Fathers who have custody of their children have many of the same problems as divorced mothers. They feel overburdened by the responsibility, depressed, and concerned about their ability to cope with the emotional needs of the children, especially girls. Some fathers lack homemaking skills. They may find it difficult at first to coordinate household tasks, school visits, and other activities associated with managing a household alone.

Parenting in Reconstituted Families

In the United States, many of the children living in homes where parents have divorced will experience another major change in their lives such as the addition of a stepparent or new siblings (Coehlo, Kaakinen, Hanson, et al., 2009).

The entry of a stepparent into a ready-made family requires adjustments for all family members. Some obstacles to the role adjustments and family problem solving include disruption of previous lifestyles and interaction patterns, complexity in the formation of new ones, and lack of social supports. Despite these problems, most children from divorced families want to live in a two-parent home.

Cooperative parenting relationships can allow more time for each set of parents to be alone to establish their own relationship with the children. Under ideal circumstances, power conflicts between the two households can be reduced and tension and anxiety can be lessened for all family members. In addition, the children's self-esteem can be increased and continued contact with grandparents is more likely. Flexibility, mutual support, and open communication are critical in successful relationships in stepfamilies and stepparenting situations.

Parenting in Dual-Earner Families

No change in family lifestyle has had more impact than the large numbers of women moving away from the traditional homemaker role and entering the workplace (Coehlo, Kaakinen, Hanson, et al., 2009). Working mothers have become the norm in the United States.

The trend toward increased numbers of dual-earner families is unlikely to diminish significantly. As a result, the family is subject to considerable stress as members attempt to meet often competing demands of occupational needs and those regarded as necessary for a rich family life.

Role definitions are frequently altered to arrange a more equitable division of time and labor, as well as to resolve conflict, especially conflict related to traditional cultural norms. Overload is a common source of stress in a dual-earner family, and social activities are significantly curtailed. Time demands and scheduling are major problems for all individuals who work. When the individuals are parents, the demands can be even more intense. Dual-earner couples may increase the strain on themselves to avoid creating stress for their children. Although no evidence indicates that the dual-earner lifestyle is stressful to children, the stress experienced by the parents may affect the children indirectly.

Maternal employment may have variable effects on preschool children's health (Mindlin, Jenkins, and Law, 2009). The quality of child care is a persistent concern for all working parents. Determinants of child care quality are based on health and safety requirements, responsive and warm interaction between staff and children, developmentally appropriate activities, trained staff, limited group size, age-appropriate caregivers, adequate staff-to-child ratios, and adequate indoor and outdoor space. Nurses play an important role in helping families find suitable sources of child care and prepare children for this experience.

Kinship Care

Since the 1980s, the proportion of children in out-of-home care placed with relatives has increased rapidly. More than 2.6 million U.S. children are raised by grandparents or other kin at some time in their lives (Annie E. Casey Foundation, 2012). According to U.S. Census Bureau data, kinship caregivers are more likely to be poor, single, older, less educated, and unemployed than families in which at least one parent is present.

Foster Parenting

The term **foster care** is defined as placement in an approved living situation away from the family of origin (Annie E. Casey Foundation, 2012). The living situation may be an approved foster home, possibly with other children, or a preadoptive home. Each state provides a standard for the role of foster parent and a process by which to become one. These "parents" contract with the state to provide a home for children for a limited duration. Most states require about 27 hours of training before being on contract and at least 12 hours of continuing education a year. Foster parents may be required to attend a foster parent support group that is often separate from a state agency. Each state has guidelines regarding the relative health of the prospective foster parents and their families, background checks regarding legal issues for the adults, personal interviews, and a safety inspection of the residence and surroundings (Chamberlain, Price, Leve, et al., 2008).

Nurses should be aware that nearly 700,000 children spend time living in foster care in a given year, many of them facing developmental concerns (Annie E. Casey Foundation, 2012). Children from lower-income, single-mother, and mother-partner families are considerably more likely to be living in foster care (Berger and Waldfogel, 2004). Children in foster care tend to have a higher-than-normal incidence of acute and chronic health problems and may experience feelings of isolation or confusion (Annie E. Casey Foundation, 2012). Foster children are often at risk because of their previous caregiving environment. Nurses should strive to implement strategies to improve the health care for this group of children. In particular, assessment and case management skills are required to involve other disciplines in meeting their needs.

SOCIAL, CULTURAL, AND RELIGIOUS INFLUENCES

Promoting the health of children requires a nurse to understand social, cultural, and religious influences on children and their families. The U.S. population is constantly evolving; patients experience negative health outcomes when social, cultural, and religious factors are not considered as influencing their health care; families may incorporate other health care systems such as Eastern medicine or traditional healing into their lives; and it is required by legislative, regulatory, and credentialing bodies (Tervalon, 2003). Educating health care providers is one way to reduce disparities in health care.

Cultural humility is a "commitment and active engagement in a lifelong process that individuals enter into for an on-going basis

CULTURAL COMPETENCE

Cultural Definitions

Culture characterizes a particular group with its values, beliefs, norms, patterns, and practices that are learned, shared, and transmitted from one generation to another (Leininger, 2001). Culture differs from both race and ethnicity. *Race* is a term with roots in anthropology, distinguishing variety in humans by physical traits. *Ethnicity* is the affiliation of a set of persons who share a unique cultural, social, and linguistic heritage. *Gender* is an individual's self-identification as man or woman, and *sex* is the biologic designation of male or female. *Social class* is a complex social construction that usually incorporates levels of education in the family, occupation, income, and access to resources. *Socialization* is the process by which society communicates its competencies, values, and expectations to children (Trawick-Smith, 2006). *Culture* is a complex whole in which each part is interrelated. It is an umbrella term that holds together many interrelated yet unique aspects of humanity, including beliefs, tradition, life ways, and heritage. It is much more than a country of origin or a demographic designation such as African-American or Caucasian.

CULTURAL COMPETENCE

Five Components of Cultural Competence

Cultural competence includes following five components (Munoz and Luckmann, 2005):

1. **Cultural awareness**—A cognitive process through which the nurse appreciates and is sensitive to the cultural values of the patient and family
2. **Cultural knowledge**—The foundation the nurse builds through formal and informal education that includes world views of different cultures, values, beliefs, and perceptions about health and illness
3. **Cultural skill**—The ability to include cultural data in the nursing assessment through the collection of cultural data in the health interview and observations
4. **Cultural encounter**—The process through which the nurse seeks opportunities to engage in cross-cultural interactions directly or indirectly
5. **Cultural desire**—The genuine and sincere motivation to work effectively with minority patients; can only be achieved if the individual wants to engage in the process of acquiring cultural competence

with patients, communities, colleagues, and themselves" (Tervalon and Murray-Garcia, 1998, p. 118). It requires that health care providers participate in continual process of self-reflection and self-critique that recognizes the power of the health care provider role, that views the patient and family as full members of the health care team, and that does not end after reading one chapter or attending one course but is an evolving aspect of being a health care provider. "Cultural competency is not an abdominal exam" (Kumagai and Lypson, 2009, p. 783). It is not a static endpoint to be checked off the list but an ongoing process that promotes deeper thinking and knowledge of oneself, others, and the world (Kumagai and Lypson, 2009). (See Cultural Competence box.)

It is important to understand nursing's contribution to culturally congruent care. A holistic view of care was first described by Madeleine Leininger, the recognized founder of transcultural nursing, in her culture care diversity and universality theory (Leininger, 2001; Munoz and Luckmann, 2005). The theory provides an intellectual framework and a research methodology for providing culturally congruent patient care. Nurses must remain aware that every family, child, and health care provider comes to a clinical encounter with a cultural lens through which they see and interpret the world.

Cultures and subcultures contribute to the uniqueness of child members in such a subtle way and at such an early age that children grow up to think that their beliefs, attitudes, values, and practices are the "correct" or "normal" ones. By age 5 years, children can identify persons who belong to their cultural background. During later primary years, children can identify those from different cultures (Trawick-Smith, 2006). A set of values learned in childhood is likely to characterize children's attitudes and behavior for life, influencing their long-range goals and their short-range, impulsive inclinations. Thus every ongoing society socializes each succeeding generation to its cultural heritage. (See Cultural Competence box.)

The manner and sequence of the growth and development phenomenon are universal and fundamental features of all children; however, children's varied behavioral responses to similar events are often determined by their culture. Culture plays a critical role in the parenting behaviors that facilitate children's development (Melendez, 2005). Children acquire the skills, knowledge, beliefs, and values important to their own family and culture. Cultural backgrounds can influence the pace of acquisition of cognitive and motor skills as well as the child's social and emotional development (Trawick-Smith, 2006).

Cultures may also differ in whether status in a group is based on age or on skill. Even children's play and their types of games are culturally determined. In some cultures, children play in groups composed of members of the same gender; in others they play in mixed-gender groups. In some cultures, team games predominate; in others, most play is limited to individual games.

Standards and norms vary from culture to culture and from location to location; a practice that is accepted in one area may meet with disapproval or create tension in another. The extent to which cultures tolerate divergence from the established norm also varies among cultures and subcultural groups. Although conforming to cultural norms provides a degree of security, it is a decided deterrent to change.

! NURSING ALERT

American cultures and subcultures can be so diverse that it is essential that nurses be aware of and knowledgeable about the predominant groups in their work community and apply this knowledge in their practice.

Social Roles

Much of children's self-concept comes from their ideas about their social roles. Roles are cultural creations; therefore the culture prescribes patterns of behavior for persons in a variety of social positions. All persons who hold similar social positions have an obligation to behave in a particular manner. A role prohibits some behaviors and allows others. Because culture outlines and clarifies roles, it is a significant influence on the development of children's self-concept (i.e., attitudes and beliefs they have about themselves).

A social group consists of a system of roles carried out in both primary and secondary groups. A **primary group** has intimate, continued, face-to-face contact; mutual support of members; and the ability to order or constrain a considerable proportion of individual members' behavior. Two such groups are the family and the peer group, both of which have a great deal of influence on the child.

Secondary groups are groups that have limited, intermittent contact and generally less concern for members' behavior. These groups offer little in terms of support or pressure toward conformity

except in rigidly limited areas. Examples of secondary groups are professional associations and social organizations such as church groups.

A concept of social role also depends largely on whether a child is reared in a primary- or secondary-group community. Children are subjected to perceptibly different forms of parental training in these two types of environments. The influences, strengths, and limitations of both groups are significant.

In a primary-group community (e.g., family; peer group; some contemporary rural, religious, or ethnic communities), all members know each other, most belong to the same subgroups, and all are concerned about each member's behavior. Community members have a high degree of material and psychologic support and one traditional set of values that the entire group agrees on and supports; thus there is little conflict of values. In a stable community where the members remain within comparatively defined limits and relatives are likely to live close together, young members have ample opportunity to observe and absorb cultural practices and customs. Any member of the community feels justified in evaluating and censuring the conduct of another member.

Children reared in the relative isolation of secondary-group environmental influences tend to learn that there is only one acceptable way to respond to any given situation. The entire group agrees, and any tendency to deviate is met with collective disapproval. It is the parents' duty to see that the children learn and follow social roles and modes of behavior defined and strengthened by the views of the community.

