huang, and Bandeira, 2005). Their arthritis can cause significant joint deformity and functional disability, requiring medication, physical therapy, and perhaps future joint replacement. Chronic and acute uveitis can cause permanent vision loss if undiagnosed and not aggressively treated.

Classification of Juvenile Idiopathic Arthritis

JIA is not a single disease but a heterogeneous group of diseases. The universal Durban classification of JIA, revised and published in 1998, lists several disease categories, each with its own set of criteria and exclusions, which continue to be revised (Petty, Southwood, Manners, et al., 2004):

- *Systemic arthritis* is arthritis in one or more joints associated with at least 2 weeks of quotidian fever, rash, lymphadenopathy, hepatosplenomegaly, and serositis.
- *Oligoarthritis* is arthritis in one to four joints for the first 6 months of disease. It is subdivided to *persistent oligoarthritis* if it remains in four joints or fewer or becomes *extended oligoarthritis* if it involves more than four joints after 6 months.
- *Polyarthritis rheumatoid factor negative* affects five or more joints in the first 6 months with a negative rheumatoid factor.
- *Polyarthritis rheumatoid factor positive* also affects five or more joints in the first 6 months, but these children have a positive rheumatoid factor.
- Psoriatic arthritis is arthritis with psoriasis or an associated dactylitis, nail pitting, or onycholysis or psoriasis in a first-degree relative.
- *Enthesitis-related arthritis* is arthritis or enthesitis associated with at least two of the following: sacroiliac or lumbosacral pain, HLA-B27 antigen, arthritis in a boy older than 6 years, acute anterior uveitis, inflammatory bowel disease, Reiter syndrome, or acute anterior uveitis in a first-degree relative.
- *Undifferentiated arthritis* fits none of the previous categories or fits more than one category.

Diagnostic Evaluation

JIA is a diagnosis of exclusion; there are no definitive tests. Classifications are based on the clinical criteria of age of onset before age 16 years, arthritis in one or more joints for 6 weeks or longer, and exclusion of other causes. Laboratory tests may provide supporting evidence of disease. The ESR may or may not be elevated. Leukocytosis is present frequently during exacerbations of systemic JIA. Antinuclear antibodies are common in JIA but are not specific for arthritis; however, they help identify children who are at greater risk for uveitis. Plain radiographs are the best initial imaging studies and may show soft-tissue swelling and joint space widening from increased synovial fluid in the joint. Later films can reveal osteoporosis, narrow joint space, erosions, subluxation, and ankylosis. A slit-lamp eye examination is necessary to diagnosis **uveitis** (i.e., inflammation in the anterior chamber of the eye), which is most common in antinuclear antibody–positive young girls with oligoarthritis. Routine examinations are necessary for early diagnosis and treatment to avoid or minimize sight-threatening disease (Qian and Acharya, 2010).

Therapeutic Management

There is no cure for JIA. The major goals of therapy are to control pain, preserve joint range of motion and function, minimize effects of inflammation such as joint deformity, and promote normal growth and development. Outpatient care is the mainstay of therapy; lengthy hospitalizations are infrequent in this era of managed care. The treatment plan can be exhaustive and intrusive for the child and family, including medications, physical and occupational therapy, ophthalmologic slit-lamp examinations, splints, comfort measures, dietary management, school modifications, and psychosocial support.

Medications. Many arthritis medications are available, and most are effective in suppressing the inflammatory process and relieving pain. These drugs may be given alone or in combination and are prescribed in a stepwise manner dependent on arthritis severity.

NSAIDs are the first drugs used. Naproxen, ibuprofen, tolmetin, indomethacin, celecoxib, meloxicam, and aspirin are approved for use in children. They are effective with few common side effects other than gastrointestinal irritation and bruising; with naproxen skin fragility is a possible side effect. NSAIDs must be taken with food. Aspirin, once the drug of choice, has been replaced by other NSAIDs because they have fewer side effects and easier administration schedules.

Methotrexate is the second-line medication used in children who have failed with NSAIDs alone. It is started in combination with an NSAID. It is effective, with acceptable toxicity, which requires monitoring of complete blood cell counts and liver functions. Patient education about possible side effects, including discussions with teens about birth defects and avoiding alcohol, is essential.

Corticosteroids are potent immunosuppressives used for life-threatening complications, incapacitating arthritis, and uveitis. They are administered at the lowest effective dosage for the briefest period and discontinued on a tapering schedule. They may be administered orally, as intraarticular joint injections, as IV infusions, or in eyedrop form for uveitis. A single intraarticular injection may provide effective relief for children with pauciarticular disease unresponsive to NSAIDs. Prolonged use of systemic steroids is associated with significant side effects, including Cushing syndrome, osteoporosis, increased infection risk, glucose intolerance, cataracts, and growth suppression.

Biologic agents that work by several mechanisms to interrupt and minimize the inflammatory process are used in children with severe or progressive arthritis. They may be used in combination with methotrexate. The Food and Drug Administration (FDA) has approved etanercept, adalimumab, and abatacept use in children with JIA. Etanercept is a tumor necrosis factor-α (TNF-α) receptor blocker and an effective drug for children with JIA unresponsive to methotrexate (Lovell, Giannini, Reiff, et al., 2003). It is given once or twice a week via subcutaneous injections. The long-term safety and efficacy of etanercept have been confirmed (Giannini, Ilowite, Lovell, et al., 2009; Kerensky, Gottlieb, Yaniv, et al., 2012). Adalimumab is a monoclonal antibody that also inhibits TNF, thereby reducing inflammation; it is a subcutaneous injection given every 2 weeks (Lovell, Ruperto, and Goodman, 2008). Abatacept reduces inflammation by inhibiting T cells and is given intravenously every 4 weeks. Possible side effects of biologics include an increased infection risk, rare reports of demyelinating disease and pancytopenia, and allergic reactions. Because of the infection risk, children should be evaluated for TB exposure before starting these medications. Live vaccines should be avoided while taking them. There is a reported potential increased risk of malignancy with anti-TNF agents etanercept, adalimumab, and infliximab at high doses (FDA, 2011). Parents and patients should be informed that biologic drugs are new therapies and more will be learned about potential side effects in the postmarketing period.

Physical and Occupational Therapy. Programs of physical management are individualized for each child and designed to reach the ultimate goal: preserving function or preventing deformity. Physical therapy is directed toward specific joints, focusing on strengthening muscles, mobilizing restricted joint motion, and preventing or correcting deformities. Occupational therapy assumes responsibility for generalized mobility and performance of activities of daily living.

General treatment or maintenance programs vary; physical therapists may be involved several times weekly to monthly in management of a home program; or their visits may be limited to infrequent review of the home program for compliance, effectiveness, and need. Normal activities of daily living and the child's natural tendency to be active are usually sufficient to maintain muscle strength and joint mobility.

Exercising in a pool is excellent therapy because it allows freedom of movement with support and minimal gravitational pull. If there is pain on motion, a hot pack or warm bath before therapy may help.

Practitioners may recommend nighttime splinting to help minimize pain and reduce flexion deformity. Joints most frequently splinted are the knees, wrists, and hands. Loss of extension in the knee, hip, and wrist causes special problems and requires vigilance to detect the earliest signs of involvement and vigorous attention to prevent deformity with specialized passive stretching, positioning, and resting splints.

CARE MANAGEMENT

Nursing the child with JIA involves assessment of the child's general health, the status of involved joints, and the child's emotional response to all ramifications of the disease (i.e., discomfort, physical restrictions, therapies, and self-concept) (see Nursing Care Plan).

The effects of JIA are manifest in every aspect of the child's life, including physical activities, social experiences, and personality development. Nursing interventions to support the parents may foster successful adaptation for the entire family. Parental concerns about the disease prognosis, financial and insurance issues, spouse and sibling relationships, and job and schedule conflicts must all be addressed. Referral to social workers, counselors, or support groups may be needed.

Relieve Pain. The pain of JIA is related to several aspects of the disease, including disease severity, functional status, individual pain threshold, family variables, and psychologic adjustment. The aim is to provide as much relief as possible with medication and other therapies to help children tolerate the pain and cope as effectively as possible. Nonpharmacologic modalities such as behavioral therapy and relaxation techniques have proved effective in modifying pain perception (see Pain Management, Chapter 30) and activities that aggravate pain. Opioid analgesics typically are avoided in juvenile arthritis; however, for children immobilized with refractory pain, short-term opioid analgesics can be part of a comprehensive plan that uses multiple pain-relief techniques (Connelly and Schanberg, 2006).

Promote General Health. The child's general health must be considered. A well-balanced diet with sufficient calories to maintain growth is essential. If the child is relatively inactive, caloric intake needs to match energy needs to avoid excessive weight gain, which places additional stress on affected joints. Sleep and rest are essential for children with JIA. Some children require rest during

NURSING CARE PLAN

The Child with Arthritis

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALE
Chronic Pain related to joint inflammation **Child's/Family's Defining Characteristics *(Subjective and Objective Data)*** Verbal report of pain Guarding behavior Change in sleep pattern	Child is able to move (joints) and complete activities of daily living with no or minimal discomfort.	Use pain-rating scale to evaluate pain (discomfort) level Administer antiinflammatory medications (nonsteroidal antiinflammatory drugs [NSAIDs]) promptly on report of pain and around the clock when discomfort is acute Administer other drugs such as methotrexate or biologic agents such as etanercept Schedule routine rest periods throughout the day Encourage child to eat a well-balanced diet and exercise daily Help child set up a routine of daily exercise Encourage nonpharmacologic pain-relief remedies such as use of heat pad, moist heat, and pool therapy Encourage child to discuss effect of pain on lifestyle and activities	To provide objective assessment of pain level To manage pain and prevent breakthrough pain To provide relief from inflammation To prevent obesity and promote wellness To prevent further joint stiffness To promote mobility of joints and relieve painful stiff joints To prevent excessive weight gain To provide outlet for emotions such as anger, frustration, depression at having a chronic illness
Impaired Physical Mobility related to pain and swelling in joints **Child's/Family's Defining Characteristics *(Subjective and Objective Data)*** Limited ability to perform fine and gross motor skills Limited range of motion Verbal report of pain Measurable pain on pain scale	Child engages in activities of daily living.	Encourage ambulation and performance of activities of daily living to maximum potential every day Assist with range-of-motion exercises for child who is severely limited Encourage child to be as active as tolerated Help with planning and encourage rest periods during the day Encourage taking pain medication such as NSAIDs before ambulation and activity Use nonpharmacologic pain adjuncts such as heat pad and hydrotherapy Encourage child to be active in self-care activities to maximum potential	To keep joints limber and prevent disuse contractures To promote muscle movement and keep joints limber To promote independence To prevent fatigue To promote activity with minimum pain To decrease pain and encourage mobility of joints To enhance self-worth and independence

the day; however, daytime napping that interferes with nighttime sleepiness should be avoided. A bedtime routine that involves comfort measures can help induce sleep. A firm mattress, electric blanket, or sleeping bag helps provide warmth, comfort, and rest. Nighttime splints needed to maintain range of motion initially might be a source of bedtime conflict. The family needs to be instructed on how to use the splint appropriately; it should not be painful or impede sleep. Behavior modification programs that reward splint and exercise compliance may be helpful in reducing adherence barriers. Well-child care to assess growth, development, and immunization requirements needs to be coordinated between the primary care provider and the rheumatologist. Common childhood illnesses such as upper respiratory tract infections may cause arthritis to worsen; consequently medical attention must be sought quickly for relatively minor illness to prevent arthritis flares. Effective communication among the family, the primary care provider, and the rheumatology team is essential for care coordination.

Children are encouraged to attend school even on days when they have some pain or discomfort. The school nurse's assistance is enlisted so a child is permitted to take the prescribed medication at school and arrange for rest in the nurse's office during the day. Split days or half days may help a child remain involved in school. Permitting the child to come to school late allows time to gain joint movement and reduces the time at school to avoid exhaustion. It is important that the child attend school to learn skills and engage in social interaction, especially if the JIA continues to limit physical skills. Arranging for two sets of textbooks eliminates the need to carry books to and from school, thus reducing discomfort and difficulty walking. A formal school hearing may be necessary to obtain an Individualized Education Program, ensured by public law, which includes intensive school modifications.

Facilitate Adherence. The child and family are involved in the therapeutic plan. They need to know the purpose and correct use of any splints and appliances and the medication regimen. The family is instructed regarding administration of medications and the value of a regular schedule of administration to maintain a satisfactory drug level in the body. They need to know that NSAIDs should not be given on an empty stomach and to be alert for signs of medication toxicity. If evidence of drug toxicity is noted, the family is

instructed to notify the health care provider and follow that person's instructions.

Encourage Heat and Exercise. Heat has been shown to be beneficial to children with arthritis. Moist heat is best for relieving pain and stiffness, and the most efficient and practical method is in the bathtub with warm water. In some cases a daily whirlpool bath, paraffin bath, or hot packs may be used as needed for temporary relief of acute swelling and pain. Hot packs are easily applied using a bath towel wrung out after being immersed in hot water or heated in a microwave oven, applied to the area, and covered with plastic for 20 minutes. Commercial pads that warm in only a few minutes in the microwave are also available. Painful hands or feet can be immersed in a pan of warm water for 10 minutes 2 or 3 times daily in addition to tub baths.

Pool therapy is the easiest method for exercising a large number of joints. Swimming activities strengthen muscles and maintain mobility in larger joints. Very small children who are frightened of the water can carry out their exercises in the bathtub. Small children love to splash, kick, and throw things in the water. Remember that adult supervision is necessary for all water activities.

Activities of daily living provide satisfactory exercise for older children to maintain maximal mobility with minimal pain. These children are encouraged in their efforts to be independent and patiently allowed to dress and groom themselves, assume daily tasks, and care for their belongings. It is often difficult for children to manipulate buttons, comb or brush their hair, and turn faucets; but, unless there is an acute flare, parents and other caregivers should not offer assistance. In addition, children should learn and understand why others do not help them. Many helpful devices such as self-adhering fasteners, tongs for manipulating difficult items, and grab bars installed in bathrooms for safety can be used to facilitate tasks. A raised (higher) toilet seat often makes the difference between dependent and independent toileting because weak quadriceps muscles and sore knees inhibit the ability to raise the body from a low sitting position.

A child's natural affinity for play offers many opportunities for incorporating therapeutic exercises. Throwing or kicking a ball and riding a tricycle (with the seat raised to achieve maximum leg extension) are excellent moving and stretching exercises for a very young child whose daily living activities are physically limited.

An effective approach to beginning the day's activities is to awaken children early to give them their medication and then to allow them to sleep for an hour. On arising children take a hot bath (or shower) and perform a simple ritual of limbering-up exercises, after which they commence the activities of the day such as going to school. Exercise, heat, and rest are spaced throughout the remainder of the day according to the child's individual needs and schedules. Parents are instructed in exercises that meet the child's needs.

The Arthritis Foundation and the American Juvenile Arthritis Alliance* (an organization within the Arthritis Foundation) provide information and services for both parents and professionals, and nurses can refer families to these agencies as an added resource.

Support Child and Family. JIA affects every aspect of life for the child and family. Physical limitations may interfere with self-care, school participation, and recreational activities. The intensive treatment plan, including multiple medications, physical therapy, comfort measures, and medical appointments, is intrusive and disruptive to the parents' work schedule and the family routine. To prevent isolation and foster independence, the family is encouraged to pursue their normal activities. Unfortunately the adaptations necessary to make that occur take resourcefulness and commitment from all family members. At diagnosis and throughout the span of JIA it is essential to recognize signs of stress and counterproductive coping and provide the necessary support to maximize adaptation. The problems and needs of these families are discussed in Chapter 36, and readers are directed to that chapter for guidance in planning care.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic, multisystem, autoimmune disease of the connective tissues and blood vessels characterized by inflammation in potentially any body tissue. Its course and symptoms are variable and unpredictable, with mild to life-threatening complications. In addition to SLE, there are other forms of lupus such as *neonatal lupus,* which occurs when maternal autoantibodies cross the placenta and cause transient lupuslike symptoms in a newborn, with the potential serious complication of heart block. The remaining discussion focuses on SLE.

A recent review of the Indianapolis Pediatric Rheumatology Disease Registry indicates that survival rates in children with SLE have improved significantly; 5-year survival rates were 99.6%, and 10-year survival rates are 98.2% (Hashkes, Wright, Lauer, et al., 2010). SLE is more common in females, with an approximate 5:1 female-to-male ratio before puberty and a 9:1 ratio during reproductive years; it typically occurs between the ages of 10 and 19 years and rarely before the age of 5, however, some cases may be diagnosed in infancy (Ardoin and Schanberg, 2011; Zulian, Pluchinotta, Martini, et al., 2008). There is a familial tendency, although many newly diagnosed patients are unaware of other affected family members. SLE has been reported in all cultures, but within the United States there has been a disproportionately higher incidence in African-American, Asian, and Hispanic children.

The cause of SLE is not known. It appears to result from a complex interaction of genetics with an unidentified trigger that activates the disease. Suspected triggers include exposure to ultraviolet light, estrogen, pregnancy, infections, and drugs. Genetic predisposition to SLE is evidenced in an increased concordance rate in twins (10-fold), increased incidence within family members (10% to 16%), and increased frequency of certain gene alleles in population-based studies.

Clinical Manifestations and Diagnostic Evaluation

The child with SLE may have any clinical manifestation with mild to life-threatening severity (Box 48-12). The diagnosis is established when four of the 11 diagnostic criteria are met (Box 48-13). Kidney involvement heralds progressive disease and the need for rigorous therapeutic management.

Therapeutic Management

The goal of treatment is to ensure the child's health by balancing the medications necessary to avoid exacerbation and complications while preventing or minimizing treatment-associated morbidity. Therapy involves the use of specific medications and general supportive care. The drugs used to control inflammation are corticosteroids administered in doses sufficient to control inflammation and then tapered to the lowest suppressive dose. Other drugs include antimalarial preparations, which are useful for rash and arthritis; NSAIDs, which relieve muscle and joint inflammation; and immunosuppressive agents such as cyclophosphamide for renal and CNS

*PO Box 7669, Atlanta, GA 30357, 800-283-7800, www.arthritis.org. In Canada: The Arthritis Society, 393 University Ave., Suite 1700, Toronto, Ontario, Canada M5G 1E6, 416-979-7228, fax: 416-979-8366, www.arthritis.ca.

BOX 48-12 CLINICAL MANIFESTATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS RELATED TO TISSUES INVOLVED

Constitutional—Fever, fatigue, weight loss, anorexia
Cutaneous—Erythematous butterfly rash over bridge of nose and across cheeks, discoid rash, photosensitivity, mucocutaneous ulceration, alopecia, periungual telangiectasias
Musculoskeletal—Arthritis, arthralgia, myositis, myalgia, tenosynovitis
Neurologic—Headache, seizure, forgetfulness, behavior change, change in school performance, psychosis, chorea, stroke, cranial and peripheral neuropathy, pseudotumor cerebri
Pulmonary and cardiac—Pleuritis, basilar pneumonitis, atelectasis, pericarditis, myocarditis, endocarditis
Renal—Glomerulonephritis, nephrotic syndrome, hypertension
Gastrointestinal—Abdominal pain, nausea, vomiting, blood in stool, abdominal crisis, esophageal dysfunction, colitis
Hepatic, splenic, and nodal—Hepatomegaly, splenomegaly, lymphadenopathy
Hematologic—Anemia, cytopenia
Ophthalmologic—Cotton wool spots, papilledema, retinopathy
Vascular—Raynaud's phenomenon, thrombophlebitis, livedo reticularis

BOX 48-13 CLASSIFICATION CRITERIA FOR SYSTEMIC LUPUS ERYTHEMATOSUS

Four of the following 11 criteria must be met for diagnosis:

1. Malar rash—Fixed malar erythema
2. Discoid rash—Patchy erythematous lesions
3. Photosensitivity—Rash with sun exposure
4. Oral ulcers—Painless ulcers in mouth, nose
5. Arthritis—Swelling, tenderness, or effusion in two or more peripheral joints (nonerosive)
6. Serositis—Pleuritis, pericarditis
7. Renal disorder—Proteinuria, casts
8. Neurologic disorder—Psychosis, seizures
9. Hematologic disorder—Hemolytic anemia, thrombocytopenia, leukopenia, lymphopenia
10. Immunologic disorder—Anti-dsDNA, anti-SM, antiphospholipid antibodies, lupus anticoagulant, false-positive syphilis test (RPR [rapid plasma reagin])
11. Antinuclear antibody

disease. Mycophenolate, azathioprine, and methotrexate are effective immunosuppressive drugs that may be used to control SLE and allow steroids to be reduced. Antihypertensives, aspirin, and antibiotics are just a few of the additional drugs that may be necessary to treat or avoid complications.

General supportive care includes sufficient nutrition, sleep and rest, and exercise. Exposure to the sun and ultraviolet B (UVB) light is limited because of its association with SLE exacerbation.

CARE MANAGEMENT

The principal nursing goal is to help the child and family positively adjust to the disease and therapy. The child and family must learn to recognize subtle signs of disease exacerbation and potential complications of medication therapy and communicate these concerns to their care provider. Consequently patient and family education is an ongoing process initiated at diagnosis and tailored to the patient's individual needs. Referral to a social worker, psychologist, or support group may help the child and family make a successful adjustment. Support groups are associated with the Lupus Foundation of America* and the Arthritis Foundation.†

Key issues include therapy compliance; body-image problems associated with rash, hair loss, and steroid therapy; school attendance; vocational activities; social relationships; sexual activity; and pregnancy. (See Chapter 36 for a discussion on adjusting to a chronic illness.) Specific instructions for avoiding exposure to the sun and UVB light such as using sunscreens, wearing sun-resistant clothing, and altering outdoor activities must be provided with great sensitivity to ensure compliance while minimizing the associated feeling of being different from peers (see Sunburn, Chapter 47). Patients need to be instructed to maintain regular medical supervision and seek attention quickly during illness or before elective surgical procedures such as dental extraction because of potential needs for increased steroids or prophylactic antibiotics. People with SLE should carry medical identification for their disease and steroid dependence.