The childrearing orientation in a secondary-group environment, such as urban communities, can differ considerably from that of a primary-group environment. The interaction between primary and secondary groups may reinforce values when both groups endorse that value or create confusion or conflict when one group rejects a value accepted by the other. An urban community is dynamic. Many of the traditional behaviors and values may not meet the needs of the changing society. Consequently, parents are often uncertain about what to teach their children. They may wish to rear their children with values consistent with their own, but the differences in experience between the generations are too great. As a result, they often grant their children autonomy in some areas of decision making early in the developmental process and other secondary groups assume a greater influence. None of the groups is highly dominant in its influence; therefore the children are exposed to an eclectic set of values and expectations, some in agreement and some in conflict. From these they must ultimately select those that they determine to be best for them and adopt them to form a consistent set of roles and behaviors to incorporate into the self-concept.

Self-Esteem and Culture

Culture influences a child's sense of self-esteem (Trawick-Smith, 2006). Some cultures are more collective in thought and action. A child from a collective culture will hold an inclusive view of himself or herself. Self-evaluation is related to the accomplishments or competencies of the entire family or community. School experiences that focus on personal achievement may promote positive self-esteem in some children but not in others who depend more on the success of a whole family or peer group. Their sense of control may not come from individual self-reliance but, rather, from a feeling of worth in their family or community (Trawick-Smith, 2006).

Families and culture also influence the criteria children use to evaluate their own abilities. In addition, cultures vary in whether they instill an internal locus of control (a belief in the ability to regulate one's own life). Effects on self-esteem are minimal if these beliefs are directed by parents and are in accordance with cultural customs (Trawick-Smith, 2006). Ethnic pride can help children maintain a positive self-image and counteract the effects of prejudice, which can have a negative impact on emotional health (Trawick-Smith, 2006).

Communities

Surveys of more than 1 million youth in the United States in grades 6 through 12 have shown that persons who experience a higher number of specific assets in their lives are more likely to make healthy choices and avoid high risk behaviors. These assets offer a framework for positive child and adolescent development. The child's or adolescent's community is made up of family, school, neighborhood, youth organization, and other members (Fig. 27-5).

Four categories of external assets that youth receive from the community are (Search Institute, 2007):

1. **Support**—Young people need to feel support, care, and love from their families, neighbors, and others. They also need organizations and institutions that offer positive, supportive environments.
2. **Empowerment**—Young people need to feel valued by their community and be able to contribute to others. They need to feel safe and secure.
3. **Boundaries and expectations**—Young people need to know what is expected of them and what activities and behaviors are within the community boundaries and what are outside of them.
4. **Constructive use of time**—Young people need opportunities for growth through constructive, enriching opportunities and through quality time at home.

FIG 27-5 Youngsters from different cultural backgrounds interact within the larger culture. (© 2012 Photos.com, a division of Getty Images. All rights reserved.)

Internal assets must also be nurtured in the community's young members. These internal qualities guide choices and create a sense of centeredness, purpose, and focus. The four categories of internal assets are (Search Institute, 2007):

1. **Commitment to learning**—Young people need to develop a commitment to education and lifelong learning.
2. **Positive values**—Youth need to have a strong sense of values that direct their choices.
3. **Social competencies**—Young people need competencies that help them make positive choices and build relationships.
4. **Positive identity**—Young people need a sense of their own power, purpose, worth, and promise.

Peer Groups

Peer groups also have an impact on the socialization of children (Fig. 27-6). Peer relationships become increasingly important and influential as children proceed through school. In school, children have what can be regarded as a culture of their own. This is even more apparent in unsupervised playgroups because the culture in school is partly produced by adults.

During their lives, children are exposed to value systems such as those of the family, ethnic group, and social class. In peer-group interactions, they confront a variety of these sets of values. The values imposed by the peer group are especially compelling because children must accept and conform to them to be accepted as members of the group. When the peer values are not too different from those of family and teachers, the mild conflict created by these small differences serves to separate children from the adults in their lives and to strengthen the feeling of belonging to the peer group.

The kind of socialization provided by the peer group depends on the subculture that develops from its members' background, interests, and capabilities. Some groups support school achievement, others focus on athletic prowess, and still others are decidedly against educative goals. Scholastic achievement is strongly related to the peer group's value system. Many conflicts between teachers and students and between parents and students can be attributed to fear of rejection by peers. What is expected from parents regarding academic achievement and what is expected from the peer culture often conflict, especially during high school.

FIG 27-6 Children from a variety of cultural and ethnic backgrounds begin to socialize in the child care setting. (© 2012 Photos.com, a division of Getty Images. All rights reserved.)

Although the peer group has neither the traditional authority of the parents nor the legal authority of the schools for teaching information, it manages to convey a substantial amount of information to its members, especially on taboo subjects such as sex and drugs. Children's need for the friendship of their peers brings them into an increasingly complex social system. Through peer relationships, children learn to deal with dominance and hostility and to relate with persons in positions of leadership and authority. Other functions of the peer subculture are to relieve boredom and to provide recognition that individual members do not receive from teachers and other authority figures.

The peer-group culture has secrets, mores, and codes of ethics that promote group solidarity and detachment from adults. They have traditions and folkways, including age-related games and other activities, that are transferred from "generation to generation" of schoolchildren and that have a great influence over the behavior of all group members. As children move from one level to the next, they discard the folkways of the younger group as they adopt those of the new group. For example, a school-age child rides a bicycle to school; the high school student prefers a car. As they advance, children are forward oriented only—they look forward with anticipation but may look backward with contempt.

Cultural Health Beliefs and Practices

Nurses encounter people of many different racial and ethnic origins in the process of meeting the health needs of children and families. Some of these families have become so enculturated to the majority culture that their health beliefs and practices are consistent with those of the health care system. For many families, however, traditional practices and beliefs are an integral part of their daily lives. Health care workers should be aware that other people might live by different rules and priorities, which decisively influence their health-related behavior. Guidelines for exploring a family's culture are found in Box 27-3.

A model for learning about health traditions that differ from the Western, or modern, health care system is based on three dimensions:

1. What are the physical aspects of caring for the body (e.g., are there special clothes, foods, medicines)?
2. What are the mental parts of caring for health (e.g., feelings, attitudes, rituals, actions)?
3. What are the spiritual aspects of health (who I am, spiritual customs, prayers, healers)?

BOX 27-3 EXPLORING A FAMILY'S CULTURE, ILLNESS, AND CARE

- What do you think caused your child's health problem?
- Why do you think it started when it did?
- How severe is your child's sickness? Will it have a short or long course?
- How do you think your child's sickness affects your family?
- What are the chief problems your child's sickness has caused?
- What kind of treatment do you think your child should receive?
- What are the most important results you hope to receive from your child's treatment?
- What do you fear most about your child's sickness?

Adapted from Kleinman A, Eisenberg L, Good B: Culture, illness, and care: clinical lessons from anthropologic and cross-cultural research, *Ann Intern Med* 88:251–258, 1978.

For each of these dimensions, one must consider the cultural traditions used to maintain health, protect health, and restore health (Spector, 2009).

Health Beliefs

The beliefs related to the cause of illness and the maintenance of health are integral parts of a family's cultural heritage. Often inseparable from religious beliefs, they influence the way families cope with health problems and respond to health care providers. Predominant among most cultures are beliefs related to natural forces, supernatural forces, and an imbalance between forces.

Natural Forces. The most common natural forces held responsible for ill health if the body is not adequately protected include cold air entering the body and impurities in the air. For example, a Chinese parent may overdress an infant in an effort to keep cold wind from entering the child's body. The Chinese believe that cold weather, rain, or wind is responsible for "cold" conditions. They also believe that an innate energy called *chi* enters and leaves the body through the mouth, nose, and ears and flows through the body in definite pathways, or meridians, at specific times and locations. The Chinese believe that a lack of chi and blood causes fatigue, low energy, and a variety of ailments.

Supernatural Forces. Some cultures view evil influences such as voodoo, witchcraft, or evil spirits as causes of illness, especially illnesses that cannot be explained by other means.

A health belief that is common among people from Latin American, Mediterranean, some Asian, and some African societies is the concept of the "evil eye" (Spector, 2009). It is part of the concept of health as a state of balance and illness as a state of imbalance (see following section). Strength and power are associated with the evil eye; therefore, as long as an individual's strength and weakness remain in balance, he or she is unlikely to become a victim of the evil eye. Weaknesses are not necessarily physical. For example, an excess of some emotion, such as envy, can create weakness. Infants and small children, because of immature development of their internal strength-weakness states, are especially vulnerable to the gaze of the evil eye. Consequently, the evil eye serves to rationalize an inexplicable onset of illness in children who display symptoms such as restlessness, crying, diarrhea, vomiting, and fever.

Imbalance of Forces. The concept of balance or equilibrium is widespread throughout the world. One of the most common imbalances is that which exists between "hot" and "cold." This belief derived from the ancient Greek concept of body humors (Andrews and Boyle, 2008), which states that illness is caused by an imbalance of the four humors: phlegm, blood, black bile, and yellow bile. These are balanced in healthy people and out of balance in those with illnesses. Such imbalance is thought to cause internal damage or altered function. Treatment of the illness is directed at restoring balance. The hot and cold understanding of disease is based in this concept. Diseases, areas of the body, foods, and illnesses are classified as either "hot" or "cold." Foods and beverages are designated hot or cold based on the effect they exert, not their actual temperature. In Chinese health belief, the forces are termed *yin* (cold) and *yang* (hot) (Spector, 2009).

Illness is treated by restoring normal balance through the application of appropriate "hot" or "cold" remedies. A "cold" condition such as a respiratory disease is believed to be caused by exposure to cold weather, rain, or cold wind entering the body; it is treated by administration of "hot" foods, herbs, or drugs. Menstruation is considered a "hot" condition; therefore women are cautioned against ingesting "hot" foods, which might increase menstrual flow or produce cramping. Ingesting too much of either "hot" or "cold" foods can also be interpreted as a cause of illness.

Health care workers who are aware of this belief are better able to understand why some persons refuse to eat certain foods. It is often useful to discuss the diet with the family to determine their beliefs regarding food choices. It is possible to help families devise a diet that contains the necessary balance of basic food groups prescribed by the medical subculture while conforming to the beliefs of the ethnic subculture.

The "hot-cold" food classification may have adverse effects. For example, in some cultures, newborn infants are often started on evaporated milk formulas. Whereas evaporated milk is considered a "hot" food, whole milk is viewed as a "cold" food. Infants tend to develop rashes, which are believed to be caused by "hot" foods; in such cases, parents may decide to switch to whole milk. However, parents fear that it is dangerous to change too rapidly, so they often feed the child some type of neutralizing substance, which may create additional health problems. The nurse can help avoid such a problem by determining the family's preference before discharge from the hospital and prescribing a formula that is agreeable to both the family and the practitioner.

Health Practices

Cultures have numerous similarities regarding prevention and treatment of illness. The folk healers are powerful persons in their community and can acquire information about an illness without resorting to probing questions. They "speak the language" of the family who seeks help and often combine their rituals and potions with prayer and entreaties to God. They also are able to create an atmosphere conducive to successful management. Furthermore, they exhibit a sincere interest in the family and their problem.

Some folk remedies are compatible with the medical regimen and are useful to reinforce the treatment plan. For example, aspirin (a "hot" medication) is an appropriate therapy for "cold" diseases such as arthritis. It is common to discover that a folk prescription has a scientific basis. In any case, respect practices that do not harm patients.