KEY POINTS

- Immobility has a profound effect on all aspects of growth and development.
- The major physical consequences of immobilization are loss of muscle strength, endurance, and muscle mass; bone demineralization; loss of joint mobility; and contractures.
- Features of children's fractures not observed in the adult include presence of growth plate, thicker and stronger periosteum, bone porosity, more rapid healing, and less joint stiffness.
- The goals of fracture management are to regain alignment and length of bony fragments, retain alignment and length, and restore function to injured parts.
- The method of fracture reduction is determined by the child's age, degree of displacement, amount of overriding, amount of edema, condition of the skin and soft tissues, sensation, and circulation distal to the fracture.
- The primary purposes of traction are to fatigue involved muscles and reduce muscle spasm, position bone ends in desired realignment, and immobilize the fracture site until realignment has been achieved to permit casting or splinting.
- The etiology of DDH appears to be related to intrauterine, genetic, and cultural factors.
- Treatment of clubfoot consists of manipulation and casting to correct the deformity, maintenance of the correction, and prevention of possible recurrence of the deformity.
- Acquired hip deformities are managed with nonweight-bearing devices (Legg-Calvé-Perthes disease) or surgical stabilization (SCFE).

- Observation for idiopathic scoliosis is an important part of an adolescent's routine physical assessment.
- Idiopathic scoliosis is managed by observation, bracing, and exercise or surgical correction.
- Bone infections are managed with vigorous antibiotic therapy, immobilization of the affected part, and (sometimes) surgical drainage.
- Osteosarcoma is a neoplasm of bone-forming tissues; Ewing sarcoma is a neoplasm that arises from bone marrow spaces.
- Rhabdomyosarcoma may occur almost anywhere in the body, but the most common sites are the head and neck.
- Nursing care of the child with juvenile arthritis consists of promoting general health, relieving discomfort, preventing deformity, and preserving function.
- SLE is a chronic autoimmune disorder that affects the collagen tissues of the body.

CHAPTER

49

Neuromuscular or Muscular Dysfunction

David Wilson

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Discuss the nursing role in helping parents care for the child with cerebral palsy.
- Formulate a nursing care plan for the preoperative and postoperative care of a child with myelomeningocele (spina bifida).
- Outline a plan of care for a child with Duchenne or Becker muscular dystrophy.
- Discuss the prevention and treatment of tetanus.
- Identify the causes of botulism in infants and children.
- List three causes of spinal cord injury in children.
- Discuss the emergent nursing care of the child or adolescent with a spinal cord injury.

CONGENITAL NEUROMUSCULAR OR MUSCULAR DISORDERS

Cerebral Palsy

Cerebral palsy (CP) has been defined as a "group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to nonprogressive disturbances that occurred in the developing fetal or infant brain" (Rosenbaum, Paneth, Leviton, et al., 2007). In addition to motor disorders, the condition often involves disturbances of sensation, perception, communication, cognition, and behavior; secondary musculoskeletal problems; and epilepsy (Rosenbaum, Paneth, Leviton, et al., 2007). The etiology, clinical features, and course vary and are characterized by abnormal muscle tone and coordination as the primary disturbances. CP is the most common permanent physical disability of childhood, and the incidence is reported to be between 2.4 and 3.6 per every 1000 live births in the United States (Hirtz, Thurman, Gwinn-Hardy, et al., 2007; Yeargin-Allsopp, Van Naarden Braun, Doernberg, et al., 2008). Prevalence of CP among extremely low-birth-weight infants (less than 28 weeks' gestation) is said to be nearly 100 times the rate in term infants; however, these rates reportedly have declined in recent years (O'Shea, 2008).

CP is currently believed to result more often from existing prenatal brain abnormalities; the exact cause of these abnormalities remains elusive but may include genetic factors, including clotting disorders as well as brain malformations. It has been estimated that as many as 80% of CP cases are attributable to unidentified prenatal factors (Johnston, 2011; Krigger, 2006). Intrauterine exposure to maternal chorioamnionitis is associated with an increased risk for CP in infants of normal birth weight and preterm infants (Hermansen and Hermansen, 2006); however, not all term infants exposed to chorioamnionitis develop CP (Grether, Nelson, Walsh, et al., 2003; Wu, Escobar, Grether, et al., 2003). Perinatal ischemic stroke is also associated with a later diagnosis of CP (Golomb, Saha, Garg, et al., 2007). One study found a higher risk for CP occurring among infants born at 42 weeks' gestation or later than among those born at 37 or 38 weeks' gestation (Moster, Wilcox, Vollset, et al., 2010). Additional factors that may contribute to the development of CP postnatally include bacterial meningitis, multiple births, viral encephalitis, motor vehicle crashes (MVCs), and child abuse (shaken baby syndrome [traumatic brain injury]). A significant percentage (15% to 60%) of children with CP also have epilepsy. In summary, as many as 80% of the total cases of CP may be linked to a perinatal or neonatal brain lesion or brain maldevelopment, regardless of the cause (Krageloh-Mann and Cans, 2009).

Pathophysiology

It is difficult to establish a precise location of neurologic lesions on the basis of etiology or clinical signs because there is no characteristic pathologic picture. In some cases, there are gross malformations

of the brain. In others, there may be evidence of vascular occlusion, atrophy, loss of neurons, and laminar degeneration that produce narrower gyri, wider sulci, and low brain weight. Anoxia appears to play the most significant role in the pathologic state of brain damage, which is often secondary to other causative mechanisms.

There are a few exceptions. In some cases, the manifestations or etiology is related to anatomic areas. For example, CP associated with preterm birth is usually spastic diplegia caused by hypoxic infarction or hemorrhage with periventricular leukomalacia in the area adjacent to the lateral ventricles. The athetoid (extrapyramidal) type of CP is most likely to be associated with birth asphyxia but can also be caused by kernicterus and metabolic genetic disorders such as mitochondrial disorders and glutaricaciduria (Johnston, 2011). Hemiplegic (hemiparetic) CP is often associated with a focal cerebral infarction (stroke) secondary to an intrauterine or perinatal thromboembolism, usually a result of maternal thrombosis or hereditary clotting disorder (Johnston, 2011). Cerebral hypoplasia and sometimes severe neonatal hypoglycemia are related to ataxic CP. Generalized cortical and cerebral atrophy often cause severe quadriparesis with cognitive impairment and microcephaly.

Clinical Classification

A revision of the Winter classification was proposed in 2005 to reflect the child's actual clinical problems and their severity, an assessment of the child's physical and quality-of-life status across time, and long-term support needs (Bax, Goldstein, Rosenbaum, et al., 2005; Nehring, 2010). The proposed new definition has four major dimensions of classification (Bax, Goldstein, Rosenbaum, et al., 2005):

- **Motor abnormalities**—Nature and typology of the motor disorder; functional motor abilities
- **Associated impairments**—Seizures; hearing or vision impairment; attentional, behavioral, communicative, or cognitive deficits; oral motor and speech function
- **Anatomic and radiologic findings**—Anatomic distribution or parts of the body affected by motor impairments or limitations; radiologic findings sometimes including white matter lesions or brain anomaly noted on computed tomography (CT) or magnetic resonance imaging (MRI)
- **Causation and timing**—Identification of a clearly identified cause such as a postnatal event (e.g., meningitis, traumatic brain injury)

Cerebral palsy has four primary types of movement disorders: spastic, dyskinetic, ataxic, and mixed (Nehring, 2010). The most common clinical type, spastic CP, represents an upper motor neuron muscular weakness (Box 49-1). The reflex arc is intact, and the characteristic physical signs are increased stretch reflexes, increased muscle tone, and (often) weakness. Early neurologic manifestations are usually generalized hypotonia or decreased tone that lasts for a few weeks or may extend for months or even as long as 1 year.

Diagnostic Evaluation

Infants at risk according to known etiologic factors associated with CP warrant careful assessment during early infancy to identify the signs of neuromotor dysfunction as soon as possible. The neurologic examination and history are the primary means for diagnosis. Neuroimaging of the child with suspected brain abnormality and CP is now recommended for diagnostic assessment, with MRI preferred to CT scan. Metabolic and genetic testing is recommended if no structural abnormality is identified by neuroimaging; laboratory tests are no longer recommended in the diagnostic process for CP.

BOX 49-1 CLINICAL CLASSIFICATION OF CEREBRAL PALSY

Spastic (Pyramidal)

- Characterized by persistent primitive reflexes, positive Babinski reflex, ankle clonus, exaggerated stretch reflexes, eventual development of contractures
  - Seventy percent to 80% of all cases of CP
  - Diplegia—All extremities affected; lower more than upper (30%-40% of spastic CP)
  - Tetraplegia—All four extremities involved: legs and trunk, mouth, pharynx, and tongue (10%-15% of spastic CP)
  - Triplegia—Three limbs involved
  - Monoplegia—Only one limb involved
  - Hemiplegia—Motor dysfunction on one side of the body; upper extremity more affected than lower (20%-30% of spastic CP)
- Other features:
  - Hypertonicity with poor control of posture, balance, and coordinated motion
  - Impairment of fine and gross motor skills

Dyskinetic (Nonspastic, Extrapyramidal)

- Athetoid—Chorea (involuntary, irregular, jerking movements); characterized by slow, wormlike, writhing movements that usually involve the extremities, trunk, neck, facial muscles, and tongue
- Dystonic—Slow, twisting movements of the trunk or extremities; abnormal posture
- Involvement of the pharyngeal, laryngeal, and oral muscles causing drooling and dysarthria (imperfect speech articulation)

Ataxic (Nonspastic, Extrapyramidal)

- Wide-based gait
- Rapid, repetitive movements performed poorly
- Disintegration of movements of the upper extremities when the child reaches for objects

Mixed Type

- Combination of spastic CP and dyskinetic CP
- May be labeled *mixed* when no specific motor pattern is dominant; however, this term is losing favor to more precise descriptions of motor function and affected area of brain involved (Rosenbaum, Paneth, Leviton, et al., 2007)

Data from Nehring W: Cerebral palsy. In Allen PJ, Vessey JA, Schapiro NA, editors: *Primary care of the child with a chronic condition*, ed 5, St Louis, 2010, Mosby; Jones MW, Morgan E, Shelton JE, et al: Cerebral palsy: introduction and diagnosis, part 1, *J Pediatr Health Care* 21(3):146–152, 2007; and National Institute of Neurologic Disorders and Stroke: *Cerebral palsy: hope through research,* 2006, www.ninds.nih.gov/disorders/cerebral_palsy/detail_cerebral_palsy.htm.
CP, Cerebral palsy.

Early recognition is made more difficult by the lack of reliable neonatal neurologic signs. However, nurses should monitor infants with known etiologic risk factors and evaluate them closely in the first 2 years of life. Because cortical control of movement does not occur until later in infancy, motor impairment associated with voluntary control is usually not apparent until after 2 to 4 months of age at the earliest. More often, the diagnosis cannot be confirmed until the age of 2 years because motor tone abnormalities may be indicative of another neuromuscular illness. In addition, some children who show signs consistent with CP before 2 years do not

demonstrate such signs after 2 years (Nehring, 2010). However, there is no consensus regarding an age cut-off for the onset of symptoms. Clinical manifestations of CP at the time of diagnosis are listed in Box 49-2; early warning signs are listed in Box 49-3, but these are not considered diagnostic.

Establishing a diagnosis may be easier with the persistence of primitive reflexes: (1) either the asymmetric tonic neck reflex or persistent Moro reflex (beyond 4 months of age); and (2) the crossed extensor reflex. The tonic neck reflex normally disappears between 4 and 6 months of age. An obligatory response is considered abnormal. This is elicited by turning the infant's head to one side and holding it there for 20 seconds. When a crying infant is unable to move from the asymmetric posturing of the tonic neck reflex when crying, it is considered obligatory and an abnormal response. The crossed extensor reflex, which normally disappears by 4 months, is elicited by applying a noxious stimulus to the sole of one foot with the knee extended. Normally, the contralateral foot responds with extensor, abduction, and then adduction movements. The possibility of CP is suggested if these reflexes occur after 4 months.

A number of assessment instruments are now available to evaluate muscle spasticity: functional independence in self-care, mobility, and cognition; self-initiated movements over time; and capability and performance of functional activities in self-care, mobility, and social function.

Therapeutic Management

The goals of therapy for children with CP are early recognition and promotion of optimal development to enable affected children to attain normalization and their potential within the limits of their existing health problems. The disorder is permanent, and therapy is primarily preventive and symptomatic.

Therapy has five broad aims:

1. To establish locomotion, communication, and self-help skills
2. To gain optimal appearance and integration of motor functions
3. To correct associated defects as effectively as possible
4. To provide educational opportunities adapted to the child's needs and capabilities
5. To promote socialization experiences with other affected and unaffected children

Each child is evaluated and managed on an individual basis. The scope of the child's needs requires multidisciplinary planning and care coordination among health care professionals and the child's family. The outcome for the child and family with CP is normalization and promotion of self-care activities that empower the child and family to achieve maximum potential.

Ankle-foot orthoses (AFOs, braces) are worn by many children with CP and are used to help prevent or reduce deformity, increase the energy efficiency of gait, and control alignment. Wheeled go-carts that provide sitting balance may serve as early "wheelchair" experience for young children. Manual or powered wheelchairs allow for more independent mobility (Figs. 49-1 and 49-2). Strollers can be equipped with custom seats for dependent mobilization.

Orthopedic surgery may be required between the ages of 5 and 7 years to correct contracture or spastic deformities, to provide stability for an uncontrollable joint, and to provide balanced muscle power. This includes tendon-lengthening procedures, release of spastic muscles, and correction of hip and adductor muscle spasticity or contracture to improve locomotion. Hip dislocation often occurs in children with CP. Spinal fusion may be done for scoliosis. Computerized motion analysis, radiographs, and clinical findings are used to make decisions about orthopedic surgery. *Selective*

BOX 49-2 CLINICAL MANIFESTATIONS OF CEREBRAL PALSY (AT TIME OF DIAGNOSIS)

Delayed Gross Motor Development
- A universal manifestation
- Delay in all motor accomplishments
- Increases as growth advances
- Delays more obvious as growth advances

Abnormal Motor Performance
- Very early preferential unilateral hand preference
- Abnormal and asymmetric crawl
- Standing or walking on toes
- Uncoordinated or involuntary movements
- Poor sucking
- Feeding difficulties
- Persistent tongue thrust

Alterations of Muscle Tone
- Increased or decreased resistance to passive movements
- Opisthotonic posturing (arching of back)
- Feels stiff on handling or dressing
- Difficulty in diapering
- Rigid and unbending at the hip and knee joints when pulled to sitting position (early sign)

Abnormal Postures
- Maintains hips higher than trunk in prone position with legs and arms flexed or drawn under the body
- Scissoring and extension of legs with feet plantar flexed in supine position
- Persistent infantile resting and sleeping position
- Arms abducted at shoulders
- Elbows flexed
- Hands fisted

Reflex Abnormalities
- Persistence of primitive infantile reflexes
- Obligatory tonic neck reflex at any age
- Nonpersistence beyond 6 months of age
- Persistence or hyperactivity of the Moro, plantar, and palmar grasp reflexes
- Hyperreflexia, ankle clonus, and stretch reflexes elicited in many muscle groups on fast, passive movements

Associated Disabilities*
- Altered learning and reasoning
- Seizures
- Impaired behavioral and interpersonal relationships
- Sensory impairment (vision, hearing)

BOX 49-3 EARLY WARNING SIGNS OF CEREBRAL PALSY

- Failure to meet any developmental milestones such as rolling over, raising head, sitting up, crawling
- Persistent primitive reflexes such as Moro, asymmetric tonic neck reflex
- Poor head control (head lag) and clenched fists after 3 months of age
- Stiff or rigid arms or legs; scissoring legs
- Pushing away or arching back; stiff posture
- Floppy or limp body posture, especially while sleeping
- Inability to sit up without support by 8 months
- Using only one side of the body or only the arms to crawl
- Feeding difficulties
  - Persistent gagging or choking when fed
  - After 6 months of age, tongue pushing soft food out of the mouth
- Extreme irritability or crying
- Failure to smile by 3 months
- Lack of interest in surroundings

Data from Pathways Awareness Foundation: *Parents … if you see any of these warning signs … don't delay,* Chicago, 1991, Author; Nehring W: Cerebral palsy. In Allen PJ, Vessey JA, editors: *Primary care of the child with a chronic condition,* St Louis, 2004, Mosby; and Jones MW, Morgan E, Shelton JE, et al: Cerebral palsy: introduction and diagnosis (part 1), *J Pediatr Health Care* 21(3): 146–152, 2007.

dorsal rhizotomy provides marked improvement in some children with CP. The procedure involves selectively cutting dorsal column sensory rootlets that have an abnormal response to electrical stimulation. Achieving the benefits from the surgery requires intensive physical therapy and family commitment. Because the procedure results in flaccid muscles, the child must be retaught to sit, stand, and walk.

Surgical intervention is usually reserved for children who do not respond to the more conservative measures such as bracing, but it is also indicated for children whose spasticity causes progressive deformities. Surgery is used primarily to improve function and enable proper sitting, standing, and walking rather than for cosmetic purposes and is followed by physical therapy.

Intense pain may occur with muscle spasms in patients with CP. Pharmacologic agents given orally (dantrolene sodium, baclofen [Lioresal], and diazepam [Valium]) have had little effectiveness in improving muscle coordination in children with CP; however, they are effective in decreasing overall spasticity. The most common side effects of these agents include hepatotoxicity (dantrolene), drowsiness, fatigue, and muscle weakness; less commonly, diaphoresis and constipation may be seen with baclofen.

Botulinum toxin A (Botox) is also used to reduce spasticity in targeted muscles, primarily those of the upper and lower extremities. Botulinum toxin A is injected into a selected muscle (commonly the quadriceps, gastrocnemius, or medial hamstrings) after a topical anesthetic is applied. The drug acts to inhibit the release of acetylcholine into a specific muscle group, thereby preventing muscle movement. When it is administered early in the course of the condition, affected muscle contractures may be minimized, particularly in lower extremities, thus avoiding surgical procedures with possible adverse effects. The goal is to allow stretching of the muscle as it relaxes and permit ambulation with an AFO. The major reported adverse effects of botulinum toxin A injection are pain at the injection site and temporary weakness (Lukban, Rosales, and Dressler, 2009). Prime candidates for botulinum toxin A injections are children with spasticity confined to the lower extremities; the drug weakens spasticity so the muscles can be stretched and the child may walk with or without orthoses. The onset of action occurs within 24 to 72 hours, with a peak effect observed at 2 weeks and a duration of action of 3 to 6 months. Diazepam has proved effective on a short-term basis in reducing spasticity in children with CP (Delgado, Hirtz, Aisen, et al., 2010).

Children with CP may also experience pain as a result of surgical procedures intended to reduce contracture deformities, position and gastroesophageal reflux, and physical therapy. Therefore pain management is an important aspect of care of children with CP.

The neurosurgical and pharmacologic approach to relieving the spasticity associated with CP involves the implantation of a pump to infuse baclofen directly into the intrathecal space surrounding the spinal cord. Intrathecal baclofen therapy is best suited for children with severe spasticity that interferes with activities of daily living (ADLs) and ambulation; however, this drug and method of administration **(intrathecal)** have had a significant number of adverse or

side effects (Delgado, Hirtz, Aisen, et al., 2010). Patients may be screened before pump placement by the infusion of a "test dose" of intrathecal baclofen delivered via a lumbar puncture, followed by close monitoring for side effects (hypotonia, somnolence, seizures, nausea, vomiting, headache). Relief of spasticity occurs for several hours after the infusion. If a positive effect is noted, the patient is considered a candidate for pump placement. The implantation procedure is done in the operating room by a neurosurgeon. The pump, which is approximately the size of a hockey puck, is placed in the subcutaneous space of the midabdomen. An intrathecal catheter is tunneled from the lumbar area to the abdomen and connected to the pump. The pump is filled with baclofen and programmed to provide a set dose using a telemetry wand and a computer. Benefits of intrathecal baclofen include fewer systemic side effects than oral baclofen, dosage titration for maximizing effects, and reversibility of therapy with removal of the pump if so desired. The patient may remain hospitalized for 3 to 7 days to adjust the dosage and ensure proper healing. Outpatient visits to refill the pump and make dosage adjustments occur about every 3 to 6 months, depending on the patient's response to the treatment. This procedure is most suited for a multidisciplinary setting where rehabilitation specialists are readily available and consistently involved in the patient's ongoing care. Abrupt withdrawal of intrathecal baclofen may result in adverse effects such as rebound spasticity, pruritus, hyperthermia, rhabdomyolysis, disseminated intravascular coagulation, multiorgan failure, and death; in some cases, intrathecal baclofen withdrawal may mimic sepsis.

Oral baclofen has also been widely used in children with CP to treat spasticity; however, side effects are common and include systemic toxicity, drowsiness, and sedation (Delgado, Hirtz, Aisen, et al., 2010).

Antiepileptic drugs (AEDs) such as carbamazepine (Tegretol) and divalproex (valproate sodium and valproic acid; Depakote) are prescribed routinely for children who have seizures. Gabapentin (Neurontin) has been used in adults with spinal cord injury (SCI) to decrease spasticity with success; no studies are available on the effectiveness of the drug in children. The α_2-adrenergic agonists *clonidine* (Catapres) and *tizanidine* (Zanaflex) have been used to decrease spasticity in adults with SCI and multiple sclerosis. The use of oral tizanidine in children has been limited, and only a few small studies have been conducted in children with CP specifically evaluating the reduction of spasticity (Delgado, Hirtz, Aisen, et al., 2010). Oral tizanidine given in conjunction with botulinum type A has been reported to be more effective than oral baclofen and botulinum type A in one study of children with CP (Dai, Wasay, and Awan, 2008). All medications should be monitored for maintenance of therapeutic levels and avoidance of subtherapeutic or toxic levels. Other medications include levodopa to treat dystonia; Artane for treating dystonia and for increasing the use of upper extremities and vocalizations; and reserpine for hyperkinetic movement disorders such as chorea or athetosis (Johnston, 2011).