In cultures that believe in the concept, overcoming the effect of the evil eye usually requires specialized rituals conducted by the appropriate practitioner. For example, the Hispanic *curandero* ascertains that the condition is truly the result of the evil eye by performing an assessment ritual and then performs a curative ritual. Sometimes faith in the folk practitioner delays obtaining needed medical treatment, although the practitioner usually suggests medical care if his or her efforts are unsuccessful.

Health practices of different cultures may also present problems of assessment and interpretation. For example, certain cultural practices or remedies can be mistakenly judged as evidence of child abuse by uninformed professionals (Box 27-4). It is important to keep the lines of communication open with families and approach the situation with a sense of cultural humility.

Faith healing and religious rituals are closely allied with many folk-healing practices. Wearing of amulets, medals, and other religious relics believed by the culture to protect the individual and facilitate healing is a common practice. It is important for health care workers to recognize the value of this practice and keep the items where the family has placed them or nearby. It offers comfort and support and rarely impedes medical and nursing care. If an item must be removed during a procedure, it should be replaced, if possible, when the procedure is completed. The nurse should explain the reason for its temporary removal to the family to reassure them their wishes will be respected (see Family-Centered Care box).

BOX 27-4 CULTURAL PRACTICES POSSIBLY CONSIDERED ABUSIVE BY THE DOMINANT CULTURE

Coining—A Vietnamese practice that may produce weltlike lesions on the child's back when the edge of a coin is repeatedly rubbed lengthwise on the oiled skin to rid the body of disease.

Cupping—An Old World practice (also practiced by the Vietnamese) of placing a container (e.g., tumbler, bottle, jar) containing steam against the skin surface to "draw out the poison" or other evil element. When the heated air within the container cools, a vacuum is created that produces a bruiselike blemish on the skin directly beneath the mouth of the container.

Burning—A practice of some Southeast Asian groups whereby small areas of skin are burned to treat enuresis and temper tantrums.

Female genital mutilation (female circumcision)—Removal of or injury to any part of the female genital organ; practiced in Africa, the Middle East, Latin America, India, Asia, North America, Australia, and Western Europe.

Forced kneeling—A child discipline measure of some Caribbean groups in which a child is forced to kneel for a long time.

Topical garlic application—A practice of Yemenite Jews in which crushed garlic cloves or garlic–petroleum jelly plaster is applied to the wrists to treat infectious disease. The practice can result in blisters or garlic burns.

Traditional remedies that contain lead—*Greta* and *azarcon* (Mexico; used for digestive problems), *payloooah* (Southeast Asia; used for rash or fever), and *surma* (India; used as a cosmetic to improve eyesight).

FAMILY-CENTERED CARE

Cultural Awareness

A 15-month-old Bosnian girl in status epilepticus was carried in by her parents. They were frightened and spoke little English. I learned that the child had received a measles, mumps, and rubella (MMR) immunization the day before. As I proceeded to unwrap her from the blanket she was in, I quickly assessed the ABCs (airway, breathing, and circulation). I noticed that she was warm (probably a febrile seizure) and that a rag soaked in alcohol was tied around each thigh. Focusing on her potential airway compromise and trying to calm the parents, I proceeded to put an oxygen mask on her, undress her for a full assessment, and remove the alcohol rags. I spoke to the parents all the while in a calm, soothing voice. Once I had established an intravenous line and given her lorazepam (Ativan), the seizures stopped. So did the communication between her parents and me. I noticed that they would no longer give me eye contact, and the mother would not even speak to me after the seizures stopped. It wasn't until I was returning to the department from admitting her that I realized why they might have stopped communicating with me—I had removed the rags! Had I only thought to replace the rags or asked their permission to remove the rags, things may have been different.

Religious Beliefs and Practices

Religion and spirituality also exert a significant influence on the health of children and families and the decisions made around health and illness. Many immigrants came to the United States for religious freedom and established a religious and moral atmosphere that persists today. However, individual differences are part of the general culture.

FIG 27-7 Soon after an infant is born, many families have special religious ceremonies.

The family's religious orientation dictates a code of behavior and influences the family's attitudes toward education, male and female role identity, and their ultimate destiny. It may also determine the school that the children attend, their companions, and often their mate selection. Religious beliefs are such an integral part of many cultures that it is difficult to distinguish the culture from the religion. In a few instances, such as in the Mennonite and Amish communities, religion is the basis for a common way of life that determines where the children are raised and their lifestyle. It is also important to remember that families who do not subscribe to a particular religion or who are atheist also have beliefs and convictions about family, the surrounding world, and life in general that influence children in these families.

Religious and spiritual dimensions are among the most important influences in many people's lives (Fig. 27-7). The terms *religion* and *spirituality* are often used interchangeably, but this is a mistake. Spirituality is "concerned with the deepest levels of human experiencing, the places of deepest…meaning in and for our lives" (Mercer, 2006). For children, in particular, spirituality possesses a relational consciousness; it concerns the child in relation to the source of power (God, Allah) that gives meaning to the relationship, other people, the surrounding world, and within oneself (Mercer, 2006). Religion, on the other hand, is a particular and culturally influenced representation of human spirituality. Nurses promote holistic nursing care through an integration of spiritual and psychosocial care. The care focuses on activities that support a person's system of beliefs and worship, such as praying, reading religious materials, and performing religious rituals. In addition, it means being attentive and open to the unique spiritual experiences and insight of children. Unfortunately, "such insights may be dismissed as cute or the product of an overactive imagination" (Mercer, 2006). Whereas meeting the spiritual needs of the child and family can provide strength, unmet spiritual needs can result in spiritual distress and debilitation. In practice, application of the nursing process for spiritual care (Box 27-5) can enhance the spiritual well-being of the child and family.

Religious beliefs that relate to health care and that may be a source of conflict between a family and the health care team remind

BOX 27-5 GUIDELINES FOR INTEGRATING SPIRITUAL CARE INTO PEDIATRIC NURSING PRACTICE

- Respect the child's and family's religious beliefs and practices.
- Consider the child's development when talking about spiritual concerns.
- Contact the institution's chaplaincy department for patients and families who have symptoms of spiritual distress or ask for specific religious rituals.
- Become knowledgeable about the religious worldviews of cultural groups found in the patients you care for.
- Encourage visitation with family members, members of the patient's spiritual community, and spiritual leaders.
- Allow children and families to teach you about the specifics of their religious beliefs.
- Develop awareness of your own spiritual perspective.
- Listen for understanding rather than agreement or disagreement.

Adapted from Barnes LL, Plotnikoff GA, Fox K, et al: Spirituality, religion, and pediatrics: intersecting worlds of healing, *Pediatrics* 106(Suppl 4):899–908, 2000; Brooks B: Spirituality. In Kline N, editor: *Essentials of pediatric oncology nursing: a core curriculum*, ed 2, Glenview, IL, 2004, Association of Pediatric Oncology Nurses.

us of the power of ordinary, daily life experience (e.g., childrearing and food preparation) to bring to life the concept of what is sacred (Mercer, 2006). Religion and spirituality influence how individuals view an illness, a treatment regimen, and the role and utility of the health care provider. They also influence actions of food preparation and dietary restrictions and rituals surrounding birth and death. A key role of nurses is to keep communication between the family and health care team open and ask about such influences.

Respecting these rituals is especially important during a physical examination or preparation for surgery. An important role of the nurse is to be aware of families' spiritual needs and convey an attitude of concern for this important element of the child's care. Religion, which offers families understanding and spiritual support, is a valuable asset to health care. Table 27-1 outlines characteristics of selected religions with beliefs that affect nursing care.

In some instances, the rights of the family and the responsibility of the state may be in conflict. For example, Jehovah's Witnesses refuse blood transfusions for themselves and for their children. Parents, by law, have the primary obligation to care for and make decisions about their minor children. However, the legal principle of *parens patriae* says that the state has an overriding interest in the health and welfare of its citizens. Parents' refusal of medical treatment for their child that is deemed essential can be interpreted as neglect. In addition to advocating for the child and family, the nurse's role may include assuming the role of consultant to the staff and family regarding new, alternative methods of transfusion and, if necessary, coordinating with officials to petition juvenile or family court for temporary guardianship of the child.

TABLE 27-1 RELIGIOUS BELIEFS THAT MAY AFFECT NURSING CARE

BIRTH AND DEATH	DIET AND FOOD PRACTICES	MEDICAL CARE
Buddhist		
Birth—No baptism Infant presentation **Death**—Last rite chanting is often practiced at bedside soon after death; the deceased's family or Buddhist priest should be contacted **Organ donation and transplantation**—Organ donation is a matter of individual conscience	Restrictions on some food combinations; extremes must be avoided Some sects are strictly vegetarian Discourage use of alcohol and drugs	Illness is believed to be a trial to aid development of soul; illness results from Karmic causes Surgery is permitted, but extremes must be avoided Cleanliness is of great importance Family, community, and Buddhist priest are supportive visitors
Church of Christ, Scientist (Christian Science)		
Birth—No baptism **Death**—No last rites; autopsy is not permitted except in cases of sudden death; individuals can choose burial or cremation **Organ donation and transplantation**—Church takes no specific position on transplantation as distinct from other medical or surgical procedures Individuals decide on organ donation	Abstain from alcohol and some forms of tea and coffee	Oppose human intervention with drugs or other therapies; however, accept legally required immunizations Accept physical and moral healing Family, friends, and members of spiritual community may visit
Church of Jesus Christ of Latter Day Saints (Mormon)		
Birth—No baptism Infant is blessed by church official at first opportunity after birth (in church) Baptism by immersion at 8 years **Death**—Believe that it is proper to bury the dead in the ground; cremation is discouraged **Organ donation and transplantation**—Individuals can choose whether to will organs to be used in transplants	Prohibit tea (except herbal), coffee, and alcohol Some individuals avoid chocolate and other products that contain caffeine Fasting for 24 hours each month	Devout adherents believe in divine healing Medical therapy is not prohibited Spiritual items—A "garment" (type of underwear) that is considered sacred; person may not want to remove it Family, friends, and church members are supportive visitors