Dental hygiene is especially important. Regular visits to the dentist and prophylaxis, including brushing, fluoride, and flossing, should be instituted as soon as the teeth erupt. Dental care is especially important for children being given phenytoin, since they often develop gum hyperplasia. Additional problems common among children with CP include constipation caused by neurologic deficits and lack of exercise, poor bladder control and urinary retention, chronic respiratory tract infections, problems with airway clearance, and aspiration pneumonia. These occur as a result of gastroesophageal reflux, abnormal muscle tone, immobility, and altered positioning, and skin problems may occur as a result of altered positioning, poor nutrition, and immobility.

A wide variety of technical aids are available to improve the functioning of children with CP. These include electromechanical toys that employ the concept of biofeedback and operate from a head unit. The toy is manipulated only when the head and trunk are in correct alignment. Eye-hand coordination can also be enhanced by computerized toys and games. Microcomputers combined with voice synthesizers help children with speech difficulties to "speak." These and other devices print messages onto screen monitors and paper.

Many other electronic devices allow independent functioning. Sensors can be activated and deactivated by using a head-stick or tongue or other voluntary muscle movement over which the child has control. Voice-activated computer technology may also allow increased mobility and ambulation with specially designed equipment such as wheelchairs. The application of this technology makes it possible for persons with CP to function eventually in their own residences and can be extended into the workplace.

There is some evidence that *neuromuscular electrical stimulation (NMES)* in addition to dynamic splinting may result in increased muscle strength, range of motion, and function of upper limbs in children with CP. Further studies are needed in children with CP to support the use of botulinum toxin A in conjunction with NMES to decrease muscle spasticity and improve function (Wright, Durham, Ewins, et al., 2012).

Behavior problems may occur and often interfere with the child's development. Attention deficit hyperactivity disorder and other learning problems require professional attention. In addition, children with CP may have vision difficulties such as strabismus, nystagmus, and optic atrophy (Johnston, 2011). Speech-language therapy involves the services of a speech-language pathologist who may also assist with feeding problems.

Physical therapy is one of the most frequently used conservative treatment modalities. It requires the specialized skills of a qualified therapist with an extensive repertoire of exercise methods who can design a program to stimulate each child to achieve his or her functional goals.

An active therapy program involves the family, the physical therapist, and often other members of the health care team, including the nurse. The most common approach uses traditional types of therapeutic exercises that consist of stretching, passive, active, and resistive movements applied to specific muscle groups or joints to maintain or increase range of motion, strength, or endurance.

Prognosis. The prognosis for the child with CP depends largely on the type and severity of the condition. Children with mild to moderate involvement (85%) have the capability of achieving ambulation between the ages of 2 and 7 years (Berker and Yalçin, 2008). If the child does not achieve independent ambulation by this time, chances are poor for ambulation and independence. Approximately 30% to 50% of individuals with CP have significant cognitive impairments, and an even higher percentage have mild cognitive and learning deficits. However, many children with severe spastic tetraplegic CP have normal intelligence. Growth is affected in children with spastic tetraplegia, and many children remain below the 5th percentile for age and gender.

Vocational rehabilitation and higher education are possible for adults with CP. Children with severe CP mobility impairment and feeding problems often succumb to respiratory tract infection in childhood (Liptak, Murphy, and Council on Children with Disabilities, 2011). The few survival rate studies on children and adults with CP show that survival is influenced by existing comorbidities (Nehring, 2010).

Neurorehabilitation involves rehabilitating and stimulating nerves (that control muscle movement) that have been damaged to improve brain development; *brain plasticity* is being examined closely as a possible avenue for reorganizing traditionally damaged neural pathways to function optimally for children with CP. Children with CP or SCI may benefit from therapies such as *constraint-induced movement* therapy wherein a stronger extremity is constrained to force the weaker extremity to function; these treatments have shown improvement in some children with CP (Aisen, Kerkovich, Mast, et al., 2011).

Prevention of CP in many children may become a reality in the near future. Studies indicate that early neuroprotection in term infants with the use of *therapeutic hypothermia* (head cooling or whole-body cooling) within 6 hours of birth improved survival without CP by approximately 40% (Johnston, Fatemi, Wilson, et al., 2011). More recent studies have found lower death rates and less severe disability with the use of therapeutic hypothermia, but overall intelligence quotient (IQ) scores at 6 to 7 years of age were not statistically significant in those receiving hypothermia (as compared with those receiving conventional treatment) (Shankaran, Pappas, McDonald, et al., 2012).

CARE MANAGEMENT

Because children with CP are being identified and treated at an earlier age, parents are participating earlier in treatment programs for their children with disabilities. They are taught the proper handling and home care of young children with CP and need a carefully planned program so that their change of role from parent to caregiver can be melded into the already established relationship. Close work with other multidisciplinary team members is essential. Nurses reinforce the therapeutic plan and assist the family in devising and modifying equipment and activities to continue the therapy program in the home. The nursing process in the care of the child with CP is outlined in the Nursing Care Plan.

NURSING CARE PLAN

The Child with Cerebral Palsy

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
Impaired Physical Mobility related to neuromuscular impairment **Child's or Family's Defining Characteristics** ***(Subjective and Objective Data)*** Postural instability during performance of routine ADLs Limited ability to perform gross motor skills Limited range of motion Limited ability to perform fine motor skills Gait changes Movement-induced tremor Persistence of primitive reflexes	Infant or toddler will demonstrate active muscle movement. Child will have adequate mobility to perform ADLs to maximum potential.	Carry out and teach family to perform stretching exercises on affected muscles Use assistive devices such as wheelchair, AFOs, and wrist splints Administer medications (specify) intended to decrease muscle spasticity Encourage and teach parent(s) to use jaw control during feedings Position child semiupright during feedings Encourage play exercises that involve joint movement and promote fine and gross motor skill acquisition and repetition	To prevent muscle contractures To increase mobility and prevent contractures To minimize pain and decrease muscle spasticity To facilitate eating To decrease chance of aspiration and facilitate mobilization of food and fluids through esophagus To promote joint movement To promote achievement of developmental milestones
Risk for Injury related to mobility limitation, neuromuscular impairment, and perception and cognition impairment **Child's or Family's Defining Characteristics** ***(Subjective and Objective Data)*** Physical factors: Altered mobility Limited ability to chew food and swallow food particles Neuromuscular factors: Limited perception of danger Uncontrollable muscular movements	Child will remain injury free. Home physical environment will be safe.	Educate family regarding child's physical limitations that place him or her at greater risk for injury Instruct family in steps to avoid injury, including padded furniture, lowered bed or side rails as appropriate, gates on stairs, avoidance of throw rugs, thick carpeting Position child in semiupright position after feedings Assess child's ability to manage (chewing and swallowing) oral feedings Use jaw support as needed during feedings Use appropriate mobilization devices and ensure they are safe for child's age Encourage mobilization and play activities that stretch muscles Teach child which ADLs are safe and appropriate to perform without assistance of another person	To prevent accidental injury during mobilization To promote family involvement in injury prevention To prevent aspiration To determine appropriate feeding method and prevent aspiration To prevent choking and possible aspiration To prevent muscle contractures To promote personal safety To promote self-care

NURSING CARE PLAN

The Child with Cerebral Palsy—cont'd

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
Chronic Pain related to involuntary muscle movements (spasticity) and treatments for muscle spasticity **Child's or Family's Defining Characteristics** ***(Subjective and Objective Data)*** Observed evidence of guarded behavior, grimace, crying, restlessness, irritability Atrophy of involved muscle group Altered ability to continue previous ADLs	Child's optimum comfort level will be maintained.	Administer medications to control spasticity (specify)	To prevent muscle spasm pain
		Perform stretching exercises after pain medication has been administered (60 minutes for oral medications)	To manage pain impulses during exercises
		Administer pain medications (specify) such as NSAIDs	To minimize pain
		For treatments such as botulinum toxin A (Botox) injections, assist with administration of appropriate pain medications and monitoring child for pain sensation (specify)	To decrease pain of injection at site
		For postoperative pain, administer pain medications on around-the-clock schedule for 48 to 72 hours; use PCA pump as child's cognitive and motor skills allow	To promote personal physical comfort
		Use objective pain scale to assess pain level	To provide objective measure of pain for intervention
		Encourage child to verbalize effects of pain on ADLs	To provide outlet for frustration related to chronic pain experience
		Use assistive devices such as AFOs or KAFOs	To decrease muscle spasticity and contractures
		Teach parent(s) and child appropriate positions to assume while sitting and recumbent to minimize effects of muscle spasticity	To promote self-care

ADLs, Activities of daily living; *AFO,* ankle-foot orthosis; *KAFO,* knee-ankle-foot orthoses; *NSAID,* nonsteroidal antiinflammatory drug; *PCA,* patient-controlled analgesia.

Because children with CP expend so much energy in their efforts to accomplish ADLs, more frequent rest periods should be arranged to avoid fatigue. The diet should be tailored to the child's activity and metabolic needs. Gastrostomy feedings may be necessary to supplement regular feedings and ensure adequate weight gain, particularly in children at risk for growth failure and chronic malnutrition, those with severe CP and subsequent oral feeding difficulties, and children whose well-being is affected by illness and decreased fluid or medication intake. Oral feedings may be continued to maintain oral motor skills. Weight gain is perceived as an important measure of adequate oral feeding efficiency.

A skin-level gastrostomy is particularly suited for children with CP. Parents may need assistance and advice with medication administration through a gastrostomy tube to prevent clogging. Because jaw control is often compromised, more normal control can be achieved if the feeder provides stability of the oral mechanism from the side or front of the face. When directed from the front, the middle finger of the nonfeeding hand is placed posterior to the body portion of the chin, the thumb is placed below the bottom lip, and the index finger is placed parallel to the child's mandible (Fig. 49-3). Manual jaw control from the side assists with head control, correction of neck and trunk hyperextension, and jaw stabilization. The middle finger of the nonfeeding hand is placed posterior to the bony portion of the chin, the index finger is placed on the chin below the lower lip, and the thumb is placed obliquely across the cheek to provide lateral jaw stability (Fig. 49-4).

FIG 49-3 Manual jaw control provided anteriorly.

Safety precautions are implemented, such as having children wear protective helmets if they are subject to falls or capable of injuring their heads on hard objects. Because children with CP are at risk for altered proprioception and subsequent falls, the home and

FIG 49-4 Manual jaw control provided from the side.

play environment should be adapted to their needs to prevent bodily harm. Appropriate immunizations should be administered to prevent childhood illnesses and protect against respiratory tract infections such as influenza and pneumonia. Dental problems may be more common in children with CP, which creates a need for meticulous attention to all aspects of dental care. Transportation of the child with motor problems and restricted mobility may be especially challenging for the family and child. Attention must be given to the child's safety when riding in a motor vehicle; a federally approved safety restraint should be used at all times. It is recommended that children with CP ride in a rear-facing position as long as possible because of their poor head, neck, and trunk control (Lovette, 2008). Car restraints especially designated for children with poor head and neck control are available and should be used.*

The involvement of physical therapy, speech therapy, and occupational therapy is particularly important in establishment and maintenance of muscle function, development of adequate speech and phonation, and identification of modifications necessary for the child's environment so that ADLs can be performed to the child's satisfaction.

As in all aspects of care, educational requirements are determined by the child's needs and potential. Children with mild to moderate cognitive involvement are generally able to participate in regular classes. Resource rooms are available in most schools to provide more individualized attention. Integration of children with CP into regular classrooms should be the initial goal. For those who are unable to benefit from formal education, a vocational training program may be appropriate. At adolescence, prevocational and vocational counseling and guidance are arranged. At any phase or in any setting, education is geared toward the child's assets.

Recreation and after-school activities should be considered for children who are unable to participate in the regular athletic programs and other peer activities. Some children can compete in athletic and artistic endeavors, and many games and pastimes are suited to their capabilities. Competitive sports are also becoming increasingly available to children with disabilities and offer an added dimension to physical activities. Recreational activities serve to stimulate children's interest and curiosity, help them adjust to their disability, improve their functional abilities, and build self-esteem. Any accomplishment that helps children approach a normal way of life enhances their self-concept.

Support the Family. Probably the nursing interventions most valuable to the family are support and help in coping with the emotional aspects of the disorder, many of which are discussed in relation to the child with a disability (see Chapter 36). Initially, the parents need supportive counseling directed toward understanding the meaning of the diagnosis and all of the feelings that it engenders. Later, they need clarification regarding what they can expect from the child and from health care professionals. Educating families in the principles of family-centered care and parent-professional collaboration is essential. The family may require help in modifying the home environment for care of the child. Home modifications to facilitate the use of a wheelchair may be necessary. The child or adolescent should be encouraged to be as independent as possible; making necessary home modifications to facilitate the child's independence is strongly encouraged. Transportation to the health care practitioner's office and other health care agencies also requires special arrangements. The home health care nurse should be consulted for assistance in making the home environment accessible to the child or adolescent with CP.

Care coordination for the child and family with CP is an important nursing role. The home health care nurse or care manager has an important role in the support and encouragement for families who assume the primary care of a child with CP. Having a child with CP implies numerous challenges of daily management and changes in family life, and the nurse can help with education, assessment, and mobilization of resources.

The nurse needs to support the parents in their frustration, problem solving, concerns, approaches to helping the child, and the positive approaches they use. Parents and other family members may need support and counseling. Siblings of a child with a disability are affected and may respond to the child's presence with overt or less evident behavioral issues. The family needs a relationship with nurses who can provide continued contact, support, and encouragement through the long process of habilitation.

Parents may also find help and comfort from parent groups, with whom they can share challenges and concerns and from whom they can derive comfort and practical information. Parent support groups are most helpful through sharing experiences and accomplishments. For example, parents can learn from others what it is like to have a child with CP, which is generally not possible from professionals (see Family-Centered Care box). The national organization *United Cerebral Palsy** has branches in most communities. The association provides a variety of services for children and families. A number of excellent books also are available to guide parents and nurses who work with children with CP.

Support the Hospitalized Child. Cerebral palsy is not a disorder that requires ongoing hospitalization; therefore, when children with CP are hospitalized, they are usually admitted for illness or corrective surgery. Nursing care of the child with CP is similar to that of any child with a disability, and children with CP should be approached as would any child in the hospital. Speech impairment

is common in children with CP, but this may not correlate with their ability to understand. Therapy programs should be continued, when appropriate, during the time they are hospitalized. Encouraging the parent to room-in and actively participate in the child's care helps promote family-centered care. However, it is also important to remember that hospitalization may be the first time a parent can defer care to a nurse and not be the primary caregiver. Discuss this with the family to find the right level of involvement for them.

Spina Bifida (Myelomeningocele)

Abnormalities that derive from the embryonic neural tube (neural tube defects [NTDs]) constitute the largest group of congenital anomalies that are consistent with multifactorial inheritance. Normally, the spinal cord and cauda equina are encased in a protective sheath of bone and meninges (Fig. 49-5, *A*). Failure of neural tube closure produces defects of varying degrees (Box 49-4). They may involve the entire length of the neural tube or may be restricted to a small area.

In the United States, rates of NTDs have declined from 1.3 per 1000 births in 1970 to 0.3 per 1000 births after the introduction of mandatory food fortification with folic acid in 1998. One concern is that NTD rates have not decreased among Hispanic and non-Hispanic Caucasian mothers since 1999 (Centers for Disease Control and Prevention [CDC], 2009). In 2005, the rates for spina bifida were estimated by the CDC to be 17.96 per 100,000 live births, thus making this one of the most common birth defects in the United States (Matthews, 2009; Wolff, Witkop, Miller, et al., 2009). Increased use of prenatal diagnostic techniques and termination of pregnancies have also affected the overall incidence of NTDs (see also Prevention, p. 1582).

Anencephaly, the most serious NTD, is a congenital malformation in which both cerebral hemispheres are absent. The condition

FAMILY-CENTERED CARE

The Reality of Acceptance of Cerebral Palsy

Acceptance is rarely achieved in the length of time implied in the literature.

In the first place, what is it? To me, it is the end of comparing my son with every other child I see. I focus on *his* gains, not society's expectations.

It is also being able to laugh periodically *at* his "clumsiness." It is "gallows humor" as he achieves adulthood; jokes about CP can be funny now.

The bitterness is gone; I am now happy for people who have children without CP.

I no longer feel sorry for my son, but rather for the people who cannot see him for the great person he is; the CP does *not* come first.

He is now a young man of 25 years and I am learning to accept his independence.

It is a "never-ending story."

–Elaine A. Dunham, RN, Shriners Hospitals for Children
Springfield, MA

BOX 49-4 NEURAL TUBE DEFECTS

Cranioschisis—A skull defect through which various tissues protrude

Exencephaly—Brain totally exposed or extruded through an associated skull defect; fetus usually aborted

Anencephaly—If fetus with exencephaly survives, degeneration of the brain to a spongiform mass with no bony covering; incompatible with life usually beyond a few days or, rarely, weeks

Encephalocele—Herniation of brain and meninges through a defect in the skull producing a fluid-filled sac

Rachischisis or spina bifida—Fissure in the spinal column that leaves the meninges and spinal cord exposed

Meningocele—Hernial protrusion of a saclike cyst of meninges filled with spinal fluid (see Fig. 49-5, *C*)

Myelomeningocele (meningomyelocele)—Hernial protrusion of a saclike cyst containing meninges, spinal fluid, and a portion of the spinal cord with its nerves (see Fig. 49-5, *D*)

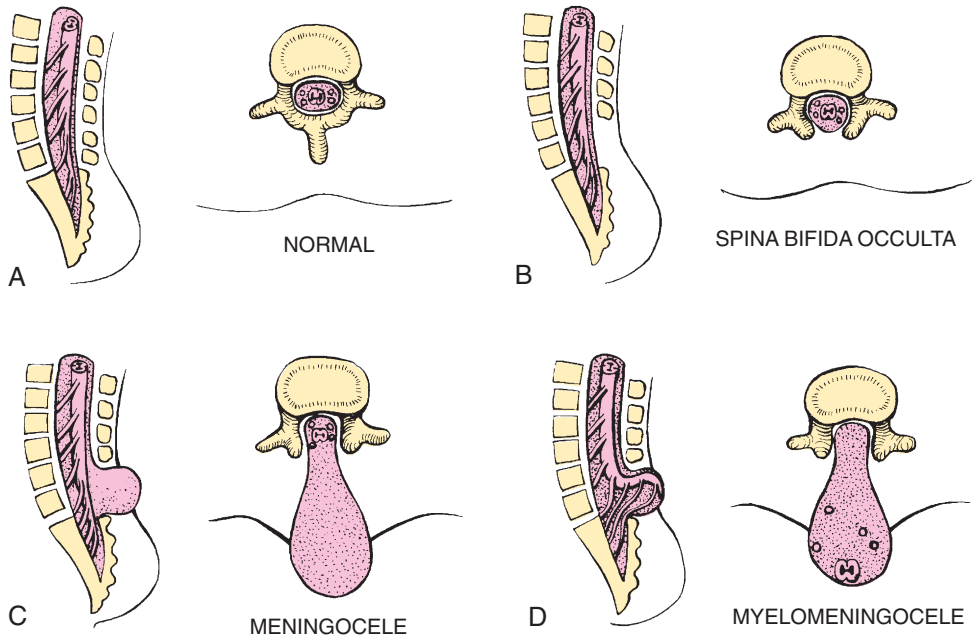

FIG 49-5 **A** through **D,** Midline defects of osseous spine with varying degrees of neural herniations.

is incompatible with life, and many affected infants are stillborn. For those who survive, no specific treatment is available. The infants have a portion of the brainstem and are able to maintain vital functions (e.g., temperature regulation and cardiac and respiratory function) for a few hours to several weeks but eventually die of respiratory failure.

Myelodysplasia refers broadly to any malformation of the spinal canal and cord. Midline defects involving failure of the osseous (bony) spine to close are called spina bifida (SB), the most common defect of the central nervous system (CNS). SB is categorized into two types—SB occulta and SB cystica.

Spina bifida occulta refers to a defect that is not visible externally. It occurs most frequently in the lumbosacral area (L5 and S1) (see Fig. 49-5, *B*). SB occulta may not be apparent unless there are associated cutaneous manifestations or neuromuscular disturbances.

Spina bifida cystica refers to a visible defect with an external saclike protrusion. The two major forms of SB cystica are meningocele, which encases meninges and spinal fluid but no neural elements (see Fig. 49-5, *C*), and myelomeningocele (MMC) (or meningomyelocele), which contains meninges, spinal fluid, and nerves (see Fig. 49-5, *D*). Meningocele is not associated with neurologic deficit, which occurs in varying, often serious, degrees in myelomeningocele. Clinically, the term *spina bifida* is used to refer to myelomeningocele.

Pathophysiology

The pathophysiology of SB is best understood when related to the normal formative stages of the nervous system. At approximately 20 days of gestation, a dedicated depression, the neural groove, appears in the dorsal ectoderm of the embryo. During the fourth week of gestation, the groove deepens rapidly and its elevated margins develop laterally and fuse dorsally to form the neural tube. Neural tube formation begins in the cervical region near the center of the embryo and advances in both directions—caudally and cephalically—until by the end of the fourth week of gestation, the ends of the neural tube, the anterior and posterior neuropores, close.

Most experts believe the primary defect in neural tube malformations is a failure of neural tube closure. However, some evidence indicates that the defects are a result of splitting of the already closed neural tube as a result of an abnormal increase in cerebrospinal fluid (CSF) pressure during the first trimester.