TABLE 27-1 RELIGIOUS BELIEFS THAT MAY AFFECT NURSING CARE—cont'd

BIRTH AND DEATH	DIET AND FOOD PRACTICES	MEDICAL CARE
Hindu		
Birth—No baptism **Death**—Certain prescribed rites are followed after death; priest may tie thread around neck or wrist to signify blessing; family will wash the body; are particular about who touches their dead; bodies are to be cremated **Organ donation and transplantation**—No religious laws prohibiting donation; individual decision	Many dietary restrictions Eating meat is forbidden	With an amputation, loss of a limb is believed to represent sins committed in previous life Accept most modern medical practices; some belief in faith healing Spiritual item—Person may wear a thread around wrist or body; do not remove it Family, community members, and priest are supportive visitors
Islam (Muslim/Moslem)		
Birth—At birth, the first words said to the infant in his or her right ear are Allah-o-Akbar (Allah is great), and the remainder of the Call for Prayer is recited; an Aqeeqa (party) to celebrate the birth of the child is arranged by the parents; male children are circumcised **Death**—At the time of death, specific rituals (e.g., bathing, wrapping the body in cloth) must be done by same-sex Muslim; before moving and handling the body, it is preferable to contact someone from the person's mosque or the local Islamic Society to perform these rituals **Organ donation and transplantation**—Individual decides	Prohibit all pork products and alcohol Fasting is practiced during the ninth month of the Islamic year (Ramadan)	Believers are encouraged in the Qu'ran to seek treatment; it is taught that only Allah cures; however, Muslims are taught not to refuse treatment in the belief that Allah will take care of them because he also chooses at times to work through the efforts of humans Other practices—Right hand is used for eating; left hand is for hygiene Family and friends are supportive visitors
Jehovah's Witnesses		
Birth—No baptism **Death**—No official last rites are practiced when death occurs **Organ donation and transplantation**—Organ donation is forbidden	No tobacco; moderate alcohol permissible	Blood or blood products are not allowed; volume expanders are permissible if not derived from blood
Judaism (Orthodox and Conservative)		
Birth—No baptism Ritual circumcision of male infants on eighth day; performed by mohel (ritual circumciser familiar with Jewish law and aseptic technique) **Death**—According to tradition, during last moments of life, relatives and close friends remain with the deceased Amputated limbs or surgically removed tissues should be made available to family for burial Cremation not allowed **Organ donation and transplantation**—A complex issue; sometimes they are practiced	Numerous dietary kosher laws exist; followers are allowed meat only from animals that are vegetable eaters and are ritually slaughtered; predatory fowl, shellfish, and pork are prohibited Milk products served first can be followed by meat in a few minutes, but milk may not be consumed for several hours after eating meat Fasting is part of Yom Kippur observance Matzo replaces leavened bread during Passover week	May resist surgical procedures during Sabbath, which extends from sundown Friday until sundown Saturday Illness is grounds for violating dietary laws Spiritual items—Men may wear prayer shawl, yarmulke (cap) while praying Family, friends, and rabbi are supportive visitors
Roman Catholic		
Birth—Infant baptism; especially urgent if poor prognosis, when it may be performed by anyone **Death**—Sacrament of the Sick is performed if prognosis is poor while patient is alive **Organ donation and transplantation**—Transplantation of organs is viewed by Catholics as ethically and morally acceptable to the Vatican; organ donation is viewed as an act of charity	Abstaining from meat is practiced on Ash Wednesday, Good Friday, and Fridays during Lent (as a rule)	Encourage anointing of the sick Spiritual items—Rosary beads, crucifix Traditional church teaching does not approve of contraceptives or abortion

Data from Galanti G: *Caring for patients from different cultures,* ed 3, Philadelphia, 2004, University of Pennsylvania Press; Lipson JG, Dibble SL, Minarik PA: *Culture and clinical care: a pocket guide,* San Francisco, 2005, UCSF Nursing Press; Purnell LD, Paulanka BJ: *Transcultural health care: a culturally competent approach,* Philadelphia, 2003, FA Davis; Spector RE: *Cultural diversity in health and illness,* ed 6, Upper Saddle River, NJ, 2004, Pearson Prentice-Hall.

CULTURAL AND RELIGIOUS AWARENESS

Cultural and religious rituals are important practices among families from various cultures. An example is the Jewish upsherenish ceremony, which celebrates a boy's first haircut when he reaches 3 years of age. Any procedure requiring haircutting, such as placement of an intravenous line in a scalp vein, must be discussed with parents to obtain their permission.

Table 27-2 outlines some characteristics of selected cultures. Nurses must assess the cultural and religious practices of families to identify how these practices are similar to and different from those of their own cultural and religious backgrounds.

! NURSING ALERT

These generalizations are presented to help nurses learn the unique beliefs and practices of various groups and are not meant to be stereotypes of any group. It is critical to remember that no cultural group is homogeneous, every racial and ethnic group contains great diversity, and knowledge of a culture may not reflect an individual member's beliefs (Kleinman and Benson, 2006).

Concepts that come from medical anthropology can provide a framework for addressing health care issues. These concepts can have a direct impact on patient care. They lead the nurse away from an ethnocentric or medicocentric view of the health care encounter into the health care reality as constructed by the patient and family. This is relevant for addressing many of the problems that plague the American health care system, including patient dissatisfaction with the health care they receive, unequal distribution of high-quality health care, and excessive costs (Kleinman and Benson, 2006).

It is also important for nurses to recognize that disease and illness are distinct entities. Clinicians diagnose and treat diseases—that is, abnormalities in the structure and function of body organs and systems. Illness and disease are not interchangeable; illness may occur even when disease is not present, and the course of a disease may vary substantially from the experience of illness.

Illness is culturally constructed; an individual's culture influences how a sickness is perceived, labeled, and explained. Culture also influences the meaning assigned to the illness, the role the individual with the sickness adopts, and the response of the family and community to the sickness.

Tension may arise when the perception of the illness and disease varies widely among the patient, family, and health care team. Failure of health care providers to recognize these disparities may be partially to blame in cases of noncompliance, delivery of inadequate care, and patient or family dissatisfaction. To begin addressing these issues, it is important for nurses to understand the various domains of health care in which individuals operate in American society, including professional (health care providers and institutions), popular (family, community, and lay literature), and folk (nonprofessional healers). Each domain possesses a method for defining and explaining the sickness and what should be done to

TABLE 27-2 BROAD CULTURAL CHARACTERISTICS RELATED TO THE HEALTH CARE OF CHILDREN AND FAMILIES

HEALTH BELIEFS	HEALTH PRACTICES	FAMILY RELATIONSHIPS	COMMUNICATION
African			
Illness classified as: Natural—affected by forces of nature without adequate protection (e.g., cold air, pollution, food and water) Unnatural—God's punishment for improper behavior May see illness as the "will of God"	Self-care and folk medicine prevalent Folk therapies usually religious in origin Folk therapies often not shared with the medical provider Prayer as common means for prevention and treatment	Strong kinship bonds in extended family; members come to aid of others in crisis Less likely to view illness as a burden Place strong emphasis on work and ambition Elders cared for and respected	Alert to any evidence of discrimination Place importance on nonverbal behavior Affection shown by touching and hugging Silence may indicate lack of trust Initial eye contact to show respect; maintaining eye contact can be viewed as aggressive Best to use direct but caring approach
Chinese			
A healthy body viewed as gift from parents and ancestors and must be cared for Health seen as one of the results of balance between the forces of yin (cold) and yang (hot)—energy forces that rule the world Illness caused by an imbalance Blood believed to be source of life and is not regenerated Chi is innate energy	Goal of therapy is to restore the balance of yin and yang Acupuncturist needles applied to appropriate meridians identified in terms of yin and yang Acupressure and tai chi replacing acupuncture in some areas Moxibustion—application of heat to skin over specific meridians Wide use of medicinal herbs procured and applied in prescribed ways Meals may or may not be planned to balance hot and cold	Extended family pattern common Strong concept of loyalty of young to old Respect for elders taught at early age—acceptance without questioning or talking back Children's behavior a reflection on family Family and individual honor and "face" important Self-reliance and self-esteem highly valued; self-expression repressed	Open expression of emotions unacceptable Often smile when they do not comprehend Eye contact avoided as a sign of respect

TABLE 27-2 BROAD CULTURAL CHARACTERISTICS RELATED TO THE HEALTH CARE OF CHILDREN AND FAMILIES—cont'd

HEALTH BELIEFS	HEALTH PRACTICES	FAMILY RELATIONSHIPS	COMMUNICATION
Haitian			
Illness seen as a punishment Natural cause *(maladi bone die*—disease of the Lord) caused by environmental factors, movement of blood within the body, changes between hot and cold, and bone displacement Supernatural (*loa*—spirits' anger) Good health seen as the maintenance of equilibrium Prayer and good spiritual habits important	Health a personal responsibility Foods have properties of "hot" or "cold" and "light" or "heavy" and must be in harmony with one's life cycle and bodily states Natural illnesses treated by home and folk remedies first May use religious medallions, rosary beads, or figure of saint to pray with	Maintenance of family reputation paramount Lineal authority supreme; children in a subordinate position in family hierarchy Children valued for parental security in old age and expected to contribute to family welfare at an early age	Recent immigrants and older persons may speak only Haitian Creole Often smile and nod in agreement when do not understand Quiet and gentle communication style and lack of assertiveness lead health care providers to falsely believe they comprehend health teaching and are compliant May not ask questions if health care provider is busy or rushed
Japanese			
Shinto religious influence Human inherently good Evil caused by outside spirits Illness caused by contact with polluting agents (e.g., blood, corpses, skin diseases) Health achieved through harmony and balance between self and society Disease caused by disharmony with society and not caring for body	Energy restored by means of acupuncture, acupressure, massage, and moxibustion along affected meridians *Kampō* medicine—use of natural herbs Believe in removal of diseased parts Trend is to use both Western and Asian healing methods Care for people with disabilities viewed as family's responsibility Take pride in child's good health Seek preventive care and medical care for illness	Close intergenerational relationships Generational categories: *Issei*—first generation to live in United States *Nisei*—second generation *Sansei*—third generation *Yonsei*—fourth generation Family tends to keep problems to self Value self-control and self-sufficiency Concept of *haji* (shame) imposes strong control; unacceptable behavior of children reflects on family	Make significant use of nonverbal communication with subtle gestures and facial expression Tend to suppress emotions Will often wait silently
Mexican-American			
Health controlled by environment, fate, and will of God Certain illnesses considered "hot" and "cold" states and are treated with food that complements those states Disease based on imbalance between individual and environment	Seek help from curandero or curandera, especially in rural areas *Curandero(a)* receives position by birth, apprenticeship, or a "calling" via dream or vision Treatments involve use of herbs, rituals, and religious artifacts Practice for severe illness—make promises, visit shrines, offer medals and candles, offer prayers Adhere to "hot" and "cold" food prescriptions and prohibitions for prevention and treatment of illness	Strong kinship—extended families include *compadres* (godparents) established by ritual kinship Children valued highly and desired, taken everywhere with family Elderly treated with respect	Spanish speaking or bilingual May have a strong preference for native language and revert to it in times of stress May shake hands or engage in introductory embrace Interpret prolonged eye contact as disrespectful Relaxed concept of time—may be late to appointments
Native American			
Believe health is state of harmony with nature and universe Respect bodies through proper management Depend on individual belief in traditional culture Traditional health beliefs holistic and wellness oriented	Distinction made between indigenous health problem requiring native healer or practice and Western disease requiring other medical care Health practices include self-sufficiency and harmonious living Participation in religious ceremonies and prayer promotes health	Cultures vary in kinship structure Extended family structure—usually includes relatives from both sides of family Elder members assume leadership roles	Use anecdotes or metaphors to discuss a situation Long pauses indicate careful consideration Nonverbal communication Respect indicated by avoiding eye contact Individuals usually speak for themselves

Continued

TABLE 27-2 BROAD CULTURAL CHARACTERISTICS RELATED TO THE HEALTH CARE OF CHILDREN AND FAMILIES—cont'd

HEALTH BELIEFS	HEALTH PRACTICES	FAMILY RELATIONSHIPS	COMMUNICATION
Puerto Rican			
Subscribe to the "hot-cold" theory of causation of illness Believe some illness caused by evil forces Destiny *(Si Dios quiere*—if God wants) is in control of health	Infrequent use of health care system Seek folk healers *(espiritistas)*—use of herbs, rituals Treatment classified as "hot" or "cold" Many varieties of herbal teas used to treat illness and promote healing	Family usually large and home centered—the core of existence Father has authority in family Great respect for elders Children valued—seen as a gift from God Children taught to obey and respect parents	Spanish speaking or bilingual Strong sense of family privacy—may view questions regarding family as impudent
Vietnamese			
Good health considered to be balance between yin and yang Concept of health based on harmony and balance Rituals used to prevent illness	Family uses all means possible before using outside agencies for health care Regard health as family responsibility; outside aid sought when resources run out Use herbal medicine, spiritual practices, and acupuncture May consider head sacred and feet profane; avoid touching head after feet May use cupping, coin rubbing, or pinching skin May inhale aromatic oils, take herbal teas, or wear strings tied on body	Family is revered institution Multigenerational families Family is chief social network Children highly valued Individual needs and interests subordinate to those of a family group Father is main decision maker Women taught submission to men Parents expect respect and obedience from children	May hesitate to ask questions Questioning authority is sign of disrespect; asking questions considered impolite May avoid eye contact with health care professionals as a sign of respect

Data from Galanti G: *Caring for patients from different cultures,* ed 3, Philadelphia, 2004, University of Pennsylvania Press; Lipson JG, Dibble SL, Minarik PA: *Culture and clinical care: a pocket guide,* San Francisco, 2005, UCSF Nursing Press; Purnell LD, Paulanka BJ: *Transcultural health care: a culturally competent approach,* Philadelphia, 2003, FA Davis; Spector RE: *Cultural diversity in health and illness,* ed 6, Upper Saddle River, NJ, 2004, Pearson Prentice Hall.

address it. The challenge for nurses and other health care providers is to address this disconnect with families and develop mutually agreed-on goals. Nurses are in a prime position to assume this role because understanding the human response to disease is central to their role. In addition, collaboration with the child and family is central to the role of the pediatric nurse.