There is evidence of a multifactorial etiology, including drugs, radiation, maternal malnutrition, chemicals, and possibly a genetic mutation in folate pathways in some cases, which may result in abnormal development. There is also evidence of a genetic component in the development of SB; myelomeningocele may occur in association with syndromes such as trisomy 18, PHAVER (limb **p**terygia, congenital **h**eart **a**nomalies, **v**ertebral defects, **e**ar anomalies, and **r**adial defects) syndrome, and Meckel-Gruber syndrome (Shaer, Chescheir, and Schulkin, 2007). Additional factors predisposing children to an increased risk for NTDs include prepregnancy maternal obesity, maternal diabetes mellitus, low maternal vitamin B_{12} status, maternal hyperthermia, and the use of AEDs in pregnancy. The genetic predisposition is supported by evidence of the risk for recurrence after one affected child (3%-4%) and a 10% risk for recurrence with two previously affected children (Kinsman and Johnston, 2011).

The degree of neurologic dysfunction depends on where the sac protrudes through the vertebrae, the anatomic level of the defect, and the amount of nerve tissue involved. The majority of myelomeningoceles (75%) involve the lumbar or lumbosacral area (Fig. 49-6). Hydrocephalus is a frequently associated anomaly in 80% to 90% of the children. About 80% of patients with myelomeningocele develop a type II Chiari malformation (Kinsman and Johnston, 2011). There is some evidence that prolonged exposure of the MMC sac to amniotic fluid predisposes an infant to the development of hindbrain herniation and Chiari II malformation (Adzick, 2013).

Diagnostic Evaluation

The diagnosis of SB is made on the basis of clinical manifestations (Box 49-5) and examination of the meningeal sac (see Fig. 49-6, *A*).

FIG 49-6 A, Myelomeningocele with intact sac. **B,** Myelomeningocele with ruptured sac. (Courtesy Dr. Robert C. Dauser, Neurosurgery, Baylor College of Medicine, Houston, TX.)

Diagnostic measures used to evaluate the brain and spinal cord include MRI, ultrasonography, and CT. A neurologic evaluation will determine the extent of involvement of bowel and bladder function as well as lower extremity neuromuscular involvement. Flaccid paralysis of the lower extremities is a common finding with absent deep tendon reflexes.

Prenatal Detection. It is possible to determine the presence of some major open NTDs prenatally. Ultrasonographic scanning of the uterus and elevated maternal concentrations of α-fetoprotein (AFP, or MS-AFP), a fetal-specific γ_1-globulin, in amniotic fluid may indicate anencephaly or myelomeningocele. The optimum time for performing these diagnostic tests is between 16 and 18 weeks of gestation before AFP concentrations normally diminish and in sufficient time to permit a therapeutic abortion. It is recommended that such diagnostic procedures and genetic counseling be considered for all mothers who have borne an affected child, and testing is offered to all pregnant women (American College of Obstetrics and Gynecology [ACOG], 2007). Chorionic villus sampling is also a method for prenatal diagnosis of NTDs; however, it carries certain risks (skeletal limb depletion) and is not recommended before 10 weeks of gestation (Simpson, Richards, Otaño, et al., 2012).

Therapeutic Management

Management of the child who has a myelomeningocele requires a multidisciplinary team approach involving the specialties of neurology, neurosurgery, pediatrics, urology, orthopedics, rehabilitation, physical therapy, occupational therapy, and social services, as well as intensive nursing care in a variety of specialty areas. The collaborative efforts of these specialists focus on:

- The myelomeningocele and the problems associated with the defect—hydrocephalus, paralysis, orthopedic deformities (e.g., developmental dysplasia of the hip, clubfoot), and genitourinary abnormalities
- Possible acquired problems that may or may not be associated, such as Chiari II malformation, meningitis, seizures, hypoxia, and hemorrhage
- Other abnormalities, such as cardiac or gastrointestinal (GI) malformations

Many hospitals have routine outpatient care by multidisciplinary teams to provide the complex follow-up care needed for children and families with myelodysplasia.

Many authorities believe that early closure, within the first 24 to 72 hours, offers the most favorable outcome. Surgical closure within the first 24 hours is recommended if the sac is leaking CSF (Kinsman and Johnston, 2011).

A variety of neurosurgical and plastic surgical procedures are used for skin closure without disturbing the neural elements or removing any portion of the sac. The objective is satisfactory skin coverage of the lesion and meticulous closure. Wide excision of the large membranous covering may damage functioning neural tissue.

Associated problems are assessed and managed by appropriate surgical and supportive measures. Shunt procedures provide relief from imminent or progressive hydrocephalus (see Chapter 45). When diagnosed, ventriculitis, meningitis, urinary tract infection, and pneumonia are treated with vigorous antibiotic therapy and supportive measures. Surgical intervention for Chiari II malformation is indicated only when the child is symptomatic (i.e., high-pitched crowing cry, stridor, respiratory difficulties, oral-motor difficulties, upper extremity spasticity).

Early surgical closure of the myelomeningocele sac through fetal surgery has been evaluated in relation to prevention of injury to the exposed spinal cord tissue and the improvement of neurologic and urologic outcomes in the affected child. The Management of Myelomeningocele Study, a clinical trial supported by the National Institutes of Health, found that prenatal surgery for myelomeningocele reduced the need for shunting (for hydrocephalus) as evaluated at 12 months and also decreased the incidence of hindbrain herniation. In addition, there was an improvement in mental and motor function scores at 30 months in the children who had prenatal surgery (compared with children who had postnatal surgery) (Adzick, Thom, Spong, et al., 2011). However, the surgery is not without risks to the fetus and mother, and premature delivery is common. Outcome data for urologic and bowel function, motor function, cognition, and spina bifida–associated outcomes are being gathered in the MOMS2 study, which is expected to end in late 2013 (Clinical Trials, 2013).

Postnatal Care. Initial care of the newborn involves preventing infection; performing a neurologic assessment, including observing for associated anomalies; and dealing with the impact of the anomaly on the family. Although meningoceles are repaired early, especially if there is danger of rupture of the sac, the philosophy regarding skin closure of myelomeningocele varies. Most authorities believe that early closure, within the first 24 to 72 hours, offers the most favorable outcome. Early closure, preferably in the first 12 to 18 hours, not only prevents local infection and trauma to the exposed tissues but also avoids stretching of other nerve roots (which may occur as the meningeal sac expands during the first hours after birth), thus preventing further motor impairment. Broad-spectrum antibiotics are initiated, and neurotoxic substances such as povidone-iodine are avoided at the malformation.

Associated problems are assessed and managed by appropriate surgical and supportive measures. Shunt procedures provide relief from imminent or progressive hydrocephalus (see Chapter 45). Improved surgical techniques do not alter the major physical disability and deformity or chronic urinary tract and pulmonary

BOX 49-5 CLINICAL MANIFESTATIONS OF SPINA BIFIDA

Spina Bifida Cystica

- Sensory disturbances usually parallel to motor dysfunction:
  - Below second lumbar vertebra—Flaccid, partial paralysis of lower extremities, varying degrees of sensory deficit, overflow incontinence with constant dribbling of urine, lack of bowel control, rectal prolapse (sometimes)
  - Below third sacral vertebra—No motor impairment, may have saddle anesthesia with bladder and anal sphincter paralysis
- Associated deformities (sometimes produced in utero):
  - Talipes valgus or varus contractures
  - Kyphosis
  - Lumbosacral scoliosis
  - Hip dislocation or subluxation

Spina Bifida Occulta

- Frequently no observable manifestations
- May be associated with one or more cutaneous manifestations:
  - Skin depression or dimple
  - Port-wine angiomatous nevi
  - Dark tufts of hair
  - Soft, subcutaneous lipomas
- May have neuromuscular disturbances:
  - Progressive disturbance of gait with foot weakness
  - Bowel and bladder sphincter disturbances

infections that affect the quality of life for these children. Superimposed on these physical problems are the disorder's effects on family life and finances and on school and hospital services.

Musculoskeletal Considerations. According to most orthopedists, musculoskeletal problems that will affect later locomotion should be evaluated early, and treatment, when indicated, should be instituted without delay. Neurologic assessment will determine the neurosegmental level of the lesion and enable recognition of spasticity and progressive paralysis, potential for deformity, and functional expectations. Orthopedic management includes prevention of joint contractures, correction of the existing deformity, prevention or minimization of the effects of motor and sensory deficits, prevention of skin breakdown, and acquisition of the best possible function of affected lower extremities. Common orthopedic problems requiring attention in SB include deformities of the knees, hips, feet, and spine; fractures and insensate skin further complicate orthopedic care. Other problems that may occur later include kyphosis and scoliosis (Lazzaretti and Pearson, 2010). Because children with this condition often have decreased sensitivity in their lower extremities, preventive skin care is important. A high percentage (60%) of children seen in a wound clinic for skin breakdown had myelomeningocele. The status of the neurologic deficit remains the most important factor in determining the child's ultimate functional abilities.

With technologic advances, a variety of lightweight orthoses, including braces, special "walking" devices, and custom-built wheelchairs, are available to provide mobility to children with spinal cord lesions (see also Chapter 36). Early in infancy, intervention with passive range-of-motion exercises, positioning, and stretching exercises may help decrease the incidence of muscle contractures. Corrective surgical procedures, when indicated, are best initiated at an early age so the child will not lag significantly behind age mates in developmental progress. When there is little hope for lower extremity functioning, surgery is seldom recommended unless it will improve sitting position in a wheelchair and function for ADLs and mobility.

Management of Genitourinary Function. Myelomeningocele is one of the most common causes of **neuropathic (neurogenic) bladder dysfunction** among children. In infants, the goal of treatment is to preserve renal function. In older children, the goal is to preserve renal function and achieve optimal urinary continence. Urinary incontinence is a chronic, often debilitating problem for the child. In addition, the neuropathic bladder may produce urinary system distress, characterized by symptomatic urinary tract infections, ureterohydronephrosis, and vesicoureteral reflux or renal insufficiency. The characteristics of bladder dysfunction in children vary according to the level of the neurologic lesion and the influence of bony growth and development on the spine. Therefore ongoing urologic monitoring is essential. Evidence is growing that early intervention, based on evaluation during the neonatal period and before complications occur, serves to improve bladder function, reduces the risk for subsequent urinary system distress, and decreases the need for reconstructive surgery of the lower urinary tract (Snodgrass and Gargollo, 2010; Tarcan, Onol, Ilker, et al., 2006).

Treatment of renal problems includes:

- Regular urologic care with prompt and vigorous treatment of infections
- A method of regular emptying of the bladder, such as **clean intermittent catheterization (CIC)** taught to and performed by parents and self-catheterization taught to children
- Medications to improve bladder storage and continence, such as oxybutynin chloride (Ditropan) and tolterodine (Detrol)
- Surgical procedures such as *vesicostomy* (bladder surgically brought out to the abdominal wall, allowing continuous urinary drainage) and *augmentation enterocystoplasty* (using a segment of bowel or stomach to increase bladder capacity, thereby reducing high bladder pressures)

However, despite the combined efforts of CIC, medication, and surgical intervention, some children with myelodysplasia may continue to experience debilitating urinary incontinence. Many of these children are able to attain social continence with a continent urinary diversion commonly referred to as a *Mitrofanoff procedure.* In this procedure, a catheterizable channel is surgically created from appendix, ureter, or tapered bowel. The proximal end of the channel is connected to the bladder with the distal end brought out as a small stoma on the abdominal wall, usually near the umbilicus. The bladder neck may be sutured to prevent urinary leakage from the urethra. CIC through the easily accessible abdominal route fosters greater independence in children, especially in those unable to transfer from wheelchair to toilet to perform CIC.

Bowel Control. Some degree of fecal continence can be achieved in most children with myelomeningocele with diet modification, regular toilet habits, and prevention of constipation and impaction. It is frequently a lengthy process. Dietary fiber supplements (recommended age of child in years + 5 = g/day of fiber), laxatives, suppositories, or enemas aid in producing regular evacuation. Older children and adolescents seeking more independence may attain bowel continence and higher quality of life after undergoing an *antegrade continence enema (ACE)* procedure (Doolin, 2006). In a procedure similar to the Mitrofanoff, the appendix or ileum is used to create a catheterizable channel with attachment of the proximal end to the colon. The distal end of the channel exits through a small abdominal stoma. Every 1 or 2 days, a catheter is passed through the stoma, allowing enema solution to be instilled directly into the colon. After administration of the enema solution, the child sits on the toilet for 30 to 60 minutes as stool is flushed out through the rectum. The frequency of enemas and volume of solution used to completely evacuate the bowel vary among individuals.

Prognosis. The early prognosis for the child with myelomeningocele depends on the neurologic deficit present at birth, including motor ability, bladder innervation, and associated neurologic anomalies. Early surgical repair of the spinal defect, antibiotic therapy to reduce the incidence of meningitis and ventriculitis, prevention of urinary system dysfunction, and early detection and correction of hydrocephalus have significantly increased the survival rate and quality of life in such children. Children with spina bifida have normal intelligence. Many children with SB achieve partial independent living and gainful employment. Reports of survival rates vary, and many include adults who were born before medical advances and surgical techniques seen in the past 25 years. Coordinated care for adults with SB is essential; however, multidisciplinary adult care is often inadequate (Lazzaretti and Pearson, 2010). In children and adolescents with SB, the achievement of urinary continence is associated with improved self-concept and esteem, especially among girls (Moore, Kogan, and Parekh, 2004). This chronic condition has an array of associated complications, including hydrocephalus and shunt malfunctions, Chiari II development, scoliosis, bowel and bladder management issues, latex allergy, and epilepsy. However, based on current medical knowledge and ethical considerations, aggressive, early management is favored for the child with myelomeningocele.

Prevention. The Centers for Disease Control and Prevention (CDC) (2009) continues to affirm that 50% to 70% of NTDs can be prevented by daily consumption of 0.4 mg of folic acid by women

of childbearing age. The data indicate that serum folate concentrations among women of childbearing age decreased 16% from 2003 to 2004 in all ethnic groups studied. Lowest serum folate levels were seen in non-Hispanic Caucasians in 2003 to 2004; however, overall serum folate levels remained below recommended levels in non-Hispanic African-Americans during all three periods studied (CDC, 2007). These results indicate that nurses and other health care workers have an important task in disseminating information that may decrease the incidence of birth defects in children by promoting maternal consumption of folic acid.*

To ensure adequate daily intake of the recommended amount of folic acid, women must take a folic acid supplement, eat a fortified breakfast cereal containing 100% of the recommended dietary allowance of folic acid (e.g., Kellogg's Product 19, General Mills Total, Multigrain Cheerios Plus), or increase their consumption of fortified foods (cereal, bread, rice, grits, pasta) and foods naturally rich in folate (green leafy vegetables and citrus fruits). For women who have had a previous pregnancy affected by NTDs, folic acid intake is increased to 4 mg/day under the supervision of a health care practitioner beginning 1 month before a planned pregnancy and continuing through the first trimester. Supplementation of 4 mg of folate should not be given solely in multivitamin preparations because of the risk for overdose of other vitamins. Drugs that affect folic acid metabolism and increase the risk for myelomeningocele should be avoided before pregnancy (if plans are to become pregnant in the near future) and during pregnancy; these include trimethoprim and the AEDs *carbamazepine, phenytoin, phenobarbital, valproic acid,* and *primidone* (Kinsman and Johnston, 2011).

CARE MANAGEMENT

At birth, an examination is performed to assess the intactness of the membranous cyst. During transport to the nursery, every effort is made to prevent trauma to this protective covering. In addition to the routine assessment of the newborn (see Chapter 23), the infant is assessed for the level of neurologic involvement. Movement of extremities or skin response, especially an anal reflex that might provide clues to the degree of motor or sensory impairment, is noted. It is important to observe the infant's behavior in conjunction with the stimulus because limb movements can be induced in response to spinal cord reflex activity that has no connection with the higher centers. Observation of urinary output, especially if a diaper remains dry, may reveal urinary retention. Abdominal assessment revealing bladder distention, even with a wet diaper, may indicate urinary overflow in a retentive bladder. The head circumference is measured daily (see Chapter 23), and the fontanels are examined for signs of tension or bulging.

! NURSING ALERT

Avoid measuring rectal temperatures in infants with SB. Because bowel sphincter function is frequently affected, the thermometer can cause irritation and rectal prolapse.

*Information is available from CDC, National Center on Birth Defects and Developmental Disabilities, Division of Birth Defects and Developmental Disabilities, 1600 Clifton Road NE, MS E-86, Atlanta, GA 30333; 800-CDC-INFO; e-mail: cdcinfo@cdc.gov; www.cdc.gov/ncbddd/folicacid; and from the March of Dimes Resource Center, 1275 Mamaroneck Ave., White Plains, NY 10605; www.marchofdimes.com.

Care of the Myelomeningocele Sac. The infant is usually placed in an incubator or warmer so temperature can be maintained without clothing or covers that might irritate the spinal lesion. Before surgical closure, the myelomeningocele is prevented from drying by the application of a sterile, moist, nonadherent dressing over the defect. The moistening solution is usually sterile normal saline. When an overhead warmer is used, the dressings over the defect require more frequent moistening because of the drying effect of the radiant heat.

Dressings are changed frequently (every 2-4 hours), and the sac is closely inspected for leaks, abrasions, irritation, and any signs of infection. The sac must be carefully cleansed if it becomes soiled or contaminated. Sometimes the sac ruptures during delivery or transport, and any opening in the sac greatly increases the risk for infection to the CNS.

! NURSING ALERT

Observe for early signs of infection, such as temperature instability (axillary), irritability, and lethargy, and for signs of increased intracranial pressure, which might indicate developing hydrocephalus.

One of the most important and challenging aspects in the early care of the infant with myelomeningocele is positioning. Before surgery, the infant is kept in the prone position to minimize tension on the sac and the risk for trauma. The prone position allows for optimal positioning of the legs, especially in cases of associated hip dysplasia. The infant is placed prone with the hips slightly flexed and supported to reduce tension on the defect. The legs are maintained in abduction with a pad between the knees to counteract hip subluxation, and a small roll is placed under the ankles to maintain a neutral foot position. A variety of aids, including diaper rolls, small foam pads, or specially designed frames and appliances, can be used to maintain the desired position.

Prevent Complications. The prone position affects other aspects of the infant's care. For example, in this position, the infant is more difficult to keep clean, pressure areas are a constant threat, and feeding becomes a problem. The infant's head is turned to one side for feeding. Fortunately, most defects are repaired early, and the infant can be held for feeding soon after surgery. Special care must be taken to avoid pressure on the operative site.

Diapering the infant may be contraindicated until the defect has been repaired and healing is well advanced or epithelialization has taken place. The padding beneath the diaper area is changed as needed to keep the skin dry and free of irritation. When urinary retention is detected, CIC is used. Because the bowel sphincter is frequently affected, there is continual passage of stool, often misinterpreted as diarrhea, which is a constant irritant to the skin and a potential source of infection to the spinal lesion.

Areas of sensory and motor impairment are subject to skin breakdown and therefore require meticulous care. Placing the infant on a special mattress or mattress overlay reduces pressure on the knees and ankles. Periodic cleansing, application of lotion, and gentle massage aid circulation.

Gentle range-of-motion exercises are carried out to prevent contractures, and stretching of contractures is performed when indicated. However, these exercises may be restricted to the foot, ankle, and knee joints. When the hip joints are unstable, stretching against tight hip flexors or adductor muscles, which act much like bowstrings, may aggravate a tendency toward subluxation. Consultation with a physical therapist is an important aspect of the short- and long-term management of infants with myelomeningocele.

Cuddling infants with unrepaired myelomeningocele may be contraindicated depending on the status of the lesion. Their need for tactile stimulation is met by caressing, stroking, and other comfort measures. Individualized developmental care with age-appropriate stimulation is provided (see Developmental Outcome, Chapter 25).

Provide Postoperative Care. Postoperative care of the infant with myelomeningocele involves the same basic care as that of any postsurgical infant and includes monitoring vital signs, monitoring intake and output, providing nourishment, observing for signs of infection, and managing pain as needed. Care of the operative site is carried out under the direction of the surgeon and includes close observation for signs of leakage of CSF. General care is continued as preoperatively.

The prone position is maintained after surgical closure, although many neurosurgeons allow a side-lying or partial side-lying position unless it aggravates a coexisting hip dysplasia or permits undesirable hip flexion. This offers an opportunity for position changes, which reduces the risk for pressure sores and facilitates feeding. If permitted, the infant can be held upright against the body, with care taken to avoid pressure on the operative site. After the effects of anesthesia have subsided and the infant is alert, feedings may be resumed unless there are other anomalies or associated complications.

Support Family and Educate About Home Care. As soon as the parents are able to cope with the infant's condition, they are encouraged to become involved in care. They need to learn how to continue at home the care that has been initiated in the hospital, including positioning, feeding, skin care, and range-of-motion exercises when appropriate. They are taught CIC technique when it is prescribed. Parents also need to know the signs of complications (urinary, neurologic, orthopedic) and how to obtain assistance when needed.

The mother who wishes to breastfeed the infant is encouraged to do so because this will be beneficial. Shortly after birth, the mother is started on a program of pumping to initiate and maintain milk supply until the infant is stable enough to begin breastfeeding (Hurtekant and Spatz, 2007). This process may require considerable support from nurses, physicians, and family members because of separation from the infant for surgical care and recovery.

The long-range planning with and support of the parents and newborn begins in the hospital and continues throughout childhood and even into young adulthood. The life expectancy of children with SB extends well into adulthood; therefore planning should involve long-term goals and plans for optimum function as an adult. Discussion about aspects of adulthood such as receiving educational or vocational training and education, living independently, having a mate, having sexual relationships, and bearing and rearing children is important and should not be overlooked. The unique service needs of adolescents with SB as they attempt to gain independence from family and establish lives of their own have not been adequately addressed in the literature (Sawyer and Macnee, 2010). Betz, Linroth, Butler, et al. (2010) interviewed young people with SB making the transition to adulthood. Some common themes that emerged among these young people were (1) challenges in preparation for self-management, (2) limited social relationships, (3) awareness of their cognitive challenges, and (4) the cost of independence. Nurses assume an important role as central members of the health care team. As a health care manager and coordinator, nurses review information with the family, take responsibility for family teaching, and act as a liaison between inpatient and outpatient services. The child may need numerous hospitalizations over the years, and each one will be a source of stress to which the younger child is especially vulnerable (see Chapter 36 for a discussion of care of the child with a disability).