Not all health care providers feel adequately prepared to care for culturally diverse populations. A study of 1700 resident physicians by Betancourt (2007) revealed that 25% to 30% of them did not feel prepared to deal with families who are mistrustful of the health care system, those with limited English proficiency, those whose health perspective differs from a Western-based model, adults who incorporate other family into the decision-making process, or those who bring their spirituality into the health care environment. Unfortunately, the numbers may not be too different for nursing and other health care professionals. Such statistics are a wake-up call for anyone who strives for high-quality patient care.

One method of addressing this disconnect with families and beginning collaboration is by understanding the family's explanatory model of illness. The questions in Box 27-3 (Kleinman and Benson, 2006) aim to elicit an individual's beliefs about the disease or illness, the meaning attached to it, goals, and expectations of the outcome and role of the health care provider. Nurses can use these questions to discern areas of discrepancy for further dialog, negotiation, and collaboration. This discussion, when conducted with a genuine interest in the family's and child's perspective, is a significant step in building trusting relationships, promoting adherence, decreasing disparities, and increasing health care satisfaction.

KEY POINTS

- Because there is no agreement about the definition of family, a family is what an individual considers it to be.
- Three areas of special concern to adoptive families include the initial attachment process, the task of telling the children they are adopted, and identity formation during adolescence.
- Marital factors within the home significantly influence a child's development. The impact of divorce on a child depends on the child's age, the outcome, and the quality of the parent-child relationship and parental care after the divorce.
- Single parenting and stepparenting create adjustment difficulties and add stress to the already demanding parental role. Significant numbers of children will live in a single-parent or reconstituted family at some point.
- Culture is the pattern of assumptions, beliefs, and practices encompassing other products of human work and thoughts specific to members of an intergenerational group, community, or population.
- Nurses have a responsibility to understand the influences of culture, race, and ethnicity on the development of social and

emotional relationships, childrearing practices, and attitudes toward health.
- Socioeconomic influences play a major role in opportunities for health promotion and wellness.
- Religious practices greatly influence health-promotion beliefs in families.
- Because verbal and nonverbal communication are important cultural considerations, nurses need to acknowledge and respect their patients' practices for productive interaction to occur.
- Cultural beliefs related to cause of illness and maintenance of health may focus on natural forces, supernatural forces, or an imbalance of forces.
- The practice of cultural humility is continual and an important concept in the nursing process. Nurses can facilitate this process by recognizing cultural differences, integrating cultural knowledge, being aware of their own beliefs and practices, and acting in a culturally appropriate manner.
- No cultural group is homogeneous; every racial and ethnic group contains great diversity.

CHAPTER

28

Developmental and Genetic Influences on Child Health Promotion

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe major trends in growth and development.
- Explain the alterations in the major body systems that take place during the process of growth and development.
- Discuss the development and relationships of personality, cognition, language, morality, spirituality, and self-concept.
- Describe the role of play in the growth and development of children.
- Demonstrate an understanding of the role of innate and environmental factors in the physical and emotional development of children.

GROWTH AND DEVELOPMENT

Foundations of Growth and Development

Growth and development, usually referred to as a unit, express the sum of the numerous changes that take place during the lifetime of an individual. The entire course is a dynamic process that encompasses several interrelated dimensions:

- **Growth**—Increase in number and size of cells as they divide and synthesize new proteins; results in increased size and weight of the whole or any of its parts
- **Development**—Gradual change and expansion; advancement from lower to more advanced stages of complexity; the emerging and expanding of the individual's capacities through growth, maturation, and learning
- **Maturation**—Increase in competence and adaptability; aging; usually used to describe a qualitative change; a change in the complexity of a structure that makes it possible for that structure to begin functioning; to function at a higher level
- **Differentiation**—Processes by which early cells and structures are systematically modified and altered to achieve specific and characteristic physical and chemical properties; sometimes used to describe the trend of mass to specific; development from simple to more complex activities and functions

All of these processes are interrelated, simultaneous, and ongoing; none occurs apart from the others. The processes depend on a sequence of endocrine, genetic, constitutional, environmental, and nutritional influences (Seidel, Ball, Dains, et al., 2007). The child's body becomes larger and more complex; the personality simultaneously expands in scope and complexity. Very simply, growth can be viewed as a quantitative change, and development as a qualitative change.

Stages of Development

Most authorities in the field of child development conveniently categorize child growth and behavior into approximate age stages or in terms that describe the features of a developmental age period. The age ranges of these stages admittedly are arbitrary and, because they do not take into account individual differences, cannot be applied to all children with any degree of precision. However, categorization affords a convenient means to describe the characteristics associated with the majority of children at periods when distinctive developmental changes appear and specific developmental tasks must be accomplished. (A **developmental task** is a set of skills and competencies peculiar to each developmental stage that children must accomplish or master to deal effectively with their environment.) It is also significant for nurses to know that there are characteristic health problems peculiar to each major phase of development. The

BOX 28-1 DEVELOPMENTAL AGE PERIODS

Prenatal Period—Conception to Birth

Germinal—Conception to ≈2 weeks
Embryonic—2 to 8 weeks
Fetal—8 to 40 weeks (birth)

A rapid growth rate and total dependency make this one of the most crucial periods in the developmental process. The relationship between maternal health and certain manifestations in the newborn emphasizes the importance of adequate prenatal care to the health and well-being of the infant.

Infancy Period—Birth to 12 Months

Neonatal—Birth to 27 or 28 days
Infancy—1 to ≈12 months

The infancy period is one of rapid motor, cognitive, and social development. Through mutuality with the caregiver (parent), the infant establishes a basic trust in the world and the foundation for future interpersonal relationships. The critical first month of life, although part of the infancy period, is often differentiated from the remainder because of the major physical adjustments to extrauterine existence and the psychologic adjustment of the parent.

Early Childhood—1 to 6 Years

Toddler—1 to 3 years
Preschool—3 to 6 years

This period, which extends from the time children attain upright locomotion until they enter school, is characterized by intense activity and discovery. It is a time of marked physical and personality development. Motor development advances steadily. Children at this age acquire language and wider social relationships, learn role standards, gain self-control and mastery, develop increasing awareness of dependence and independence, and begin to develop a self-concept.

Middle Childhood—6 to 11 or 12 Years

Frequently referred to as the *school age,* this period of development is one in which the child is directed away from the family group and centered around the wider world of peer relationships. There is steady advancement in physical, mental, and social development with emphasis on developing skill competencies. Social cooperation and early moral development take on more importance with relevance for later life stages. This is a critical period in the development of a self-concept.

Later Childhood—11 to 19 Years

Prepubertal—10 to 13 years
Adolescence—13 to ≈18 years

The tumultuous period of rapid maturation and change known as adolescence is considered to be a transitional period that begins at the onset of puberty and extends to the point of entry into the adult world—usually high school graduation. Biologic and personality maturation are accompanied by physical and emotional turmoil, and there is redefining of the self-concept. In the late adolescent period the young person begins to internalize all previously learned values and focus on an individual rather than a group identity.

sequence of descriptive age periods and subperiods that are used here and elaborated on in subsequent chapters is listed in Box 28-1.

Patterns of Growth and Development

There are definite and predictable patterns in growth and development that are continuous, orderly, and progressive. These patterns, or trends, are universal and basic to all humans, but each person accomplishes these in a manner and time unique to that individual.

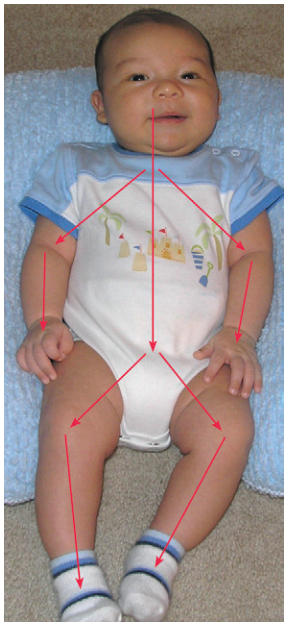

FIG 28-1 Directional trends in growth.

Directional Trends. Growth and development proceed in regular, related directions or gradients and reflect the physical development and maturation of neuromuscular functions (Fig. 28-1). The first pattern is the cephalocaudal, or head-to-tail, direction. The head end of the organism develops first and is large and complex; the lower end is small and simple and takes shape at a later period. The physical evidence of this trend is most apparent during the period before birth, but it also applies to postnatal behavior development. Infants achieve structural control of their heads before they have control of their trunks and extremities, hold their backs erect before they stand, use their eyes before their hands, and gain control of their hands before they have control of their feet.

Second, the **proximodistal,** or near-to-far, trend applies to the midline-to-peripheral concept. A conspicuous illustration is the early embryonic development of limb buds, which is followed by rudimentary fingers and toes. In infants shoulder control precedes mastery of the hands; the whole hand is used as a unit before the fingers can be manipulated; and the central nervous system develops more rapidly than the peripheral nervous system.

These trends or patterns are bilateral and appear symmetric (i.e., each side develops in the same direction and at the same rate as the other). For some of the neurologic functions this symmetry is only external because of unilateral differentiation of function at an early stage of postnatal development. For example, by the age of approximately 5 years, children have demonstrated a decided preference for the use of one hand over the other, although previously either one had been used.

The third trend, differentiation, describes development from simple operations to more complex activities and functions. From broad, global patterns of behavior, more specific, refined patterns emerge. All areas of development (physical, mental, social, and emotional) proceed in this direction. Through the process of development and differentiation, early embryonal cells with vague, undifferentiated functions progress to an immensely complex organism composed of highly specialized and diversified cells, tissues, and

organs. Generalized development precedes specific or specialized development; gross, random muscle movements take place before fine-muscle control.

Sequential Trends. In all dimensions of growth and development, there is a definite, predictable sequence, with each child normally passing through every stage. Children crawl before they creep, creep before they stand, and stand before they walk. Later facets of the personality are built on the early foundation of trust. The child babbles and then forms words and finally sentences; writing emerges from scribbling.

Developmental Pace. Although development has a fixed, precise order, it does not progress at the same rate or pace. There are periods of accelerated growth and periods of decelerated growth in both total body growth and the growth of subsystems. Not all areas of development occur at the same pace. When a spurt occurs in one area such as gross motor, minimal advances may take place in language, fine motor, or social skills. After the gross motor skill has been achieved, development focus shifts to another area. The rapid growth before and after birth gradually levels off throughout early childhood. Growth is relatively slow during middle childhood, markedly increases at the beginning of adolescence, and levels off in early adulthood. Each child grows at his or her own pace. Distinct differences are observed among children as they reach **developmental milestones.**

Sensitive Periods. At limited times during the process of growth the organism interacts with a particular environment in a specific manner. Periods termed critical, sensitive, vulnerable, and optimal are the times in the lifetime of an organism when it is more susceptible to positive or negative influences.

The quality of interactions during these sensitive periods determines whether the effects on the organism will be beneficial or harmful. For example, physiologic maturation of the central nervous system is influenced by the adequacy and timing of contributions from the environment such as stimulation and nutrition. The first 3 months of prenatal life are sensitive periods for physical growth of fetuses.

Psychologic development also appears to have sensitive periods when an environmental event has maximal influence on the developing personality. For example, primary socialization occurs during the first year when the infant makes the initial social attachments and establishes a basic trust in the world. A warm relationship with a parent figure is fundamental to a healthy personality. The same concept might be applied to readiness for learning skills such as toilet training or reading. In these instances there appears to be an opportune time when the skill is best learned.

Individual Differences

Each child grows in his or her own unique and personal way. Great individual variation exists in the age at which developmental milestones are reached. The sequence is predictable; the exact timing is not. Rates of growth vary, and measurements are defined in terms of ranges to allow for individual differences. Some children are fast growers, others are moderate, and some are slower to reach maturity. Periods of fast growth such as the pubescent growth spurt may begin earlier or later in some children than in others. Children may grow fast or slowly during the spurt and may finish sooner or later than other children. Gender is an influential factor because girls seem to be more advanced in physiologic growth at all ages.

Biologic Growth and Physical Development

As children grow their external dimensions change. These changes are accompanied by corresponding alterations in structure and function of internal organs and tissues that reflect the gradual acquisition of physiologic competence. Each part has its own rate of growth, which may be directly related to alterations in the size of the child (e.g., the heart rate). Skeletal muscle growth approximates whole body growth; brain, lymphoid, adrenal, and reproductive tissues follow distinct and individual patterns (Fig. 28-2). When growth deficiency has a secondary cause such as severe illness or acute malnutrition, recovery from the illness or the establishment of an adequate diet produces a dramatic acceleration of the growth rate that usually continues until the child's individual growth pattern is resumed.

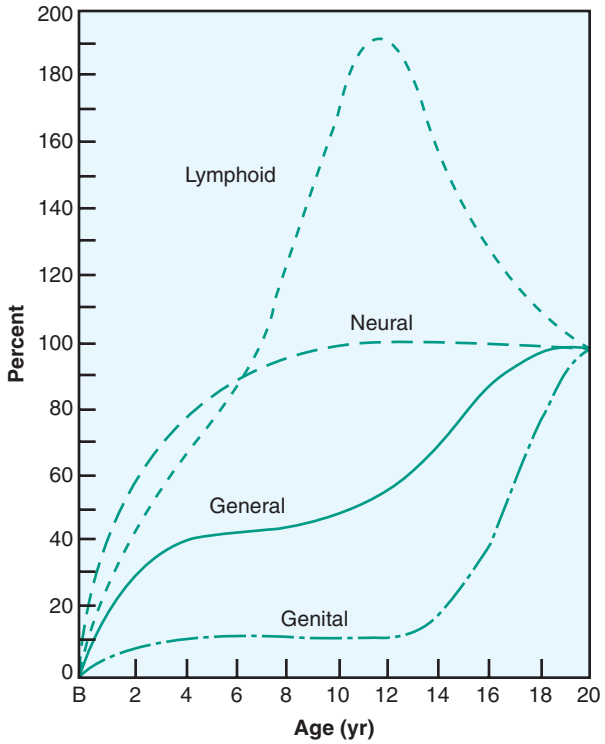

FIG 28-2 Growth rates for the body as a whole and three types of tissues. *Lymphoid:* thymus, lymph nodes, and intestinal lymph masses. *Neural:* brain, dura, spinal cord, optic apparatus, and head dimensions. *General:* body as a whole; external dimension; and respiratory, digestive, renal, circulatory, and musculoskeletal systems. (Data from Jackson JA, Patterson DG, Harris RE: *The measurement of man,* Minneapolis, 1930, University of Minnesota Press.)

External Proportions

Variations in the growth rate of different tissues and organ systems produce significant changes in body proportions during childhood. The cephalocaudal trend of development is most evident in total body growth as indicated by these changes. During fetal development the head is the fastest growing body part; at 2 months of gestation it constitutes 50% of total body length. During infancy growth of the trunk predominates; the legs are the most rapidly growing part during childhood; in adolescence the trunk again elongates. In newborn infants the lower limbs are one third the total body length but only 15% of the total body weight; in adults the lower limbs constitute half of the total body height and 30% or more of the total body weight. As growth proceeds the midpoint in head-to-toe measurements gradually descends from a level even with the umbilicus at birth to the level of the symphysis pubis at maturity.

FIG 28-3 Changes in body proportions occur dramatically during childhood.

Biologic Determinants of Growth and Development

The most prominent feature of childhood and adolescence is physical growth (Fig. 28-3). Throughout development various tissues in the body undergo changes in growth, composition, and structure. In some tissues the changes are continuous (e.g., bone growth and dentition); in others significant alterations occur at specific stages (e.g., appearance of secondary sex characteristics). When these measurements are compared with standardized norms, a child's developmental progress can be determined with a high degree of confidence (Table 28-1). Growth in children with Down syndrome differs from that in other children. They have slower growth velocity between 6 months and 3 years and then again in adolescence. Puberty occurs earlier, and they achieve shorter stature. This population of patients is frequent users of the health care system, often with multiple providers, and benefit from the use of the Down syndrome growth chart to monitor their growth (Cronk, Crocker, Pueschel, et al., 1988; Myrelid, Gustafsson, Ollars, et al., 2002).

Linear growth, or height, occurs almost entirely as a result of skeletal growth and is considered a stable measurement of general growth. Growth in height is not uniform throughout life but ceases when maturation of the skeleton is complete. The maximum rate of growth in length occurs before birth, but newborns continue to grow at a rapid although slower rate.

At birth, weight varies more than height and is to a greater extent a reflection of the intrauterine environment. The average newborn weighs from 3175 to 3400 g (7 to 7.5 lbs). In general the birth weight doubles by 4 to 7 months of age and triples by the end of the first year. By the age of 2 to 2.5 years the birth weight usually quadruples. After this point the "normal" rate of weight gain, just as the growth in height, assumes a steady annual increase of approximately 2 to 2.75 kg (4.4 to 6 lbs) per year until the adolescent growth spurt.

Both bone age determinants and state of dentition are used as indicators of development. Because both are discussed elsewhere, neither is elaborated here (see next section for bone age; see also Chapter 31 for dentition).

Skeletal Growth and Maturation

The most accurate measure of general development is skeletal or bone age, the radiologic determination of osseous maturation. Skeletal age appears to correlate more closely with other measures of physiologic maturity (e.g., onset of menarche) than with chronologic age or height. Bone age is determined by comparing the mineralization of ossification centers and advancing bony form to age-related standards.

TABLE 28-1 GENERAL TRENDS IN HEIGHT AND WEIGHT GAIN DURING CHILDHOOD

AGE-GROUP	WEIGHT*	HEIGHT*
Infants		
Birth-6 months	Weekly gain: 140-200 g (5-7 oz) Birth weight doubles by end of first 4-7 months†	Monthly gain: 2.5 cm (1 inch)
6-12 months	Weight gain: 85-140 g (3-5 oz) Birth weight triples by end of first year	Monthly gain: 1.25 cm (0.5 inch) Birth length increases by ≈50% by end of first year
Toddlers	Birth weight quadruples by age 2.5	Height at age 2 is ≈50% of eventual adult height Gain during second year: about 12 cm (4.7 inches) Gain during third year: about 6-8 cm (2.4-3.1 inches)
Preschoolers	Annual gain: 2-3 kg (4.5-6.5 lbs)	Birth length doubles by age 4 years Annual gain: 5-7.5 cm (2-3 inches)
School-age children	Annual gain: 2-3 kg (4.5-6.5 lbs)	Annual gain after age 7: 5 cm (2 inches) Birth length triples by about age 13 years
Pubertal Growth Spurt		
Females 10-14 years	Weight gain: 7-25 kg (15.5-55 lbs) Mean: 17.5 kg (38.5 lbs)	Height gain: 5-25 cm (2-10 inches); ≈95% of mature height achieved by onset of menarche or skeletal age of 13 years Mean: 20.5 cm (8 inches)
Males 11-16 years	Weight gain: 7-30 kg (15.5-66 lbs) Mean: 23.7 kg (52.2 lbs)	Height gain: 10-30 cm (4-12 inches); ≈95% of mature height achieved by skeletal age of 15 years Mean: 27.5 cm (11 inches)

*Annual height and weight gains for each age-group represent averaged estimates from a variety of sources.
†Jung FE, Czajka-Narins DM: Birth weight doubling and tripling times: an updated look at the effects of birth weight, sex, race, and type of feeding, *Am J Clin Nutr* 42:182–189, 1985.

Bone formation begins during the second month of fetal life when calcium salts are deposited in the intercellular substance (matrix) to form calcified cartilage first and then true bone. Bone formation exhibits some differences. In small bones the bone continues to form in the center, and cartilage continues to be laid down on the surfaces. In long bones the ossification begins in the diaphysis (the long central portion of the bone) and continues in the epiphysis (the end portions of the bone). Between the diaphysis and the epiphysis, an epiphyseal cartilage plate (or growth plate) unites with the

diaphysis by columns of spongy tissue, the metaphysis. Active growth in length takes place in the epiphyseal growth plate. Interference with this growth site by trauma or infection can result in deformity.

The first centers of ossification appear in 2-month-old embryos, and at birth the number is approximately 400, about half the number at maturity. New centers appear at regular intervals during the growth period and provide the basis for assessment of bone age. Postnatally the earliest centers to appear (at 5 to 6 months of age) are those of the capitate and hamate bones in the wrist. Therefore radiographs of the hand and wrist provide the most useful areas for screening to determine skeletal age, especially before age 6 years. These centers appear earlier in girls than in boys.

Nurses must understand that the growing bones of children possess many unique characteristics. Bone fractures occurring at the growth plate may be difficult to discover and may significantly affect subsequent growth and development (Urbanski and Hanlon, 1996). Factors that may influence skeletal muscle injury rates and types in children and adolescents include (Caine, DiFiori, and Maffulli, 2006; Kaczander, 1997):

- Less protective sports equipment for children.
- Less emphasis on conditioning, especially flexibility.
- In adolescents, fractures are more common than ligamentous ruptures because of the rapid growth rate of the physeal (segment of tubular bone that is concerned mainly with growth) zone of hypertrophy.