BOX 49-6 MEDICAL CONDITIONS ASSOCIATED WITH RISK FOR LATEX ALLERGY

- Spina bifida
- Urogenital anomalies
- Imperforate anus
- Tracheoesophageal fistula
- VATER association (**v**ertebral defects, imperforate **a**nus, **t**racheo**e**sophageal fistula, and **r**adial and **r**enal dysplasia)
- Preterm infants
- Ventriculoperitoneal shunt
- Cognitive impairment
- Cerebral palsy
- Tetraplegia
- Multiple surgeries
- Atopy

Habilitation involves not only solving problems of self-help and locomotion but also solving the most distressing challenge of urinary or bowel incontinence, which threatens the child's social acceptability. Assistance in preparing the child and the school regarding the child's special needs helps provide a better initial adjustment to this broader social experience.

A Life Course Model has been developed for patients, families, caregivers, teachers, and clinicians to facilitate, through a developmental approach, the care of the child and young person with SB; this program has been made into a web-based tool that can be used to assist in the transition to adulthood (Dicianno, Fairman, Juengst, et al., 2010). Additional information regarding this program is available through the Spina Bifida Association's website at www.sbpreparations.org.

The Spina Bifida Association of America* is organized to provide services and support for families of children with spinal lesions.

Latex Allergy

Latex allergy, or **latex hypersensitivity,** was identified as being a serious health hazard when a report linked intraoperative anaphylaxis with latex in children with SB. Latex, a natural product derived from the rubber tree, is used in combination with other chemicals to give elasticity, strength, and durability to many products. Children with SB are at high risk for developing latex allergy because of repeated exposure to latex products during surgery and procedures. Therefore such children should not be exposed to latex products from birth onward to minimize the occurrence of latex hypersensitivity. Allergic reactions range from urticaria, wheezing, watery eyes, and rashes to anaphylactic shock. More severe reactions tend to occur when latex comes in contact with mucous membranes, wet skin, the bloodstream, or an airway. There also can be cross-reactions to a number of foods (e.g., banana, avocado, kiwi, chestnut).

Allergic reactions to latex protein can also occur when the substance is transferred to food by food handlers wearing latex gloves, prompting several states to pass legislation that prohibits the use of latex gloves in food service. In addition to patients with SB, high-risk populations include patients with urogenital anomalies or multiple surgeries as well as health care workers. See Box 49-6 for medical conditions associated with the risk for latex allergy.

The most important goals are prevention of latex sensitivity and identification of children with a known hypersensitivity (see Guidelines box). High risk and latex-allergic individuals must be managed in a **latex-free environment.** Take care that they do not come in

*4590 McArthur Blvd., NW, Suite 250, Washington, DC 20007-4226; 202-944-3285, 800-621-3141; fax: 202-944-3295; www.sbaa.org.

GUIDELINES

Identifying Latex Allergy

- Does your child have any symptoms, such as sneezing, coughing, rashes, or wheezing, when handling rubber products (e.g., balloons, tennis or Koosh balls, adhesive bandage strips) or when in contact with rubber hospital products (e.g., gloves, catheters)?
- Has your child ever had an allergic reaction during surgery?
- Does your child have a history of rashes, asthma, or allergic reactions to medication or foods, especially milk, kiwi, bananas, or chestnuts?
- How would you identify or recognize an allergic reaction in your child?
- What would you do if an allergic reaction occurred?
- Has anyone ever discussed latex or rubber allergy or sensitivity with you?
- Has your child had any allergy testing?
- When did your child last come in contact with any type of rubber product? Were you present?

direct or secondary contact with products or equipment containing latex at *any time* during medical treatment. Allergy testing can identify latex sensitivity with varying success. Skin prick testing and provocation testing carry the risk for allergic reaction or anaphylaxis. Several commercially available assays can be useful in confirming latex sensitivity. To date, none of these tests demonstrates complete diagnostic reliability, and they should not be the sole determinant of the presence or absence of an allergic response to latex.

Because children who have SB are prone to develop sensitivity to latex, reducing exposure from birth on may decrease the chance of allergy development. Nonlatex products lists are available to parents and health care workers; these products may be substituted for those containing latex. In the health care arena, it is important to use products with the lowest potential risk for sensitizing patients and staff members.*

The identification of those sensitive to latex is best accomplished through careful screening of all patients. During the health interview with the parent or child, ask *all* patients, not only those at risk, about sensitivity to latex. Be certain this is a routine part of all preoperative and preprocedural histories. Stress the importance of the allergy history to all personnel (e.g., phlebotomists, respiratory therapists). (See Guidelines box for questions related to latex allergy.) Children with latex hypersensitivity should carry some form of allergy identification, such as a MedicAlert bracelet. Education programs regarding latex hypersensitivity are aimed at those who care for high risk groups, such as children with SB, and may include relatives, school nurses, teachers, child care workers, and babysitters. In addition to educating caregivers about the child's exposure to medical products that contain latex, nurses need to inform them of common nonmedical latex objects such as water toys, pacifiers, and plastic storage bags.† Items brought to the hospital, such as floral bouquets, should also be screened for latex toys and balloons. Parents should also receive literature explaining signs and symptoms of latex hypersensitivity and appropriate emergency treatment. (See Anaphylaxis, Chapter 42.)

*For a list of latex products and alternative products, see the SBAA National Resource Center and the Latex List on the Spina Bifida Association's home page, www.spinabifidaassociation.org.

†Latex-free product lists are available from the American Latex Allergy Association's online resource manual, available at www.latexallergyresources.org/ResourceManual/section1/index.cfm. Spinal Muscular Atrophy Type 1 (Werdnig-Hoffmann Disease)

Spinal muscular atrophy (SMA) type 1 (Werdnig-Hoffmann disease) is a disorder characterized by progressive weakness and wasting of skeletal muscles caused by degeneration of anterior horn cells. It is inherited as an autosomal recessive trait and is the most common paralytic form of the *floppy infant syndrome* (congenital hypotonia). The sites of the pathologic condition are the anterior horn cells of the spinal cord and the motor nuclei of the brainstem, but the primary effect is atrophy of skeletal muscles. The age of onset is variable, but the earlier the onset, the more disseminated and severe the motor weakness. The disorder may be manifested early—often at birth—and almost always before 2 years of age; death may occur as a result of respiratory failure by age 2 years (Iannaccone and Burghes, 2002; Lunn and Wang, 2008). The manifestations (Box 49-7) and prognosis are categorized according to the age of onset, severity of weakness, and clinical course; some children may fluctuate between exhibiting symptoms of types 1 and 2 or types 2 and 3 in regard to clinical function (Sarnat, 2011c). Some experts also categorize SMA according to the highest level of motor function (Lunn and Wang, 2008); type 1 includes "nonsitters," type 2 includes "sitters," and type 3 includes "walkers" (Iannaccone, 2007). A severe rare fetal form of SMA, classified as *type 0,* is reported to be quite lethal in the perinatal period; motor neuron degeneration may be noted as early as midgestation in type 0 (Sarnat, 2011c). Type 4 may present between 20 and 30 years of age and may be referred to as *proximal adult type SMA* (Prior, 2010).

Diagnostic Evaluation and Therapeutic Management

The diagnosis is based on the molecular genetic marker for the *SMN* (survival motor neuron) gene, which is located on chromosome *5q13.* Prenatal diagnosis may be made by genetic analysis of circulating fetal cells in maternal blood or circulating fetal cells in amniotic fluid. The risk for subsequent affected offspring in carriers of the mutant gene or in families with known cases of SMA may also be evaluated genetically. Further diagnostic studies include muscle electromyography (EMG), which demonstrates a denervation pattern, and muscle biopsy; however, the genetic analysis has become the gold standard for diagnosis of the condition.

There is no cure for the disease, and treatment is symptomatic and preventive, primarily preventing joint contractures and treating orthopedic problems, the most serious of which is scoliosis. Hip subluxation and dislocation may also occur. Many children benefit from powered wheelchairs, lifts, special pressure-adjustable mattresses, and accessible environmental controls. Muscle and joint contractures require careful attention and care to prevent further complications. Nutritional growth failure may occur in infants and toddlers as a result of poor feeding; supplemental gastrostomy feedings may be required to maintain adequate nutritional status and maintain weight gain. The use of lower extremity orthoses may assist with ambulation, but eventually, the child may be confined to a wheelchair as muscle atrophy progresses. Restrictive lung disease is the most serious complication of SMA (Iannaccone, 2007). Upper respiratory tract infections often occur and are treated with antibiotic therapy; they are the cause of death in many children. Rapid eye movement (REM)–related sleep-disordered breathing is common in children with SMA type 1; this progresses to sleep-disordered breathing during REM and non-REM sleep followed by respiratory failure, which often requires nocturnal

BOX 49-7 CLINICAL MANIFESTATIONS OF SPINAL MUSCULAR ATROPHY

Type 1 (Werdnig-Hoffmann Disease)

- Disease acquired in utero or during first 2 months of life
- Hypotonia and inactivity most prominent features
- Infant lying in the frog position with legs externally rotated, abducted, and flexed at knees
- Weakness
- Absent deep tendon reflexes
- Limited movements of shoulder and arm muscles
- Active movement usually limited to fingers and toes
- Diaphragmatic breathing with intercostal retractions (diaphragmatic paralysis may occur)
- Abnormal tongue movements
- Weak cry and cough (may be absent)
- Secretions tending to pool in oropharynx
- Alert facies
- Normal sensation and intellect
- Tiring quickly during feedings (if breastfed, may lose weight before noticeable)
- Affected infants failing to progress to sitting alone, rolling over, or walking
- Early death (usually by 2 years of age) from respiratory failure or infection

Type 2 (Intermediate Spinal Muscular Atrophy)

- Symptoms manifest between 2 and 12 months of age:
  - **Early**—Weakness confined to arms and legs
  - **Later**—Weakness becomes generalized
- Legs usually involved to greater extent than arms
- Prominent pectus excavatum
- Movements absent during complete relaxation or sleep
- Some infants able to sit if placed in position
- Failure to walk is common
- Life span varies from 7 months to 7 years or even longer in some cases

Type 3 (Kugelberg-Welander Disease)

- Onset of symptoms in late childhood or adolescence (may be initially misdiagnosed as muscular dystrophy [limb-girdle])
- Normal head control and ability to sit unassisted by 6 to 8 months of age
- Thigh and hip muscles weak
- In those who manage to walk:
  - Lumbar lordosis
  - Waddling gait
  - Genu recurvatum
  - Protuberant abdomen
  - Ambulation increasingly difficult
  - Age of onset influences ambulatory difficulty—the later (after 2 years) the onset, the better the prognosis
  - Confined to a wheelchair by second decade (may vary)
- Deep tendon reflexes may be present early but disappear
- Scoliosis common

NOTE: These classifications are general, and experts suggest there may be variations in life span and other characteristics (Iannaccone and Burghes, 2002; Russman, 1996; Russman, Iannaccone, Buncher, et al., 1992).

noninvasive mechanical ventilation (Schroth, 2009). **Noninvasive ventilation** methods such as bilevel positive airway pressure (BiPAP) have decreased the morbidity and increased the survival rate of children with SMA types 1 and 2. Children with SMA type 1 who undergo tracheotomy and invasive ventilation often remain ventilator dependent for the rest of their lives; some families choose to withdraw support when invasive ventilation becomes necessary (Mercuri, Bertini, and Iannaccone, 2012). *Palliative care* is an important aspect of care for families of children with SMA type 1. A decreased ability to cough and clear secretions may be managed with **airway clearance therapies** such as the cough-assist machine and manual cough assistance. Guidelines for the standardization of respiratory care for patients with SMA have been published elsewhere (Schroth, 2009).

Prognosis. Prognosis varies according to the age of onset or group as described in Box 49-7. Individuals with SMA type 1 may succumb to respiratory infections or failure between 1 and 24 months of age (Iannaccone and Burghes, 2002; Sarnat, 2011c); however, some may live longer with enteral feeding and noninvasive mechanical ventilation techniques (Mercuri, Bertini, and Iannaccone, 2012). A significant number of infants with SMA require a tracheotomy, and associated medical conditions in survivors include gastroesophageal reflux, scoliosis, early-onset puberty, hip dysplasia, and recurrent oral candidiasis (Bach, 2007). Drug therapy with riluzole, valproic acid, gabapentin, and oral phenylbutyrate has been shown to slow the progression of the condition, but none has demonstrated significant overall benefits (Bosboom, Vrancken, van den Berg, et al., 2009; Sarnat, 2011c).

CARE MANAGEMENT

An infant or small child with progressive muscle weakness requires nursing care similar to that of an immobilized patient (see Chapter 48). However, the underlying goal of treatment should be to assist the child and family in dealing with the illness while progressing toward a life of normalization within the child's capabilities. Special attention should be directed to preventing muscle and joint contractures, promoting independence in performance of ADLs, and becoming incorporated into the mainstream of school when possible. In addition, parents need support and resources to be able to provide for the child and remain an intact family. Because children with neuromuscular disease have abnormal breathing patterns that often contribute to early death, it is important to assess adequate oxygenation, especially during the sleep phase when shallow breathing occurs and hypoxemia may develop. Home pulse oximetry may be used to assess the child during sleep and provide noninvasive mechanical ventilation as necessary (Bush, Fraser, Jardine, et al., 2005; Young, Lowe, Fitzgerald, et al., 2007) (see Duchenne [Pseudohypertrophic] Muscular Dystrophy on p. 1588 for respiratory management). Supportive care also includes management of orthoses and other orthopedic equipment as required. Because children with SMA are intellectually normal, verbal, tactile, and auditory stimulation are important aspects of developmental care. Supporting them so they can see the activities around them and transporting them in appropriate equipment (e.g., wagon, power wheelchair) for a change of environment provide stimulation and a broader scope of contacts.

Children who are able to sit require proper support and attention to alignment to prevent deformities and other complications. Children who survive beyond infancy need attention to educational needs and opportunities for social interaction with other children. The parents of a child who is chronically ill require much support

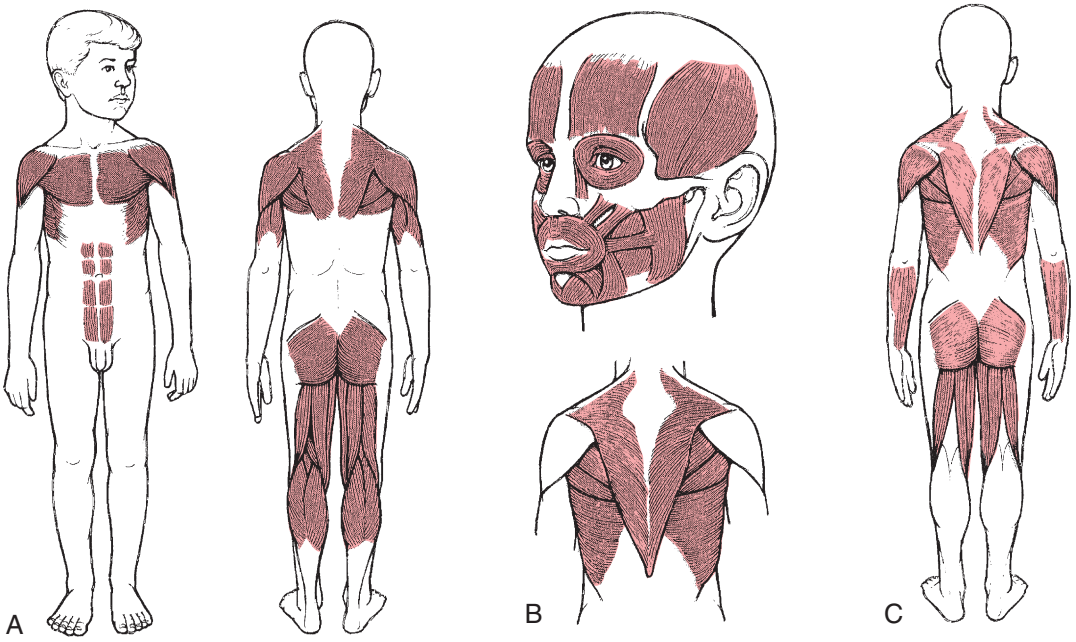

FIG 49-7 Initial muscle groups involved in muscular dystrophies. **A,** Pseudohypertrophic. **B,** Facioscapulohumeral. **C,** Limb-girdle.

and encouragement* (see Chapter 38). Parents who have not sought genetic counseling should be encouraged to do so to evaluate further risk potential.

Spinal Muscular Atrophy Type 3 (Kugelberg-Welander Disease)

Spinal muscular atrophy type 3 (Kugelberg-Welander disease) is a result of anterior horn cell and motor nerve degeneration. The disease is characterized by a pattern of muscular weakness similar to that of infantile SMA (see Box 49-7). Several modes of inheritance have been reported for the disease: autosomal recessive, autosomal dominant, and X-linked recessive.

The onset occurs from younger than 1 year of age into adulthood, with symptoms resembling type 3 SMA. Proximal muscle weakness (especially of the lower limbs) and muscular atrophy are the predominant features. The disease runs a slowly progressive course. Some children lose the ability to walk 8 to 9 years after the onset of symptoms, but many can still walk after 30 years or more. One source notes that approximately one half of all children with SMA type 3 lose ambulation by age 14 years and may require a wheelchair for times when falls are more frequent (Mercuri, Bertini, and Iannaccone, 2012). Many affected persons have a normal life expectancy (Lunn and Wang, 2008).

THERAPEUTIC MANAGEMENT AND CARE MANAGEMENT

The management is primarily symptomatic and supportive and is related to maintaining mobility as long as possible, preventing complications such as skin breakdown, optimizing and maintaining respiratory function, and providing support to the child and family. The discussion of family support in the section for Duchenne muscular dystrophy is also applicable to families of children with SMA.

Muscular Dystrophies

Muscular dystrophies (MDs) constitute the largest and most important single group of muscle diseases of childhood. The MDs have a genetic origin in which there is gradual degeneration of muscle fibers, and they are characterized by progressive weakness and wasting of symmetric groups of skeletal muscles, with increasing disability and deformity. In all forms of MD, there is an insidious loss of strength, but each type differs in regard to the muscle groups affected (Fig. 49-7), age of onset, rate of progression, and inheritance pattern. The most common form, Duchenne muscular dystrophy (DMD), is discussed separately in the next section.

Facioscapulohumeral (Landouzy-Dejerine) *muscular dystrophy* is inherited as an autosomal dominant disorder with onset in early adolescence. It is characterized by difficulty in raising the arms over the head, lack of facial mobility, and a forward slope of the shoulders. The progression is slow, and the life span is usually unaffected.

Limb-girdle muscular dystrophy (LGMD) is a heterogenous group of disorders with autosomal dominant and recessive inheritance whose clinical manifestations often appear in later childhood, adolescence, or early adulthood with variable but usually slow progression (Quan, 2011). All types of LGMD are characterized by weakness of proximal muscles of the pelvic and shoulder girdles. Other forms of MD include myotonic dystrophy, scapulohumeral MD (Emery-Dreifuss MD), fascioscapulohumeral MD (Landouzy-Dejerine disease), and congenital MD; these forms consist of subtypes of MD and are discussed at length elsewhere (see Sarnat, 2011a).

Treatment of the MDs consists mainly of supportive measures, including physical therapy, orthopedic procedures to minimize

deformity, ventilation support, and assistance for the affected child in meeting the demands of daily living.

Duchenne (Pseudohypertrophic) Muscular Dystrophy

Duchenne muscular dystrophy is the most severe and the most common MD of childhood. It is inherited as an X-linked recessive trait, and the single-gene defect is located on the short arm of the X chromosome. DMD has a high mutation rate, with a positive family history in about 65% of cases. Genetic counseling is an important aspect of the care of the family. In about 30% of cases, it is a new mutation and the mother is *not* the carrier (Sarnat, 2011a).

As in all X-linked disorders, males are affected almost exclusively. The female carrier may have an elevated serum creatine kinase, but muscle weakness is usually not a problem; however, about 10% of female carriers develop cardiomyopathy (Manzur, Kinali, and Muntoni, 2008). In rare instances, a female may be identified with DMD disease yet with muscular weakness that is milder than in boys (Sarnat, 2011a). At the genetic level, both DMD and Becker MD (a milder variant) result from mutations of the gene that encodes *dystrophin,* a protein product in skeletal muscle. Dystrophin is absent from the muscles of children with DMD and is reduced or abnormal in children with Becker MD. Children with Becker MD have a later onset of symptoms, which are usually not as severe as those seen in DMD. The incidence is approximately 1 in 3600 male births for the Duchenne form and approximately 1 in 30,000 live births for the Becker type (Sarnat, 2007, 2011a). Box 49-8 describes the characteristics of DMD.

Most children with DMD reach the appropriate developmental milestones early in life, although they may have mild, subtle delays. Evidence of muscle weakness usually appears during the third to seventh year, although there may have been a history of delay in motor development, particularly walking. Difficulties in running, riding a bicycle, and climbing stairs are usually the first symptoms noted. Typically, affected boys have a waddling gait and lordosis, fall frequently, and develop a characteristic manner of rising from a squatting or sitting position on the floor **(Gower sign).** Lordosis occurs as a result of weakened pelvic muscles, and the waddling gait is a result of weakness in the gluteus medius and maximus muscles (Battista, 2010). In the early years, rapid developmental gains may mask the progression of the disease.

Muscles, especially in the calves, thighs, and upper arms, become enlarged from fatty infiltration and feel unusually firm or woody on palpation (Box 49-9). The term pseudohypertrophy is derived from this muscular enlargement. Profound muscular atrophy occurs in the later stages; contractures and deformities involving large and small joints are common complications as the disease progresses. Ambulation usually becomes impossible by 12 years of age. The loss of mobilization further increases the spectrum of complications, which may include osteoporosis, fractures, constipation, skin breakdown, and psychosocial and behavioral problems. Atrophy of facial, oropharyngeal, and respiratory muscles does not occur until the advanced stage of the disease. Ultimately, the disease process involves the diaphragm and auxiliary muscles of respiration, and cardiomyopathy is seen in approximately 50% to 80% of patients with DMD (Sarnat, 2011a).

Obesity is a common complication that contributes to premature loss of ambulation. Children who have restricted opportunities for physical activity and who are bored easily consume calories in excess of their needs. This may be compounded by overfeeding by well-meaning family and friends. Proper dietary intake and a diversified recreational program help reduce the likelihood of obesity and enable children to maintain ambulation and functional independence for a longer time.

Mild to moderate cognitive impairment is commonly associated with MD. A deficiency of dystrophin isoforms in brain tissue causes cognitive and intellectual impairment (Manzur, Kinali, and Muntoni, 2008). The mean IQ is approximately 20 points below normal, and frank mental deficit is present in 20% to 30% of these children. Verbal IQ is markedly low in boys with DMD, and emotional disturbance is more common than in other children with disabilities; however, children with DMD should be involved in early learning programs and eventually moved into regular classrooms as much as possible. Patients with Becker MD present later in life than those with DMD, but they often do not survive past the middle of the second decade, with few patients living into their 40s (Sarnat, 2011a).

Diagnostic Evaluation. The diagnosis of DMD is primarily established by blood polymerase chain reaction (PCR) for the dystrophin gene mutation (Sarnat, 2011a). Prenatal diagnosis is also possible as early as 12 weeks of gestation. Serum enzyme measurement, muscle biopsy, and EMG may also be used in establishing the diagnosis. Serum creatine kinase (CK) levels are extremely high in the first 2 years of life before the onset of clinical weakness. If the child demonstrates the usual characteristics, has a positive family history for DMD, and the PCR result is positive, the muscle biopsy may be deferred.

Therapeutic Management. No effective treatment exists for childhood MD. The use of the corticosteroids *prednisone* and

BOX 49-8 CHARACTERISTICS OF DUCHENNE MUSCULAR DYSTROPHY

- Early onset, usually between 3 and 5 years of age
- Progressive muscular weakness, wasting, and contractures
- Calf muscle hypertrophy in most patients
- Loss of independent ambulation by 9 to 11 years of age
- Slowly progressive, generalized weakness during teenage years
- Relentless progression until death from respiratory or cardiac failure

BOX 49-9 CLINICAL MANIFESTATIONS OF DUCHENNE MUSCULAR DYSTROPHY

- Waddling gait
- Lordosis
- Frequent falls
- Gower sign (child turning onto side or abdomen, flexing knees to assume a kneeling position, then with knees extended gradually pushing torso to an upright position by "walking" the hands up the legs)
- Enlarged muscles (especially thighs and upper arms); feel unusually firm or woody on palpation
- Later stages: profound muscular atrophy
- Cognitive impairment (common):
  - Mild (about 20 IQ points below normal)
  - Cognitive impairment present in 25% to 30% of patients
- Complications:
  - Contracture deformities of hips, knees, and ankles
  - Disuse atrophy
  - Obesity

deflazacort has been evaluated as a treatment for DMD. Several clinical trials demonstrated increased muscle strength and improved performance and pulmonary function, with significant decrease in the progression of weakness, when prednisone was administered for 6 months to 2 years (Manzur, Kuntzer, Pike, et al., 2008). The American Academy of Neurology has published a practice parameter for the administration of corticosteroids in the treatment of DMD (Moxley, Ashwal, Pandya, et al., 2005). Major side effects in these studies included weight gain and a cushingoid facial appearance.

Maintaining optimal function in all muscles for as long as possible is the primary goal; secondary is the prevention of contractures. Children with DMD who remain as active as possible are able to avoid wheelchair confinement for a longer time. Maintenance of function often involves stretching exercises, strength and muscle training, breathing exercises to increase and maintain vital lung capacity, range-of-motion exercises, surgery to release contracture deformities, bracing, and performance of ADLs.

Parents should always be involved in making decisions about the child's care, and teaching regarding home safety and prevention of falls is important as well. Parents should also be encouraged to have the child keep follow-up appointments for medical care and physical and occupational therapy. Because respiratory tract infections are most troublesome in these children, influenza and pneumococcal vaccines are encouraged and contact with persons with respiratory tract infections should be avoided. Action plans for prompt treatment of respiratory illness are important.

Eventually, respiratory and cardiac problems become the central focus of the debilitating illness. Children with neuromuscular disease develop abnormal breathing patterns, and hypoxia may occur as a result of inadequate oxygenation. The child and parents should be involved in a discussion of long-term ventilation options. Cardiac and respiratory assessment during wake-sleep cycles is imperative. Respiratory care for children with neuromuscular conditions such as SMA and DMD may involve the use of noninvasive ventilation with BiPAP on a temporary or full-time basis, **mechanically assisted coughing (MAC),** or tracheostomy and relief of airway obstruction with coughing and suctioning devices; the tracheostomy, however, is associated with more complications (Simonds, 2006; Young, Lowe, Fitzgerald, et al., 2007). Home pulse oximetry may be used to monitor oxygenation during sleep or to aid in decision making regarding the use of MAC to clear the airways.

Several devices are available for children with neuromuscular disease to assist in clearing the airway when the cough reflex is ineffective or diminished. The mechanical cough in-exsufflator (MIE; also referred to as *cough assist*) has been found to be safe and effective in the daily management of respiratory function (Kravitz, 2009; Miske, Hickey, Kolb, et al., 2004). The MIE delivers positive inspiratory pressures at a set rate followed by negative pressure exsufflation coordinated with the patient's own breathing rhythm. The exsufflation is designed to mimic a cough reflex so mucus can be effectively cleared. Airway suctioning after exsufflation is accomplished as necessary to clear the airways. In children, the MIE device may be connected directly to a tracheostomy or used with a mouthpiece or face mask. The Boitano (2009) reference contains a variety of equipment options, including various masks that can be used to deliver noninvasive positive pressure.

Manual cough-assisting techniques include glossopharyngeal breathing or air stacking (frog breathing); the abdominal thrust, which is similar to the Heimlich maneuver (Kravitz, 2009); and manual hyperinflation with a self-inflating resuscitation bag (without oxygen) and a mouthpiece. Hyperinflation may be used in conjunction with abdominal thrusts to improve peak cough flows (Boitano, 2009).

The use of routine chest physiotherapy (postural drainage) for DMD has not been adequately evaluated for its effectiveness in clearing the airway of mucus except when there is focal atelectasis and mucus plugging the airways (Kravitz, 2009).

Survival in individuals with DMD may be prolonged several years with the use of noninvasive ventilation and MAC as alternatives to tracheostomy and airway suctioning (Simonds, 2006). The American Thoracic Society (2004) has published extensive guidelines for respiratory monitoring and care of children and adults with DMD.

The American Academy of Pediatrics (AAP, 2005) recommends an extensive cardiac evaluation of the child diagnosed with either DMD or Becker MD. Patients with neuromuscular conditions may not be seen with the typical signs and symptoms of cardiac dysfunction. Therefore symptoms such as weight loss, nausea and vomiting, cough, increased fatigue on performance of ADLs, and orthopnea should be carefully evaluated to detect early signs of cardiomyopathy.

Genetic counseling is recommended for parents, sisters, and maternal aunts and their daughters. Long-term care, end-of-life care, and palliative care options are issues that the health care team must discuss with the child and family affected by MD (Finder, 2009). Professional counseling is necessary in some cases to allow frank discussion of these issues, and referrals should be made as appropriate.

CARE MANAGEMENT

The care and management of a child with MD involve the combined efforts of a multidisciplinary health care team. Nurses can help clarify the roles of these health care professionals to family and others. The major emphasis of nursing care is to help the child and family cope with a chronic, progressive, incapacitating disease; to help design a program that will afford maximal independence and reduce the predictable and preventable disabilities associated with the disorder; and to help the child and family deal constructively with the limitations the disease imposes on their daily lives. Because of advances in technology, children with MD may live into early adulthood; therefore the goals of care should also involve decisions regarding quality of life, achievement of independence, and transition to adulthood.

Working closely with other team members, nurses assist the family in developing the child's self-help skills to give the child the satisfaction of being as independent as possible for as long as possible. This requires continual evaluation of the child's capabilities, which are often difficult to assess. Fortunately, most children with MD instinctively recognize the need to become as independent as possible and strive to do so.

Practical difficulties faced by families are physical limitations of housing and mobility. Some families live in houses or apartments that are unsuited to wheelchairs. Transportation may also be a barrier for families of children with MD. Assisting with these challenges requires team problem solving. Diet, nutritional needs, and nutrition modification are discussed according to the needs of the individual child and family.

Children with MD tend to become socially isolated as their physical condition deteriorates to the point that they can no longer keep up with their friends and classmates. Their physical capabilities diminish, and their dependency increases at the age at which most children are expanding their range of interests and relationships. To

gain peer associations, they often learn and use behaviors that bring them the rewards of other children's company. These friends are often children who have been rejected by more able-bodied classmates.

The parents' social activities are also restricted, and the family's activities must be continually modified to accommodate the needs of the affected child. When the child becomes increasingly incapacitated, the family may consider home-based care, an assisted living facility, or respite care. Unless the child is severely incapacitated, he should also be involved in the decisions regarding such care. Nurses can assist with decision making by exploring all available options and resources and support the child and family in the decision. Older boys with MD may also need psychiatric or psychologic counseling to deal with issues such as depression, anger, and quality of life. Parents also need to be encouraged to become involved in support groups because evidence indicates that adequate social support from family, community, and other parents is crucial to appropriate coping in families with children with chronic illness.

Regardless of how successful the program or how well the family adapts to the disorder, superimposed on the physical and emotional problems associated with a child with a long-term disability is the constant knowledge of the ultimate outcome of the disease. All of the manifestations seen in the child with a chronic fatal illness are encountered in these families (see Chapter 38).

Nurses are especially valuable health care professionals as they come to know the family and the family's problems. Nurses can be alert to the family's problems and needs and make necessary referrals when supplementary services are indicated. The Muscular Dystrophy Association—USA* has branches in most communities to assist families who have a member with MD.

ACQUIRED NEUROMUSCULAR DISORDERS

Guillain-Barré Syndrome (Infectious Polyneuritis)

Guillain-Barré syndrome (GBS), also known as *infectious polyneuritis,* is an uncommon acute demyelinating polyneuropathy with a progressive, usually ascending flaccid paralysis. The hallmark of GBS is acute peripheral motor weakness. The paralysis usually occurs approximately 10 days after a nonspecific viral infection; GBS has also been reported after administration of certain vaccines (rabies, influenza, polio, and meningococcal) (Sarnat, 2011b). Several subtypes of GBS include acute inflammatory demyelinating neuropathy, acute motor axonal neuropathy, acute motor sensory axonal neuropathy, and Miller Fisher syndrome. Children are less often affected than adults; among children, those between ages 4 and 10 years have higher susceptibility. The male-to-female ratio is reported to be 1.5 to 1. Two peak periods with an increased incidence of GBS have been identified: late adolescence and young adulthood.

Chronic inflammatory demyelinating polyradiculoneuropathies (CIDPs) are chronic types of GBS that recur intermittently or do not improve over a period of months to years (Sarnat, 2011b). The following discussion focuses on GBS.

Congenital GBS is rare yet may occur in the neonatal period and consists of hypotonia, weakness, and decreased or absent reflexes. Maternal neuromuscular disease may or may not be present. Diagnosis is established by the same criteria as in older children, but the symptoms gradually subside over the first few months of life and disappear by 12 months (Sarnat, 2011b).

Pathophysiology

Guillain-Barré syndrome is an immune-mediated disease often associated with a number of viral or bacterial infections or the administration of certain vaccines. It has been associated with infectious mononucleosis, measles, mumps, *Campylobacter jejuni* (gastroenteritis), cytomegalovirus, *Borrelia burgdorferi* (Lyme disease), Epstein-Barr virus, *Helicobacter pylori,* and *Mycoplasma* and *Pneumocystis* infections. Onset of GBS symptoms usually occurs within 10 days of the primary infection. Pathologic changes in spinal and cranial nerves consist of inflammation and edema with rapid, segmented demyelination and compression of nerve roots within the dural sheath. Nerve conduction is impaired, producing ascending partial or complete paralysis of muscles innervated by the involved nerves. GBS has three phases:

1. **Acute**—Phase starts when symptoms begin and continues until new symptoms stop appearing or deterioration ceases; it may last as long as 4 weeks.
2. **Plateau**—Symptoms remain constant without further deterioration; it may last from days to weeks.
3. **Recovery**—Patient begins to improve and progress to optimal recovery; it usually lasts a few weeks to months depending on the deficits incurred by the illness.

Diagnostic Evaluation

The diagnosis of GBS is based on clinical manifestations (Box 49-10), CSF analysis, and EMG findings. CSF analysis reveals an abnormally elevated protein concentration, normal glucose, and fewer than 10 white blood cells (WBCs)/mm^3 (Sarnat, 2011b). EMG shows evidence of acute muscle denervation, but other laboratory studies are usually noncontributory. The symmetric nature of the

BOX 49-10 CLINICAL MANIFESTATIONS OF GUILLAIN-BARRÉ SYNDROME

Initial Symptoms
- Muscle tenderness
- Paresthesia and cramps (sometimes)
- Proximal symmetric muscle weakness

Paralysis
- Ascending bilateral paralysis from lower extremities
- Frequent involvement of muscles of trunk and upper extremities and those supplied by cranial nerves (especially facial)
- Flaccid paralysis with loss of reflexes
- May involve facial, extraocular, labial, lingual, pharyngeal, and laryngeal muscles
- Intercostal and phrenic nerves:
  - Breathlessness in vocalizations
  - Shallow, irregular respirations

Other Manifestations
- Tendon reflexes depressed or absent
- Variable degrees of sensory impairment
- Muscle tenderness or sensitivity to slight pressure
- Urinary incontinence or retention and constipation

*3300 E. Sunrise Drive, Tucson, AZ 85718; 800-572-1717; e-mail: mda@mdausa.org; www.mda.org. In Canada: Muscular Dystrophy Canada, 2345 Yonge St., Suite 900, Toronto, Ontario, Canada M4P 2E5; 866-MUSCLE-8; fax: 416-488-7523; www.muscle.ca/national/home.html.

paralysis helps differentiate this disorder from spinal paralytic poliomyelitis, which usually affects sporadic muscles.

Therapeutic Management

Treatment of GBS is primarily supportive. In the acute phase, patients are hospitalized because respiratory and pharyngeal involvement may require assisted ventilation, sometimes with a temporary tracheostomy. Treatment modalities include aggressive ventilatory support in the event of respiratory compromise, intravenous (IV) administration of immunoglobulin (IVIG), and sometimes steroids; plasmapheresis and immunosuppressive drugs may also be used. Plasmapheresis has been shown to decrease the length of recovery in patients with severe GBS; however, it is expensive, and side effects include hypotension, fever, bleeding disorders, chills, urticaria, and bradycardia. Further evidence reports equal benefits to treatment of GBS with IVIG administration or plasmapheresis; both sped up recovery time in studies reviewed (Hughes and Cornblath, 2005). There is evidence, however, of significant improvement in children with high-dose IVIG therapy (versus supportive treatment alone) (Hughes, Swan, and van Doorn, 2010). IVIG is now recommended as the primary treatment of GBS when administered within 2 weeks of disease onset (Hughes, 2008). Corticosteroids alone do not decrease the symptoms or shorten the duration of the disease.

Medications that may be administered during the acute phase include a low-molecular-weight heparin to prevent deep vein thrombosis (DVT), a mild laxative or stool softener to prevent constipation, pain medication such as acetaminophen, and a histamine-antagonist to prevent stress ulcer formation. Chronic neuropathic pain after GBS may be treated with gabapentin, which is reported to be more effective than carbamazepine (Sarnat, 2011b).

Rehabilitation after the acute phase may involve physical therapy, occupational therapy, and speech therapy. Additional consideration should be given to problems of general weakness and retraining for toileting and feeding (Lyons, 2008).

Course and Prognosis. Better outcomes are associated with younger age, no requirement for mechanical respiratory assistance, slower progression of disease, normal peripheral nerve function on EMG, and treatment with either IVIG or plasmapheresis. Recovery usually begins within 2 to 3 weeks, and most patients regain full muscle strength. The recovery of muscle strength progresses in the reverse order of onset of paralysis, with lower extremity strength being the last to recover. Poor prognosis with subsequent residual effects in children is reportedly associated with cranial nerve involvement, extensive disability at time of presentation, and intubation.

Most deaths associated with GBS are caused by respiratory failure; therefore early diagnosis and access to respiratory support are especially important. The rate of recovery is usually related to the degree of involvement and may extend from a few weeks to months. The greater the degree of paralysis, the longer the recovery phase.

CARE MANAGEMENT

Nursing care is primarily supportive and is the same as that required for children with immobilization and respiratory compromise. The emphasis of care is on close observation to assess the extent of paralysis and on prevention of complications, including aspiration, **ventilator-associated pneumonia (VAP),** atelectasis, DVT, pressure ulcer, fear and anxiety, autonomic dysfunction, and pain.

During the acute phase of the disease, the nurse should carefully observe the child's condition for possible difficulty in swallowing and respiratory involvement. The child's respiratory function is closely monitored, and oxygen source, appropriate-size insufflation bag and mask, endotracheal intubation and suctioning equipment, tracheotomy tray, and vasoconstrictor drugs are kept available. Vital signs are monitored frequently along with neurologic signs and level of consciousness. For children who develop respiratory impairment, the care is the same as that for any child with respiratory distress requiring mechanical ventilation.

Respiratory care, if intubation is required, requires close monitoring of oxygenation status (usually by pulse oximetry and sometimes arterial blood gases), maintenance of an open airway with suctioning, and postural changes to prevent pneumonia. Consideration should be given to preventing opportunistic infections such as VAP; meticulous oral care and hypopharynx suctioning, elevation of the head of bed 30 degrees, and strict asepsis with suctioning equipment (including catheters, a Yankauer device, or both) should be implemented to prevent VAP. Children with oral and pharyngeal involvement may be fed via a nasogastric or gastrostomy tube to ensure adequate feeding. It is also important to consider the possibility of stress ulcers in such patients and to administer a proton pump inhibitor. Immobilization, which occurs with GBS, decreases GI function; therefore problems such as decreased gastric emptying, constipation, and feeding residuals require nursing assessment and appropriate collaborative interventions. Temporary urinary catheterization may be required; urinary retention is common, and appropriate assessment of urinary output is vital. Sensory impairment and paralysis in the lower extremities make the child susceptible to skin breakdown; therefore attention should be given to meticulous skin care. Passive range-of-motion exercises and application of orthoses to prevent muscle contractures are important when paralysis is present. Prevention of DVT is accomplished with pneumatic compression (antiembolism) devices, administration of a low-molecular-weight heparin, and early mobilization and ambulation. Autonomic dysfunction may be life threatening; thus close monitoring of vital signs in the acute phase is essential.

A key to recovery in the child with GBS is the prevention of muscle and joint contractures, so passive range-of-motion exercises must be carried out routinely to maintain vital function. Although the child may have a generalized paralysis, cognitive function remains intact; therefore it is important for nursing care to involve communication with the child or adolescent regarding procedures and treatments that may be frightening, especially if mechanical ventilation is required. Encourage parents to talk to the child and make eye and physical contact and to reassure the child during this phase of the illness.

Pain management is crucial in the care of children with GBS. Although neuromuscular impairment may make pain perception more difficult to accurately evaluate, objective pain scales should be used. Gabapentin and carbamazepine may be used to manage neuropathic pain in patients with GBS.

Physical therapy may be limited to passive range-of-motion exercises during the evolving phase of the disease. Later, as the disease stabilizes and recovery begins, an active physical therapy program is implemented to prevent contracture deformities and facilitate muscle recovery. This may include active exercise, gait training, and bracing.

Throughout the course of the illness, child and parent support are paramount. The usual rapidity of the paralysis and the long recovery period greatly tax the emotional reserves of all family members. The parents and child benefit from repeated reassurance that recovery is occurring and from realistic information regarding the possibility of permanent disability. In the event of a residual

disability, the family needs assistance in accepting and adjusting to the loss of function. (See Chapter 38.) The GBS/CIDP Foundation International* is a nonprofit organization devoted to support, education, and research. It provides families with support from recovered persons, publishes informational literature and a newsletter, and maintains a list of health care practitioners experienced with the disease.

Tetanus

Tetanus, or lockjaw, is an acute, preventable, but often fatal disease caused by an exotoxin produced by the anaerobic spore-forming, gram-positive bacillus *Clostridium tetani.* It is characterized by painful muscular rigidity primarily involving the masseter and neck muscles. There are four requirements for the development of tetanus: (1) presence of tetanus spores or vegetative forms of the bacillus, (2) injury to the tissues, (3) wound conditions that encourage multiplication of the organism, and (4) a susceptible host.

Tetanus spores are found in soil, dust, and the intestinal tracts of humans and animals, especially herbivorous animals. The organisms are more prevalent in rural areas but are readily carried to urban areas by the wind. The organisms are not invasive but enter the body by way of wounds, particularly a puncture wound, burn, or crushed area. They may enter through a minor, unnoticed break in the skin, such as a thorn or needle prick, bee sting, or scratch. In newborns, infection may occur through the umbilical cord, usually in situations in which infants are delivered in severely contaminated surroundings or the mother is not adequately immunized. The disease has the greatest incidence in months when persons are more involved in outdoor activities.