Neurologic Maturation

In contrast to other body tissues, which grow rapidly after birth, the nervous system grows proportionately more rapidly before birth. Two periods of rapid brain cell growth occur during fetal life: a dramatic increase in the number of neurons between 15 and 20 weeks of gestation and another increase at 30 weeks, which extends to 1 year of age. The rapid growth of infancy continues during early childhood and slows to a more gradual rate during later childhood and adolescence.

Postnatal growth consists of increasing the amount of cytoplasm around the nuclei of existing cells, increasing the number and intricacy of communications with other cells, and advancing their peripheral axons to keep pace with expanding body dimensions. This allows for increasingly complex movement and behavior. Neurophysiologic changes also provide the foundation for language, learning, and behavior development. Neurologic or electroencephalographic development is sometimes used as an indicator of maturational age in the early weeks of life.

Lymphoid Tissues

Lymphoid tissues contained in the lymph nodes, thymus, spleen, tonsils, adenoids, and blood lymphocytes follow a growth pattern unlike that of other body tissues. These tissues are small in relation to total body size, but they are well developed at birth. They increase rapidly to reach adult dimensions by 6 years of age and continue to grow. At approximately 10 to 12 years of age they reach a maximum development that is approximately twice their adult size. This is followed by a rapid decline to stable adult dimensions by the end of adolescence.

Development of Organ Systems

All tissues and organ systems undergo changes during development. Some are striking; others are subtle. Many have implications for assessment and care. Because the major importance of these changes relates to their dysfunction, the developmental characteristics of various systems and organs are discussed throughout the book as they relate to these areas. Physical characteristics and physiologic changes that vary with age are included in age-group descriptions.

Physiologic Changes

Physiologic changes that take place in all organs and systems are discussed as they relate to dysfunction. Other changes such as pulse and respiratory rates and blood pressure are an integral part of physical assessment (see Chapter 29). In addition, there are changes in basic functions, including metabolism, temperature, and patterns of sleep and rest.

Metabolism

The rate of metabolism when the body is at rest (basal metabolic rate or BMR) demonstrates a distinctive change throughout childhood. Highest in newborn infants, the BMR closely relates to the proportion of surface area to body mass, which changes as the body increases in size. In both sexes the proportion decreases progressively to maturity. The BMR is slightly higher in boys at all ages and further increases during pubescence over that in girls.

The rate of metabolism determines the caloric requirements of the child. The basal energy requirement of infants is about 108 kcal/kg of body weight and decreases to 40 to 45 kcal/kg at maturity. Water requirements throughout life remain at approximately 1.5 mL/calorie of energy expended. Children's energy needs vary considerably at different ages and with changing circumstances. The energy requirement to build tissue steadily decreases with age following the general growth curve; however, energy needs vary with the individual child and may be considerably higher. For short periods (e.g., during strenuous exercise) and more prolonged periods (e.g., illness), the needs can be very high.

Temperature

Body temperature, reflecting metabolism, decreases over the course of development (see Appendix C). Thermoregulation is one of the most important adaptation responses of infants during the transition from intrauterine to extrauterine life. In healthy neonates hypothermia can result in several negative metabolic consequences such as hypoglycemia, elevated bilirubin levels, and metabolic acidosis. Skin-to-skin care, also referred to as *kangaroo care,* is an effective way to prevent neonatal hypothermia in infants. Unclothed, diapered infants are placed on the parent's bare chest after birth, promoting thermoregulation and attachment (Galligan, 2006). After the unstable regulatory ability in the neonatal period, heat production steadily declines as the infant grows into childhood. Individual differences of 0.5° to 1° F are normal, and occasionally a child normally displays an unusually high or low temperature. Beginning at approximately 12 years of age, girls display a temperature that remains relatively stable, but the temperature in boys continues to fall for a few more years. Females maintain a temperature slightly above that of males throughout life.

Even with improved temperature regulation, infants and young children are highly susceptible to temperature fluctuations. Body temperature responds to changes in environmental temperature and is increased with active exercise, crying, and emotional stress. Infections can cause a higher and more rapid temperature increase in infants and young children than in older children. In relation to body weight, an infant produces more heat per unit than adolescents. Consequently during active play or when heavily clothed, an infant or small child is likely to become overheated.

Sleep and Rest

Sleep, a protective function in all organisms, allows for repair and recovery of tissues after activity. As in most aspects of development,

COMMUNITY FOCUS

Healthy Food Choices

Current research indicates that new lower fat recipes in school lunch programs are well accepted by children (Matvienko, 2007). However, less-healthy foods are still more readily available than more-healthy foods in schools in the United States (Delva, O'Malley, and Johnston, 2007).

individual children vary widely in the amount and distribution of sleep at various ages. As they mature the total time they spend in sleep and the amount of time they spend in deep sleep changes.

Newborn infants sleep much of the time that is not occupied with feeding and other aspects of their care. As they grow older, the total time spent in sleep gradually decreases, they remain awake for longer periods, and they sleep longer at night. For example, the length of a sleep cycle increases from approximately 50 to 60 minutes in newborn infants to approximately 90 minutes in adolescents (Anders, Sadeh, and Appareddy, 2005). During the latter part of the first year, most children sleep through the night and take one or two naps during the day. By the time they are 12 to 18 months old, most children have eliminated the second nap. After age 3 years children have usually given up daytime naps except in cultures in which an afternoon nap or siesta is customary. Sleep time declines slightly from ages 4 to 10 years and increases somewhat during the pubertal growth spurt.

The quality of sleep changes as children mature. As they develop through adolescence, their need for sleep does not decline; but their opportunity for sleep may be affected by social, activity, and academic schedules. The time spent in deep, restful sleep increases from 50% in infancy to 80% in older children.

Nutrition

Nutrition is probably the single most important influence on growth. Dietary factors regulate growth at all stages of development, and their effects are exerted in numerous and complex ways. During the rapid prenatal growth period poor nutrition may influence development from the time of implantation of the ovum until birth. During infancy and childhood the demand for calories is relatively great, as evidenced by the rapid increase in both height and weight. At this time protein and caloric requirements are higher than at almost any period of postnatal development. As the growth rate slows with its concomitant decrease in metabolism, caloric and protein requirements are reduced correspondingly.

Growth is uneven during the periods of childhood between infancy and adolescence, when there are plateaus and small growth spurts. Children's appetites fluctuate in response to these variations until the turbulent growth spurt of adolescence, when adequate nutrition is extremely important but may be subjected to numerous emotional influences. Adequate nutrition is closely related to good health throughout life, and an overall improvement in nourishment is evidenced by the gradual increase in size and early maturation of children in this century (see Community Focus box).

Temperament

Temperament is defined as "the manner of thinking, behaving, or reacting characteristic of an individual" (Chess and Thomas, 1999) and refers to the way in which a person deals with life. From the time of birth children exhibit marked individual differences in the way they respond to their environment and the way others, particularly the parents, respond to them and their needs. A genetic basis has been suggested for some differences in temperament. Nine characteristics of temperament have been identified through interviews with parents (Box 28-2). Temperament refers to behavioral tendencies, not to discrete behavioral acts. There are no implications of good or bad. Most children can be placed into one of three common categories based on their overall pattern of temperamental attributes:

- The easy child—Easygoing children are even tempered, are regular and predictable in their habits, and have a positive approach to new stimuli. They are open and adaptable to change and display a mild-to–moderately intense mood that is typically positive. Approximately 40% of children fall into this category.
- The difficult child—Difficult children are highly active, irritable, and irregular in their habits. Negative withdrawal responses are typical, and they require a more structured environment. These children adapt slowly to new routines, people, and situations. Mood expressions are usually intense and primarily negative. They exhibit frequent periods of crying, and frustration often produces violent tantrums. This group represents about 10% of children.
- The slow-to-warm-up child—Slow-to-warm-up children typically react negatively and with mild intensity to new stimuli and, unless pressured, adapt slowly with repeated contact. They respond with only mild but passive resistance to novelty or changes in routine. They are inactive and moody but show only moderate irregularity in functions. Fifteen percent of children demonstrate this temperament pattern.

Thirty-five percent of children either have some, but not all, of the characteristics of one of the categories or are inconsistent in their behavioral responses. Many normal children demonstrate this wide range of behavioral patterns.

BOX 28-2 ATTRIBUTES OF TEMPERAMENT

Activity—Level of physical motion during activity such as sleeping, eating, playing, dressing, and bathing

Rhythmicity—Regularity in the timing of physiologic functions such as hunger, sleep, and elimination

Approach-withdrawal—Nature of initial responses to a new stimulus such as people, situations, places, foods, toys, and procedures. (**Approach** responses are positive and displayed by activity or expression; **withdrawal** responses are negative expressions or behaviors.)

Adaptability—Ease or difficulty with which the child adapts or adjusts to new or altered situations

Threshold of responsiveness (sensory threshold)—Amount of stimulation such as sounds or light required to evoke a response in the child

Intensity of reaction—Energy level of the child's reactions regardless of quality or direction

Mood—Amount of pleasant, happy, friendly behavior compared with unpleasant, unhappy, crying, unfriendly behavior exhibited by the child in various situations

Distractibility—Ease with which a child's attention or direction of behavior can be diverted by external stimuli

Attention span and persistence—Length of time a child pursues a given activity **(attention)** and the continuation of an activity despite obstacles **(persistence)**

Significance of Temperament

Observations indicate that children who display the difficult or slow-to-warm-up patterns of behavior are more vulnerable to the development of behavior problems in early and middle childhood. Any child can develop behavior problems if there is dissonance

between his or her temperament and the environment. Demands for change and adaptation that are in conflict with the child's capacities can become excessively stressful. However, authorities emphasize that it is not the temperament patterns of children that place them at risk; rather it is the degree of fit between children and their environment, specifically their parents, that determines the degree of vulnerability. The potential for optimum development exists when environmental expectations and demands fit with the individual's style of behavior and the parents' ability to navigate this period (Chess and Thomas, 1999).

Early identification of temperament provides a useful tool for caregivers in anticipating probable areas of difficulty or risk associated with development. For example, "difficult" children may be prone to colic in infancy; active children require more vigilance to prevent injury; and school entry requires different approaches for children with different temperaments.

Research indicates that irritable and unadaptable infants can raise doubts in mothers about their competence (Beck, 1996). Additional research indicates that a child's temperament can affect parent-child interactions and influence the parents' self-esteem, marital harmony, mood, and overall satisfaction as parents (Carey, 1998). Studies on the relationship between temperament and the ability to perform a task successfully (mastery motivation) have found that infants with high mastery are more cooperative and less difficult (Morrow and Camp, 1996). Principles that can be used by nurses in direct patient care and providing anticipatory guidance are listed in Box 28-3.

DEVELOPMENT OF PERSONALITY AND MENTAL FUNCTION

Personality and cognitive skills develop in much the same manner as biologic growth—new accomplishments build on previously mastered skills. Many aspects depend on physical growth and maturation. This is not a comprehensive account of the multiple facets of personality and behavior development. Many aspects are integrated with the child's emotional and social development in a later discussion of various age-groups. Table 28-2 summarizes some of the developmental theories.