Pathophysiology

When prevention efforts are not effective and conditions are favorable, the organisms proliferate and form potent exotoxins, one of which is *tetanospasmin.* Tetanospasmin affects the CNS to produce the clinical manifestations of the disease. The ideal conditions for the organisms' growth are devitalized tissues without access to air, such as wounds that have not been washed or kept clean and those that have crusted over, trapping pus beneath. The exotoxin appears to reach the CNS by way of either the neuron axons or the vascular system. The toxin becomes fixed on nerve cells of the anterior horn of the spinal cord and the brainstem. The toxin acts at the myoneural junction to produce muscular stiffness and lower the threshold for reflex excitability.

The incubation period for tetanus varies from 2 days to months and averages 8 days; most cases occur within 14 days. In neonates, it is usually 5 to 14 days. Shorter incubation periods have been associated with more heavily contaminated wounds, more severe disease, and a worse prognosis (AAP, 2012).

The manner of onset varies, but the initial symptoms are usually a progressive stiffness and tenderness of the muscles in the neck and jaw. Eventually, all voluntary muscles are affected (Box 49-11). As the child recovers from the disease, the paroxysms become less frequent and gradually subside. Survival beyond 4 days usually indicates recovery, but complete recovery may require weeks.

Therapeutic Management

Primary prevention is key and occurs through immunization and boosters (AAP, 2012). After an injury has occurred, further preventive measures are based on the child's immune status and the nature of the injury. Specific prophylactic therapy after trauma is administration of tetanus toxoid (note that equine tetanus antitoxin [TAT] is not available in the United States) (see Immunizations, Chapter 31, for age-specific recommendations).

An unprotected or inadequately immunized child who sustains a "tetanus-prone" wound (including wounds contaminated with dirt, feces, soil, and saliva; puncture wounds; avulsions; and wounds resulting from missiles, crushing, burns, and frostbite) should receive tetanus immunoglobulin (TIG). Concurrent administration of both TIG and tetanus toxoid at separate sites is recommended both to provide protection and to initiate the active immune process.

After the individual has received primary tetanus immunization, antitoxin is believed to provide protection for at least 10 years and for a longer period after booster immunization (AAP, 2012). Recently, the Advisory Committee on Immunization Practices (CDC, 2011) recommended no specific time intervals between the administration of a tetanus- or diphtheria-toxoid containing vaccine and Tdap (tetanus, diphtheria, and pertussis) to provide protection against pertussis; other than a localized pain reaction, no other side effects were noted in persons who received the tetanus and diphtheria (Td) and Tdap at intervals as short as 18 months. Completion of active immunization is carried out according to the usual pattern. Antibiotic treatment with penicillin G (or erythromycin or tetracycline in older children with allergy to penicillin) is important in the management of tetanus as an adjunct against clostridia; metronidazole is a viable alternative (Arnon, 2011b).

BOX 49-11 CLINICAL MANIFESTATIONS OF TETANUS

Initial Symptoms
- Progressive stiffness and tenderness of muscles in neck and jaw
- Characteristic difficulty in opening the mouth *(trismus)*
- *Risus sardonicus* (sardonic smile) caused by facial muscle spasm

Progressive Involvement
- **Opisthotonic** positioning (severe back arching)
- Boardlike rigidity of abdominal and limb muscles
- Difficulty swallowing
- High sensitivity to external stimuli (slight noise, gentle touch, or bright light):
  - Trigger paroxysmal muscular contractions that last seconds to minutes
  - Contractions recur with increased frequency until almost continuous (sustained tetanic)
- Laryngospasm and tetany of respiratory muscles:
  - Accumulated secretions
  - Respiratory arrest
  - Atelectasis
  - Pneumonia

Other Aspects
- Mentation unaffected; patient alert
- Pain and distress are reflected in:
  - Rapid pulse
  - Sweating
  - Anxious expression
- Fever usually absent or only mild

*The Holly Building, 104½ Forrest Ave., Narberth, PA 19072; 610-667-0131, 866-224-3301; www.gbs-cidp.org.

MEDICATION ALERT

TIG and tetanus toxoid are always administered via the intramuscular route in separate syringes and at separate sites; they are never administered by the intravenous route.

Aggressive supportive care is necessary to treat tetanus in the acute phase. Acutely ill children are best treated in an intensive care facility where close and constant observation and equipment for monitoring and respiratory support are readily available. A quiet environment is preferred to reduce external stimuli.

General supportive care is indicated, including maintaining an adequate airway and fluid and electrolyte balance, managing pain, and ensuring adequate caloric intake. Indwelling NG or tube feedings may be required to maintain adequate fluid and caloric intake; continued laryngospasm may necessitate total parenteral nutrition or gastrostomy feeding. Severe or recurrent laryngospasm or excessive secretions may require advanced airway management such as endotracheal intubation or tracheotomy.

Tetanus immunoglobulin therapy to neutralize toxins is the most specific therapy for tetanus. Local care of the wound by surgical debridement and cleansing helps reduce the numbers of proliferating organisms at the site of injury. The cleansing should be repeated several times during the first 48 hours, and deep, infected lacerations are usually exposed and debrided. Infiltration of the wound with TIG is no longer considered necessary (AAP, 2012).

Diazepam is the drug of choice for seizure control and muscle relaxation (Arnon, 2011b), but lorazepam (Ativan) may be used in some cases. Intrathecal baclofen, IV magnesium sulfate, dantrolene sodium, and midazolam may also be used in the management of muscle spasticity associated with tetanus. Patients with severe tetanus and those who do not respond to other muscle relaxants may require the administration of a neuromuscular blocking agent, such as rocuronium or vecuronium; intrathecal baclofen may be used as a muscle relaxant but only in the intensive care unit because it often induces apnea. Because of their paralytic effect on respiratory muscles, use of these drugs requires mechanical ventilation with endotracheal intubation or tracheotomy and constant cardiopulmonary monitoring. Endotracheal tube insertion or tracheotomy is often indicated and should be performed before severe respiratory distress develops. Despite the absence of pain manifestation with these drugs, it is important to provide adequate analgesia. The administration of corticosteroids has met with success in some cases.

CARE MANAGEMENT

The care of the child with tetanus requires supportive management with particular attention to airway and breathing. Respiratory status is carefully evaluated for any signs of distress, and appropriate emergency equipment is kept available at all times. The location, extent, and severity of muscle spasms are important nursing observations. Muscle relaxants, opioids, and sedatives that may be prescribed can also cause respiratory depression; therefore the child should be assessed for excessive CNS depression. Attention to hydration and nutrition involves monitoring an IV infusion, monitoring nasogastric or gastrostomy feedings, and suctioning oropharyngeal secretions when indicated.

In caring for a child with tetanus during the acute phase, every effort should be made to control or eliminate stimulation from sound, light, and touch. Although a darkened room is ideal, sufficient light is essential so that the child can be carefully observed; light appears to be less irritating than vibratory or auditory stimuli. The infant or child is handled as little as possible, and extra effort is expended to avoid any sudden or loud noise to prevent seizures.

If a potent muscle relaxant such as vecuronium is used, the total paralysis makes oral communication impossible. The drug is not a sedative, however, and anxiety should be considered in children who are intubated. Therefore all the child's needs must be anticipated and procedures carefully explained beforehand. Additional care is focused on preventing the complications associated with prolonged immobility, including decreased bowel and bladder tone and subsequent constipation, anorexia, DVT, pneumonia, and skin breakdown.

BOX 49-12 CLINICAL MANIFESTATIONS OF BOTULISM

General Signs
- Weakness
- Dizziness
- Headache
- Difficulty talking and speaking
- Diplopia
- Vomiting
- Progressive, life-threatening respiratory paralysis

Infant Botulism*
- Constipation (a common symptom)
- Generalized weakness
- Decrease in spontaneous movements
- Diminished or absent deep tendon reflexes
- Loss of head control
- Difficulty feeding
- Weak cry
- Reduced gag reflex
- Progressive respiratory paralysis

*Most commonly diagnosed as a "rule out sepsis" in the acute phase because of clinical presentation.

Botulism

Botulism is an acute flaccid paralysis caused by the preformed toxin produced by the anaerobic bacillus *Clostridium botulinum*. In classic, or foodborne, botulism, the most common source of the toxin is a contaminated food source. The disease has a wide variation in severity, from constipation to progressive sequential loss of neurologic function and respiratory failure. The most common source of the toxin is improperly sterilized home-canned foods. CNS symptoms appear abruptly approximately 12 to 36 hours after ingestion of contaminated food and may or may not be preceded by acute digestive disturbance (Box 49-12).

Human botulism is caused by neurotoxins A, B, E, and, rarely, F (AAP, 2012). In addition to foodborne botulism, other forms include wound botulism; infant botulism; and artificial botulism, usually a result of bioterrorism.

Treatment consists of IV administration of botulism antitoxin and general supportive measures, primarily respiratory and nutritional. Toxins vary in protein-binding capacity. Some have a relatively short half-life and do not bind to tissues firmly; therefore therapy is continued until paralysis subsides. Other toxins appear to bind irreversibly to nerve endings and are therefore not amenable to neutralization.

Infant Botulism

Infant botulism, unlike foodborne botulism in older persons, is caused by ingestion of spores or vegetative cells of *C. botulinum* and

the subsequent release of the toxin from organisms colonizing the GI tract. *C. botulinum* types A and B are the most common causative strains of infant botulism. This form of botulism has become more prevalent than any other form. Many cases of infant botulism occur in breastfed infants who are being introduced to nonhuman milk substances (AAP, 2012). There appears to be no common food or drug source of the organisms; however, the *C. botulinum* organisms have been found in honey. Botulism may occur in infants as young as 1 week of age up to 12 months of age with peak incidence between 2 and 4 months of age.

The severity of the disease varies widely, from mild constipation to progressive sequential loss of neurologic function and respiratory failure (see Box 49-12). The affected infant is usually well before the onset of symptoms. Constipation is a common presenting symptom, and almost all infants exhibit generalized weakness and a decrease in spontaneous movements. Deep tendon reflexes are usually diminished or absent. Cranial nerve deficits are common, as evidenced by loss of head control, difficulty in feeding, weak cry, and reduced gag reflex. SMA type 1 and metabolic disorders are often mistaken for infant botulism in the initial diagnostic phase because of the similarities in clinical manifestations of hypotonia, lethargy, and poor feeding (Arnon, 2011a). Presenting clinical signs also often mimic those of sepsis in young infants. Botulism toxin exerts its effect by inhibiting the release of acetylcholine at the myoneural junction, thereby impairing motor activity of muscles innervated by affected nerves.

Diagnosis is made on the basis of the clinical history, physical examination, and laboratory detection of the organism in the patient's stool and, less commonly, blood. However, isolation of the organism may take several days; therefore suspicion of botulism by clinical presentation should require emergent treatment (Arnon, 2011a). EMG may be helpful in establishing the diagnosis; however, results may be normal early in the course of the illness.

Treatment consists of immediate administration of botulism immune globulin intravenously (BIG-IV) (Arnon, 2011b) without delaying for laboratory diagnosis. Early administration of BIG-IV neutralizes the toxin and stops the progression of the disease. The human-derived botulism antitoxin (BIG-IV) has been evaluated and is now available nationwide for use only in infant botulism. Infants treated with BIG-IV usually have a shortened hospital stay from approximately 6 weeks to 2 weeks, reportedly as a result of decreased requirements for mechanical ventilation and intensive care (Arnon, 2011a). Approximately 50% of affected infants require intubation and mechanical ventilation; therefore respiratory support is crucial, as is nutritional support because theses infants are unable to feed. Trivalent equine botulinum antitoxin and bivalent antitoxin, used in adults and older children, are *not* administered to infants. Antibiotic therapy is not part of the management because the botulinum toxin is an intracellular molecule and antibiotics would not be effective; aminoglycosides in particular should not be administered because they may potentiate the blocking effects of the neurotoxin (Arnon, 2011a).

The prognosis is generally good if the patient is adequately treated, although recovery may be slow, requiring a few weeks after severe illness. Untreated patients may require a longer hospitalization.

! NURSING ALERT

Although the precise source of *C. botulinum* spores has not been identified as originating from honey in many cases of infant botulism, it is still recommended that honey not be given to infants younger than 12 months because the spores have been found in honey (CDC, 2010).

CARE MANAGEMENT

Nursing responsibilities include observing, recognizing, and reporting signs of poor feeding, constipation, and muscle impairment in the infant with botulism and providing intensive nursing care when an infant is hospitalized. (See Care Management for the infant with SMA, p. 1586, and Nursing Care of High Risk Newborns, Chapter 25.) Parental support and reassurance are important. Most infants recover when the disorder is recognized and BIG-IV therapy is implemented. Nursing care of the infant on mechanical ventilation requires observation of oxygenation status and vigilance for any complications. Parents should be aware that during recovery, infants fatigue easily when muscular action is sustained. This has important implications for timing the resumption of feedings because of the risk for aspiration. Parents should also be advised that normal bowel activity may not return for several weeks. Therefore a stool softener can be beneficial.

Spinal Cord Injuries

Spinal cord injuries (SCIs) with major neurologic involvement traditionally have not been a common cause of physical disability in children. However, a sufficient number of children with these injuries are admitted to major medical centers, and because of the increased survival rate as a result of improved management, nurses are often involved in the care and rehabilitation of children with SCI.

Mechanisms of Injury

The most common cause of serious spinal cord damage in children is trauma involving motor vehicle crashes (MVCs) (including automobile-bicycle, all-terrain vehicles, and snowmobiles), sports injuries (especially from diving, trampoline activities, gymnastics, and football), birth trauma, and nonaccidental trauma. MVCs accounted for 56% of SCIs in children and adolescents, and falls and firearm injury caused 14% and 9% of SCIs. The children injured (SCI) in MVCs were not properly restrained in 67.7% of the cases (Vitale, Goss, Matsumoto, et al., 2006). The increased use of recreational activities involving motorized vehicles such as jet water skis, all-terrain vehicles, and motorcycles has also increased the incidence of SCIs in children. Congenital defects of the spine such as *myelomeningocele* also may in some cases produce the effects of SCI.

Transverse myelitis (inflammation of the spinal cord) may be caused by illness and has also been reported to develop from inadvertent intraarterial administration of long-acting penicillin injected into the buttocks. Damage can be extensive enough to result in paraplegia or even lower limb amputation.

In MVCs, most SCIs in children are a result of indirect trauma caused by sudden hyperflexion or hyperextension of the neck, often combined with a rotational force. Trauma to the spinal cord without evidence of vertebral fracture or dislocation (SCI without radiographic abnormality, or SCIWORA) is particularly likely to occur in an MVC when proper safety restraints are not used. An unrestrained child becomes a projectile during sudden deceleration and is subject to injury from contact with a variety of objects inside and outside the vehicle. Individuals who use only a lap seat belt restraint are at greater risk for SCI than those who use a combination lap and shoulder restraint. High cervical spine injuries have been reported in children younger than 2 years who are improperly restrained in forward-facing car seats. Infants who are improperly restrained in an infant car seat may experience cervical trauma in a car crash. Small children may also be severely injured by deploying front seat air bags.

Falling from heights occurs less often in children than in adults, but vertebral compression from blows to the head or buttocks can occur in water sports (diving and surfing), falls from horses, or other athletic activities. Birth injuries may occur in breech births from traction force on the spinal cord during birth of the head and shoulders. When shaken, infants commonly sustain cervical cord damage, as well as subdural hematoma and retinal hemorrhage; cognitive impairment and death may occur subsequent to the traumatic event. Infants have weak neck muscles, and during vigorous shaking, their large and heavy heads rapidly wobble back and forth. A significant number of adolescents receive SCIs secondary to gunshot wounds, stabbings, and other violent inflicted injury.

Because of the marked mobility of the neck, fracture or **subluxation** (partial dislocation) is the most common immediate cause of SCI, particularly in the lower cervical region. Although unusual in adults, SCI without fracture is common in children, whose spines are suppler, weaker, and more mobile than those of adults. Therefore the force is more easily dissipated over a larger number of segments. In infants and small children younger than 5 years, upper cervical spine fractures and spinal compression are more common, but adolescents tend to have lower cervical and thoracolumbar fracture dislocations (Retake, 2011).

The severity of the force, the mechanisms of the injury, and the degree of the individual's muscular relaxation at the time of the injury greatly influence the extent of the trauma. SCIs are classified as either *complete* or *incomplete.* In a complete injury, there is no motor or sensory function more than three segments below the neurologic level of the injury (Mathison, Kadom, and Krug, 2008). Incomplete lesions have several typical characteristics (Mathison, Kadom, and Krug, 2008):

- **Central cord syndrome**—Central gray matter destruction and preservation of peripheral tracts; tetraplegia with sacral sparing common; some motor recovery gained
- **Anterior cord syndrome**—Complete motor and sensory loss with trunk and lower extremity proprioception and sensation of pressure
- **Posterior cord syndrome**—Loss of sensation, pain, and proprioception with normal cord function, including motor function; able to move extremities but have difficulty controlling such movements
- **Brown-Séquard syndrome**—Unilateral cord lesion with a motor deficit on the opposite side of the body from the primary insult; absence of pain and temperature sensation on the opposite side from the injury
- **Spinal cord concussion**—Transient loss of neural function below the level of the acute spinal cord lesion, resulting in flaccid paralysis and loss of tendon, autonomic, and cutaneous reflex activity; may last hours to weeks

The American Spinal Injury Association (ASIA) International Standards for Neurological Classification of Spinal Cord Injury worksheet (2011) is available online at http://www.asia-spinalinjury.org/elearning/ISNCSCI_Exam_Sheet_r4.pdf. The ASIA Impairment Scale (Box 49-13) combines motor and sensory function and is used to determine the severity of impairment from the injury (complete or incomplete). It may also be used to measure neurologic changes and functional goals for rehabilitation (Mathison, Kadom, and Krug, 2008).

The injury sustained can affect any of the spinal nerves, and the higher the injury, the more extensive the damage. The child can be left with complete or partial paralysis of the lower extremities **(paraplegia)** or with damage at a higher level and without functional use of any of the four extremities **(tetraplegia).** A high cervical cord injury that affects the phrenic nerve paralyzes the diaphragm and leaves the child dependent on mechanical ventilation.

A mild but equally frightening form of cord trauma is spinal cord compression, a temporary neural dysfunction without visible damage to the cord. Complete quadriplegia can result but initially may not be differentiated from serious cord injury.

BOX 49-13 AMERICAN SPINAL INJURY ASSOCIATION IMPAIRMENT SCALE

A—Complete: No motor or sensory function is preserved in the sacral segments S4-S5.

B—Sensory Incomplete: Sensory but not motor function is preserved below the neurologic level and includes the sacral segments S4-S5, AND no motor function is preserved more than 3 levels below the motor level on either side of the body.

C—Motor Incomplete: Motor function is preserved below the neurologic level, and more than half of key muscle functions below the single neurologic level of injury have a muscle grade less than 3.

D—Motor Incomplete: Motor function is preserved below the neurologic level, and at least half (or more) of key muscles below the neurologic level have a muscle grade of 3 or more.

E—Normal: If sensation and motor function as tested with the ISNCSCI are graded as normal in all segments and the patient had prior deficits, then the AIS grade is E.

For further details and instructions, see the online page at http://www.asia-spinalinjury.org/elearning/ISNCSCI_Exam_Sheet_r4.pdf. Used with permission, American Spinal Injury Association, 2011.

Clinical Manifestations

It is often difficult to determine the extent and severity of damage at first. Immediate loss of function is caused by both anatomic and impaired physiologic function, and improved function may not be evident for weeks or even months. Manifestation of the initial response to acute SCI is flaccid paralysis below the level of the damage. This stage is often referred to as **spinal shock syndrome** and is caused by the sudden disruption of central and autonomic pathways. Local effects of cord edema and ischemia produce a physiologic transection with or without an anatomic severance. Most children with an SCI experience some spinal shock. Manifestations include the absence of reflexes at or below the cord lesion, with flaccidity or limpness of the involved muscles, loss of sensation and motor function, and autonomic dysfunction (symptoms of hypotension, low or high body temperature, loss of bladder and bowel control, and autonomic dysreflexia).

Autonomic paralysis also affects thermoregulatory functions. Afferent impulses from temperature receptors in the skin are not integrated; therefore the patient is subject to temperature increases or decreases in response to alterations in environmental temperature. Hyperthermia can result from excessive ambient temperature, such as too many covers.

Except in the situations previously mentioned, flaccid paralysis is replaced by spinal reflex activity and increasing spasticity or, in incomplete lesions, greater or lesser degree of neurologic recovery.

The paralytic nature of autonomic function is replaced by **autonomic dysreflexia,** especially when the lesions are above the midthoracic level. This autonomic phenomenon is caused by visceral distention or irritation, particularly of the bowel or bladder. Sensory

impulses are triggered and travel to the cord lesion, where they are blocked, which causes activation of sympathetic reflex action with disturbed central inhibitory control. Excessive sympathetic activity is manifested by a flushing face, sweating forehead, pupillary constriction, marked hypertension, headache, and bradycardia. The precipitating stimulus may be merely a full bladder or rectum or other internal or external sensory input. It can be a catastrophic event unless the irritation is relieved.

Additional clinical findings of SCI may include numbness, tingling, or burning; priapism; weakness; and loss of bowel and bladder control (Hayes and Arriola, 2005).

Neurogenic shock occurs as a result of a disruption in the descending sympathetic pathways with loss of vasomotor tone and sympathetic innervations to the cardiovascular system (Hayes and Arriola, 2005). Hypotension, bradycardia, and peripheral vasodilation occur as a result of neurogenic shock.

Children with suspected SCI may have suffered multiple injuries (e.g., head injury); therefore multiple clinical manifestations may occur that may mask those of an SCI.

Therapeutic Management

Initial care begins at the scene of the accident with proper immobilization of the cervical, thoracic, and lumbar spine. Because of the complexity of these injuries, it is usually recommended that these persons be transported to a spinal injury center for care by specially trained health care personnel as soon as possible after the injury for appropriate diagnostic evaluation and intervention.