Theoretic Foundations of Personality Development

Psychosexual Development (Freud)

According to Freud all human behavior is energized by psychodynamic forces, and this psychic energy is divided among three components of personality: the id, ego, and superego (Freud, 1933). The id, the unconscious mind, is the inborn component that is driven by instincts. It obeys the pleasure principle of immediate gratification of needs, regardless of whether the object or action can actually do so. The ego, the conscious mind, serves the reality principle. It functions as the conscious or controlling self that is able to find realistic means for gratifying the instincts while blocking the irrational thinking of the id. The superego, the conscience, functions as the moral arbitrator and represents the ideal. It is the mechanism

BOX 28-3 ACTIVITIES TO PROMOTE MASTERY MOTIVATION

- Encourage unobtrusive assistance during play.
- Share pleasure with infant in accomplishments.
- Don't give immediate assistance during tasks.
- Don't interrupt infant during tasks.
- Let infant initiate activities.
- Limit controlling feedback during play.
- Provide audio and visually responsive toys.
- Provide early kinesthetic stimulation (picking up, rocking).

From Morrow JD, Camp BW: Mastery motivation and temperament of 7-month-old infants, *Pediatr Nurs* 22(3):211–217, 1996.

TABLE 28-2 SUMMARY OF PERSONALITY, COGNITIVE, AND MORAL DEVELOPMENT THEORIES

PSYCHOSEXUAL (FREUD)	PSYCHOSOCIAL (ERIKSON)	COGNITIVE (PIAGET)	MORAL JUDGMENT (KOHLBERG)	SPIRITUAL (FOWLER)
I. Infancy: Birth to 1 Year				
Oral	Trust vs. mistrust	Sensorimotor (birth-2 years)		Undifferentiated
II. Toddlerhood: 1 to 3 Years				
Anal	Autonomy vs. shame and doubt	Preoperational thought, preconceptual phase (transductive reasoning [e.g., specific to specific]) (2-4 years)	Preconventional (premoral) level Punishment and obedience orientation	Intuitive-projective
III. Early Childhood: 3 to 6 Years				
Phallic	Initiative vs. guilt	Preoperational thought, intuitive phase (transductive reasoning) (4-7 years)	Preconventional (premoral) level Naive instrumental orientation	Mythical-literal
IV. Middle Childhood: 6 to 12 Years				
Latency	Industry vs. inferiority	Concrete operations (inductive reasoning and beginning logic) (7-11 years)	Conventional level Good-boy, nice-girl orientation Law-and-order orientation	Synthetic-convention
V. Adolescence: 12-18 Years				
Genital	Identity vs. role confusion	Formal operations (deductive and abstract reasoning) (11-15 years)	Postconventional or principled level Social-contract orientation	Individuating-reflexive

that prevents individuals from expressing undesirable instincts that might threaten the social order.

Freud considered the sexual instincts to be significant in the development of the personality (Freud, 1964). However, he used the term psychosexual to describe any sensual pleasure. During childhood certain regions of the body assume a prominent psychologic significance as the source of new pleasures and conflicts gradually shifts from one part of the body to another at particular stages of development:

- **Oral stage** (birth to 1 year)—During infancy the major source of pleasure seeking is centered on oral activities such as sucking, biting, chewing, and vocalizing. Children may prefer one of these over the others, and the preferred method of oral gratification can provide some indication of the personality they develop.
- **Anal stage** (1 to 3 years)—Interest during the second year of life centers in the anal region as sphincter muscles develop and children are able to withhold or expel fecal material at will. At this stage the climate surrounding toilet training can have lasting effects on children's personalities.
- **Phallic stage** (3 to 6 years)—During the phallic stage the genitalia become an interesting and sensitive area of the body. Children recognize differences between the sexes and become curious about the dissimilarities. This is the period around which the controversial issues of the Oedipus and Electra complexes, penis envy, and castration anxiety are centered.
- **Latency period** (6 to 12 years)—During the latency period children elaborate on previously acquired traits and skills. Physical and psychic energy is channeled into acquisition of knowledge and vigorous play.
- **Genital stage** (age 12 years and older)—The last significant stage begins at puberty with maturation of the reproductive system and production of sex hormones. The genital organs become the major source of sexual tensions and pleasures, but energies are also invested in forming friendships and preparing for marriage.

Psychosocial Development (Erikson)

The most widely accepted theory of personality development is that advanced by Erikson (1963). Although built on Freudian theory, it is known as psychosocial development and emphasizes a healthy personality as opposed to a pathologic approach. Erikson also uses the biologic concepts of critical periods and epigenesis, describing key conflicts or core problems that the individual strives to master during critical periods in personality development. Successful completion or mastery of each of these core conflicts is built on the satisfactory completion or mastery of the previous stage.

Each psychosocial stage has two components (i.e., the favorable and the unfavorable aspects of the core conflict), and progress to the next stage depends on resolution of this conflict. No core conflict is ever mastered completely but remains a recurrent problem throughout life. No life situation is ever secure. Each new situation presents the conflict in a new form. For example, when children who have satisfactorily achieved a sense of trust encounter a new experience (e.g., hospitalization), to master the situation they must again develop a sense of trust in those responsible for their care. Erikson's life-span approach to personality development consists of eight stages; however, only the first five relating to childhood are included here:

- **Trust versus mistrust** (birth to 1 year)—The first and most important attribute to develop for a healthy personality is basic trust. Establishing basic trust dominates the first year of life and describes all of the child's satisfying experiences at this age. Corresponding to Freud's oral stage, it is a time of "getting" and "taking in" through all the senses. It exists only in relation to something or someone; therefore consistent, loving care by a mothering person is essential for development of trust. **Mistrust** develops when trust-promoting experiences are deficient or lacking or basic needs are inconsistently or inadequately met. Although shreds of mistrust are sprinkled throughout the personality, from a basic trust in parents stems trust in the world, other people, and oneself. The result is faith and optimism.
- **Autonomy versus shame and doubt** (1 to 3 years)—Corresponding to Freud's anal stage, the problem of autonomy can be symbolized by the holding on and letting go of the sphincter muscles. The development of autonomy during the toddler period is centered on children's increasing ability to control their bodies, themselves, and their environment. They want to do things for themselves using their newly acquired motor skills of walking, climbing, and manipulating and their mental powers of selecting and decision making. Much of their learning is acquired by imitating the activities and behavior of others. Negative feelings of doubt and shame arise when children are made to feel small and self-conscious, when their choices are disastrous, when others shame them, or when they are forced to be dependent in areas in which they are capable of assuming control. The favorable outcomes are self-control and willpower.
- **Initiative versus guilt** (3 to 6 years)—The stage of initiative corresponds to Freud's phallic stage and is characterized by vigorous, intrusive behavior; enterprise; and a strong imagination. Children explore the physical world with all their senses and powers (Fig. 28-4). They develop a conscience. No longer guided only by outsiders, they have an inner voice that warns and threatens. Children sometimes undertake goals or activities that are in conflict with those of parents or others, and being made to feel that their activities or imaginings are bad produces a sense of guilt. They must learn to retain a sense of initiative without impinging on the rights and privileges of others. The lasting outcomes are direction and purpose.

FIG 28-4 The stage of initiative is characterized by physical activity and imagination while children explore the physical world around them.

- **Industry versus inferiority** (6 to 12 years)—The stage of industry is the latency period of Freud. Having achieved the more crucial stages in personality development, children are ready to be workers and producers. They want to engage in tasks and activities that they can carry through to completion; they need and want real achievement. Children learn to compete and cooperate with others, and they learn the rules. It is a decisive period in their social relationships with others. Feelings of inadequacy and inferiority may develop if too much is expected of them or if they believe that they cannot measure up to the standards set for them by others. The ego quality developed from a sense of industry is competence.
- **Identity versus role confusion** (12 to 18 years)—Corresponding to Freud's genital period, the development of identity is characterized by rapid and marked physical changes. Previous trust in their bodies is shaken, and children become overly preoccupied with the way they appear in the eyes of others compared with their own self-concept. Adolescents struggle to fit the roles they have played and those they hope to play with the current roles and fashions adopted by their peers, to integrate their concepts and values with those of society, and to come to a decision regarding an occupation. An inability to solve the core conflict results in role confusion. The outcome of successful mastery is devotion and fidelity to others and to values and ideologies.

Theoretic Foundations of Intellectual Development

The term *cognition* refers to the process by which developing individuals become acquainted with the world and the objects it contains. Children are born with inherited potentials for intellectual growth, but they must develop that potential through interaction with the environment. By assimilating information through the senses, processing it, and acting on it, they come to understand relationships between objects and between themselves and their world. With cognitive development children acquire the ability to reason abstractly, think in a logical manner, and organize intellectual functions or performances into higher-order structures. Language, morals, and spiritual development emerge as cognitive abilities advance.

Cognitive Development (Piaget)

Cognitive development consists of age-related changes that occur in mental activities. The best-known theory regarding children's thinking, and a more comprehensive developmental theory than those already described, was developed by the Swiss psychologist Jean Piaget (1969). According to Piaget intelligence enables individuals to make adaptations to the environment that increase the probability of survival; and through their behavior individuals establish and maintain equilibrium with the environment.

Piaget (1969) proposed three stages of reasoning: (1) intuitive, (2) concrete operational, and (3) formal operational. When they enter the stage of concrete logical thought at about age 7 years, children are able to make logical **inferences,** classify, and deal with quantitative relationships about concrete things. Not until adolescence are they able to reason abstractly with any degree of competence. Each stage is derived from and builds on the accomplishments of the previous stage in a continuous, orderly process. The course of intellectual development is both maturational and invariant and is divided into the following stages (ages are approximate):

- **Sensorimotor** (birth to 2 years)—The sensorimotor stage of intellectual development consists of six substages (see pp. 875 to 876 and pp. 924 and 925) that are governed by sensations in which simple learning takes place. Children progress from reflex activity through simple repetitive behaviors to imitative behavior. They develop a sense of cause and effect as they direct behavior toward objects. Problem solving is primarily by trial and error. They display a high level of curiosity, experimentation, and enjoyment of novelty and begin to develop a sense of self as they are able to differentiate themselves from their environment. They become aware that objects have permanence (i.e., that an object exists even though it is no longer visible). Toward the end of the sensorimotor period, children begin to use language and representational thought.
- **Preoperational** (2 to 7 years) —The predominant characteristic of the preoperational stage of intellectual development is **egocentrism,** which in this sense does not mean selfishness or self-centeredness but the inability to put oneself in the place of another. Children interpret objects and events not in terms of general properties but in terms of their relationships or their use to them. They are unable to see things from any perspective other than their own; they cannot see another's point of view, nor can they see any reason to do so (see Cognitive Development, Chapter 33).

  Preoperational thinking is concrete and tangible. Children cannot reason beyond the observable, and they lack the ability to make deductions or generalizations. Thought is dominated by what they see, hear, or otherwise experience. However, they are increasingly able to use language and symbols to represent objects in their environment. Through imaginative play, questioning, and other interactions, they begin to elaborate concepts and make simple associations between ideas. In the latter stage of this period their reasoning is intuitive (e.g., the stars have to go to bed just as they do); and they are only beginning to deal with problems of weight, length, size, and time. Reasoning is also transductive (i.e., because two events occur together, they cause each other, or knowledge of one characteristic is transferred to another [e.g., all women with big bellies have babies]).