The initial management of the child with a suspected SCI should begin with an assessment of the ABCs: **a**irway, **b**reathing, and **c**irculation. The airway should be opened using the jaw-thrust technique to minimize damage to the cervical spine. The child is monitored for cardiovascular instability, and measures are taken to support systemic blood pressure and maintain optimal cardiac output. Because MVCs and other trauma in children may involve internal organ damage and potential bleeding, abdominal distention and other signs are acted on immediately to prevent further systemic shock. After the child is stabilized and transported to a regional trauma center, a thorough evaluation of neurologic status and any other associated trauma is carried out by the multidisciplinary team. In the emergency department, spinal immobilization should be maintained until a thorough neurologic assessment is completed and spinal cord injury is ruled out; in children, this typically involves a CT scan and possibly an MRI. Additional interventions are discussed in the Care Management section.

Spinal cord injury management guidelines and standards of care have been published for adult and pediatric patients with SCIs by the American Association of Neurological Surgeons and the Congress of Neurological Surgeons. However, there are no evidence-based guidelines for the management of SCI in children (Mathison, Kadom, and Krug, 2008).

Intravenous methylprednisone may be started within the first 12 hours after the injury to decrease inflammation and minimize further injury; however, its use in small children is controversial.

A number of progressive rehabilitation modalities have been developed in recent years that have the potential for increasing the quality of life for children with SCI. One treatment is functional electrical stimulation (FES), also referred to as *functional neuromuscular stimulation,* or *neuromuscular electrical stimulation.* With this treatment, an electrical stimulator is surgically implanted under the skin in the abdomen and electrode leads are tunneled to paralyzed leg muscles, enabling the child to sit, stand, and walk with the aid of crutches, a walker, or other orthoses. The stimulator can also be used to elicit a voluntary grasp and release with the hand. Before the latter can be accomplished, a number of surgical tendon transfers may be required for elbow extension, wrist extension, and finger and thumb flexion. In addition, FES has therapeutic benefits, which include increased muscle strength, improved gait function, and increased cardiovascular fitness (Thrasher and Popovic, 2008). Tendon transfers have been shown to be successful in enhancing hand and arm function, increasing pinch force, and facilitating independence in ADLs (Hosalkar, Pandya, Hsu, et al., 2009). Restoration of hand and arm function enables children with SCI to perform self-catheterization and achieve greater independence in personal hygiene.

Exercise is considered an integral part of SCI rehabilitation; exercise may enhance neuroplasticity and decrease further muscle atrophy. Examples of exercise modalities in SCI patients include upper body strength training and hand cycling (Hosalkar, Pandya, Hsu, et al., 2009).

Administration of pharmacologic agents such as clonidine hydrochloride may improve ambulation in patients with partial SCIs, and exercise therapy through interactive locomotor training has helped some individuals with SCI regain ambulatory function.

A number of orthoses or ambulation aids such as braces may still be necessary to achieve upright mobility, yet as robotic technology advances, so do the chances for improved mobilization in children with SCI. Mechanical or robotic orthoses may be used in conjunction with FES to enable ambulation in persons with SCI (To, Kirsch, Kobetic, et al., 2005). Gait training may be achieved with a number of different modalities, including a stationary cycle; however, no specific method has proved superior to the others. FES has also been effective in reducing complications from bladder and bowel incontinence and in assisting males in achieving penile erection. Ambulation is an important part of rehabilitation in SCI; retrospective studies found that ambulation was dependent on age at injury and extent of neurologic injury (as measured by ASIA motor scales) (Vogel, Mendoza, Schottler, et al., 2007). Knee-ankle-foot orthosis and reciprocating gait orthosis may also be used to assist with early rehabilitation and ambulation (Vogel, Betz, and Mulcahey, 2012).

Surgical interventions for SCI include early cord decompression (decompression laminectomy) and cervical or thoracic fusion. Crutchfield, Vinke, or Gardner-Wells tongs and skeletal traction may be used for early cervical vertebral stabilization. A halo vest may be suited for ambulation after the acute phase. (See also Cervical Traction, Chapter 48.) After cervical spinal fusion, a hard cervical collar or sterno-occipital-mandibular immobilizer brace may be worn until the fusion is solidified. When SCI occurs in young children and preteens, scoliosis develops over time and often requires surgical consideration (Parent, Mac-Thiong, Roy-Beaudry, et al., 2011).

CARE MANAGEMENT

The nursing care of the child affected by SCI is complex and challenging. A multidisciplinary SCI team is equipped to manage the acute phase of the injury, and some members, including the nurse, may follow the patient to eventual recovery. Nursing management is concerned with ensuring adequate initial stabilization of the entire spinal column with a rigid cervical collar with supportive blocks on a rigid backboard. The traumatic event causing the injury may or may not be recalled if the child lost consciousness; such events are extremely frightening to the child. The young child may also be frightened by the immobilization process and the inability to move

the extremities; therefore it is important to reassure and comfort the child during this process.

During the acute phase of the injury, it is imperative that airway patency be ensured, complications prevented, and function maintained. Evaluate the extent of the neurologic damage early to establish a baseline for neurologic function. Continual assessment of sensory and motor function should occur to prevent further deterioration of neurologic status as a result of spinal cord edema. The ASIA Impairment Scale can be used to assess neurologic function on a routine basis during the patient's recovery. After the patient is admitted, further evaluation of his or her ability to perform ADLs and need for assistance during recovery can be made with the Functional Independence Measure scale.

Nursing care during the acute phase should also focus on frequent monitoring of neurologic signs to determine any changes in neurologic function that require further intervention (e.g., level of consciousness using the Glasgow Coma Scale). In addition to airway maintenance, the nurse should monitor for changes in hemodynamic status that may require immediate medical attention. Neurogenic shock consists of hypotension, bradycardia, and vasodilation. Inotropic medications may be required to maintain adequate perfusion. Renal function is closely monitored by measuring urinary output and fluids administered.

The child with a head injury may experience elevated intracranial pressure; therefore changes in neurologic status are reported to the health care practitioner. Fluid restriction may be required if intracranial pressure is elevated, so fluid intake should be closely monitored.

The nursing care of the child with an SCI is, in most respects, the same as that of any immobilized child (see The Immobilized Child, Chapter 48). Additional aspects of care that should be addressed on an individual basis include hypercalcemia in adolescent boys, DVT, latex sensitization, pain, spasticity, autonomic dysreflexia, and sleep-disordered breathing (Vogel, Hickey, Klaas, et al., 2004; Vogel, Betz, and Mulcahey 2012).

Respiratory care often focuses on maintaining an adequate airway and effective ventilation. The child with a high-level cervical injury (C3 and above) requires continuous ventilatory assistance. In most instances, a tracheostomy is the method of choice for greater ease in clearing secretions and for less trauma to tissues during long-term ventilatory dependence. In some children, breathing pacemaker devices (phrenic nerve stimulators) are implanted to stimulate the phrenic nerve and produce diaphragmatic contractions and lung expansion without assisted ventilation. In the child who does not require mechanical ventilation, special attention to clearance of secretions is vital because of decreased pulmonary function. In addition to percussion and postural drainage, the child may require a cough-assist device to clear secretions effectively (see Duchenne Muscular Dystrophy: Therapeutic Management).

Temperature is often poorly regulated in children with SCI; therefore body temperature must be monitored closely for fluctuations. Response to environmental temperature changes may be slow or absent, and the ability to dissipate heat through the process of shivering may be compromised.

Children with SCI have unique needs in relation to skin care. Because of decreased sensation and impaired mobility, they depend on others to assess and assist in the management of intact skin. Skin care practices are the same as those for any child who is immobilized. A skin score scale such as the Braden Q Scale should be used to objectively evaluate risks for skin breakdown and skin conditions (Noonan, Quigley, and Curley, 2011). An alternating-pressure mattress or other pressure relief or reduction device is kept underneath the child, and the skin is thoroughly inspected at least once a day (or more often if there is increased risk) for signs of pressure and breakdown, especially over bony prominences. Children and adolescents confined to a wheelchair also require meticulous skin care to prevent skin breakdown on insensate areas; frequent position changes and air or gel cushions are helpful but do not eliminate the need for close observation of skin status (McCaskey, Kirk, and Gerdes, 2011).

Bowel and bladder function are often affected in the child with SCI. CIC may be required to regularly empty the neurogenic bladder and prevent urinary tract infections. A regular bowel management program is tailored to the child's needs.

Pain management is vital in children and adolescents with SCI. In children with upper motor neuron involvement, the spasticity that develops may require administration of an antispasmodic medication such as diazepam. Baclofen is considered the drug of choice for reducing muscle spasticity. Gabapentin may be used to treat neuropathic pain. Botulinum toxin type A and α_2-adrenergic agonists may be used in older children with SCI to decrease muscle spasticity.

All adaptive devices help children increase their mobility, function, and endurance. Children with some lower extremity function progress to parallel bars and then to a walker; children with tetraplegia learn to use a wheelchair—among the most valuable aids available to children with SCIs (Fig. 49-8). The wheelchair should be selected carefully in relation to where it will be used, the architectural barriers, and the child's functional capacity. For children with severe upper extremity paralysis, a variety of motorized wheelchairs are used; however, the more complex they are, the greater their cost, weight, and tendency to break down. Wheelchair tolerance is gained over time and is accompanied by measures to prevent orthostatic hypotension and pressure ulcers.

A variety of orthoses and other appliances can be adapted for use by many children. The primary purpose of lower extremity bracing in children with SCIs is for ambulation.

During the recovery and rehabilitation phase, patients with SCI must be carefully monitored for complications of immobility such as DVT and pulmonary embolus. Children with high-level lesions

FIG 49-8 Wheelchair allows adolescent mobility and independence. (Courtesy Texas Children's Hospital, Houston, TX.)

are susceptible to the development of autonomic dysreflexia, which requires prompt action to prevent encephalopathy and shock. Clinical manifestations of autonomic dysreflexia include a drastic increase in systemic blood pressure, headache, bradycardia, profuse diaphoresis, cardiac dysrhythmias, flushing, piloerection, blurred vision, nasal congestion, anxiety, spots on the visual field, or absent or minimum symptoms (Vogel, Hickey, Klaas, et al., 2004). Small children who are unable to verbalize may only become irritable. Early recognition of autonomic dysreflexia by caregivers is essential, especially in small children who are unable to verbalize their feelings. Medications such as nitropaste, nifedipine, prazosin, or terazosin may be administered to counteract the effects of the condition depending on the child's response to interventions (Vogel, Betz, and Mulcahey, 2012).

The child and family with SCI are prepared for the eventual discharge from the acute care facility to a rehabilitation center. The major aims of physical rehabilitation are to prepare the child and family to achieve normalization and resume life at home and in the community. Additional goals of rehabilitation in children with SCI are to promote independence in mobility and self-care skills, academic achievement, independent living, and employment.

The nurse is a crucial member of the health care team in relation to helping the family cope with the magnitude of the injury and disability, understand the extent of the disability, verbalize expected outcomes, and move toward eventual rehabilitation and normalization within the child's capabilities. The goals of rehabilitation include preparing the child and family to live at home and function as independently as possible.

KEY POINTS

- Clinical manifestations of CP include delayed gross motor development; abnormal motor performance; alterations of muscle tone; abnormal postures; reflex abnormalities; and associated disabilities such as cognitive impairment, seizures, and sensory impairment.
- Therapy for CP takes into account the nature of the physical disability, defects associated with the disorder, and interpersonal and social influences encountered by the affected child.
- Care of the infant and child with myelomeningocele is directed toward protecting the meningeal sac, preventing infection and skin breakdown, observing for signs of urologic and bowel complications, and planning appropriate interventions to optimize the child's development.
- SMA is characterized by progressive weakness and wasting of skeletal muscles caused by degeneration of anterior horn cells of the spinal cord.
- MDs are the greatest and most important cause of muscular dysfunction of childhood.
- Major complications of DMD include joint contractures, disuse atrophy, obesity, and respiratory and cardiac problems.
- Nursing care of the child with GBS consists of monitoring vital signs, providing respiratory support and physical therapy, providing reassurance, and providing support to the child and family.
- Tetanus occurs when tetanus spores or vegetative bacilli enter a wound and multiply in a susceptible host.
- Infant botulism results from the release of toxins from *C. botulinum* colonizing the gastrointestinal tract.
- Therapeutic management of SCI is directed toward immobilizing the entire spinal column at the scene of the traumatic event, safely transporting the patient by health care personnel trained to transport possible spinal trauma victims, evaluating neurologic damage, preventing further neurologic damage, and implementing an aggressive rehabilitation program designed to help achieve independence and movement.

APPENDIX

B

Common Laboratory Tests and Test Results*

TEST/SPECIMEN	AGE/GENDER/ REFERENCE	NORMAL RANGES CONVENTIONAL UNITS		INTERNATIONAL UNITS (SI)	
Acetaminophen					
Serum or plasma	Therap. conc.	10-30 mcg/mL		66-200 μmol/L	
	Toxic conc.	>200 mcg/mL		>1300 μmol/L	
Ammonia nitrogen					
Plasma or serum	Newborn	90-150 mcg/dL		64-107 μmol/L	
	0-2 wk	79-129 mcg/dL		56-92 μmol/L	
	>1 mo	29-70 mcg/dL		21-50 μmol/L	
	Thereafter	0-50 mcg/dL		0-35.7 μmol/L	
Antistreptolysin O titer (ASO)					
Serum	2-4 yr	<160 Todd units			
	School-age children	170-330 Todd units			
Base excess					
Whole blood	Newborn	(–10)-(–2) mEq/L		(–10)-(–2) mmol/L	
	Infant	(–7)-(–1) mEq/L		(–7)-(–1) mmol/L	
	Child	(–4)-(+2) mEq/L		(–4)-(+2) mmol/L	
	Thereafter	(–3)-(+3) mEq/L		(–3)-(+3) mmol/L	
Bicarbonate (HCO_3)					
Serum	Arterial	21-28 mEq/L		21-28 mmol/L	
	Venous	22-29 mEq/L		22-29 mmol/L	
Bilirubin, total		**Premature** (mg/dL)	**Full term** (mg/dL)	**Premature** (μmol/L)	**Full term** (μmol/L)
Serum	Cord	<2.0	<2.0	<34	<34
	0-1 d	<8.0	<6.0	<137	<103
	1-2 d	<12.0	<8.0	<205	<137
	2-5 d	<16.0	<12.0	<274	<205
	Thereafter	<20.0	<10.0	<340	<171
Bilirubin, direct (conjugated)					
Serum		0.0-0.2 mg/dL		0-3.4 μmol/L	
Bleeding time					
Blood from skin puncture					
Ivy	Normal	2-7 min		2-7 min	
	Borderline	7-11 min		7-11 min	
Simplate (G-D)		2.75-8 min		2.75-8 min	
Blood volume					
Whole blood	Male	52-83 mL/kg		0.052-0.083 L/kg	
	Female	50-75 mL/kg		0.050-0.075 L/kg	
C-reactive protein (CRP)					
Serum	Cord	52-1330 ng/mL		52-1330 mcg/L	
	2-12 yr	67-1800 ng/mL		67-1800 mcg/L	

Continued

TEST/SPECIMEN	AGE/GENDER/ REFERENCE	NORMAL RANGES	
		CONVENTIONAL UNITS	INTERNATIONAL UNITS (SI)
Calcium, ionized			
Serum, plasma, or whole blood	Cord	5.0-6.0 mg/dL	1.25-1.50 mmol/L
	Newborn, 3-24 hr	4.3-5.1 mg/dL	1.07-1.27 mmol/L
	24-48 hr	4.0-4.7 mg/dL	1.00-1.17 mmol/L
	Thereafter	4.8-4.92 mg/dL or 2.24-2.46 mEq/L	1.12-1.23 mmol/L
Calcium, total			
Serum	Cord	9.0-11.5 mg/dL	2.25-2.88 mmol/L
	Newborn, 3-24 hr	9.0-10.6 mg/dL	2.3-2.65 mmol/L
	24-48 hr	7.0-12.0 mg/dL	1.75-3.0 mmol/L
	4-7 d	9.0-10.9 mg/dL	2.25-2.73 mmol/L
	Child	8.8-10.8 mg/dL	2.2-2.70 mmol/L
	Thereafter	8.4-10.2 mg/dL	2.1-2.55 mmol/L
Carbon dioxide, partial pressure (PCO_2)			
Whole blood, arterial	Newborn	27-40 mm Hg	3.6-5.3 kPa
	Infant	27-41 mm Hg	3.6-5.5 kPa
	Thereafter:		
	Male	35-48 mm Hg	4.7-6.4 kPa
	Female	32-45 mm Hg	4.3-6.0 kPa
Carbon dioxide, total (tCO_2)			
Serum or plasma	Cord	14-22 mEq/L	14-22 mmol/L
	Premature (1 wk)	14-27 mEq/L	14-27 mmol/L
	Newborn	13-22 mEq/L	13-22 mmol/L
	Infant, child	20-28 mEq/L	20-28 mmol/L
	Thereafter	23-30 mEq/L	23-30 mmol/L
Cerebrospinal fluid (CSF)			
Pressure		70-180 mm H_2O	70-180 mm H_2O
Volume	Child	60-100 mL	0.06-0.10 L
	Adult	100-160 mL	0.10-0.16 L
Chloride			
Serum or plasma	Cord	96-104 mEq/L	96-104 mmol/L
	Newborn	97-110 mEq/L	97-110 mmol/L
	Thereafter	98-106 mEq/L	98-106 mmol/L
Sweat	Normal (homozygote)	<40 mEq/L	<40 mmol/L
	Marginal (e.g., asthma, Addison disease, malnutrition)	45-60 mEq/L	45-60 mmol/L
	Cystic fibrosis	>60 mEq/L	>60 mmol/L
Cholesterol, total			
Serum or plasma†	Acceptable	<170 mg/dL	<4.4 mmol/L
	Borderline	170-199 mg/dL	4.4-5.1 mmol/L
	High	≥200 mg/dL	≥5.2 mmol/L
Clotting time (Lee-White)			
Whole blood		5-8 min (glass tubes)	5-8 min
		5-15 min (room temp)	5-15 min
		30 min (silicone tube)	30 min
Creatine kinase (CK, CPK)			
Serum	Cord	70-380 U/L	70-380 U/L
	5-8 hr	214-1175 U/L	214-1175 U/L
	24-33 hr	130-1200 U/L	130-1200 U/L
	72-100 hr	87-725 U/L	87-725 U/L
	Adult	5-130 U/L	5-130 U/L

TEST/SPECIMEN	AGE/GENDER/ REFERENCE	NORMAL RANGES	
		CONVENTIONAL UNITS	INTERNATIONAL UNITS (SI)
Creatinine			
Serum	Cord	0.6-1.2 mg/dL	53-106 μmol/L
	Newborn	0.3-1.0 mg/dL	27-88 μmol/L
	Infant	0.2-0.4 mg/d	18-35 μmol/L
	Child	0.3-0.7 mg/dL	27-62 μmol/L
	Adolescent	0.5-1.0 mg/dL	44-88 μmol/L
	Adult:		
	Male	0.6-1.2 mg/dL	53-106 μmol/L
	Female	0.5-1.1 mg/dL	44-97 μmol/L
Urine, 24 hr	Premature	8.1-15.0 mg/kg/24 hr	72-133 μmol/kg/24 hr
	Full term	10.4-19.7 mg/kg/24 hr	92-174 μmol/kg/24 hr
	1.5-7 yr	10-15 mg/kg/24 hr	88-133 μmol/kg/24 hr
	7-15 yr	5.2-41 mg/kg/24 hr	46-362 μmol/kg/24 hr
Creatinine clearance (endogenous)			
Serum or plasma and urine	Newborn	40-65 mL/min/1.73 m^2	
	<40 yr:		
	Male	97-137 mL/min/1.73 m^2	
	Female	88-128 mL/min/1.73 m^2	
Digoxin			
Serum, plasma; collect at least 12 hr after dose	Therap. conc.		
	CHF	0.8-1.5 ng/mL	1.0-1.9 nmol/L
	Arrhythmias	1.5-2.0 ng/mL	1.9-2.6 nmol/L
	Toxic conc.		
	Child	>2.5 ng/mL	>3.2 nmol/L
	Adult	>3.0 ng/mL	>3.8 nmol/L
Eosinophil count			
Whole blood, capillary blood		50-250 cells/mm^3 (μL)	50-250 × 10^6 cells/L
Erythrocyte (RBC) count			
Whole blood	Cord	3.9-5.5 million/mm^3	3.9-5.5 × 10^{12} cells/L
	1-3 d	4.0-6.6 million/mm^3	4.0-6.6 × 10^{12} cells/L
	1 wk	3.9-6.3 million/mm^3	3.9-6.3 × 10^{12} cells/L
	2 wk	3.6-6.2 million/mm^3	3.6-6.2 × 10^{12} cells/L
	1 mo	3.0-5.4 million/mm^3	3.0-5.4 × 10^{12} cells/L
	2 mo	2.7-4.9 million/mm^3	2.7-4.9 × 10^{12} cells/L
	3-6 mo	3.1-4.5 million/mm^3	3.1-4.5 × 10^{12} cells/L
	0.5-2 yr	3.7-5.3 million/mm^3	3.7-5.3 × 10^{12} cells/L
	2-6 yr	3.9-5.3 million/mm^3	3.9-5.3 × 10^{12} cells/L
	6-12 yr	4.0-5.2 million/mm^3	4.0-5.2 × 10^{12} cells/L
	12-18 yr:		
	Male	4.5-5.3 million/mm^3	4.5-5.3 × 10^{12} cells/L
	Female	4.1-5.1 million/mm^3	4.1-5.1 × 10^{12} cells/L
Erythrocyte sedimentation rate (ESR)			
Whole blood			
Westergren (modified)	Child	0-10 mm/hr	0-10 mm/hr
	<50 yr:		
	Male	0-15 mm/hr	0-15 mm/hr
	Female	0-20 mm/hr	0-20 mm/hr
Wintrobe	Child	0-13 mm/hr	0-13 mm/hr
	Adult:
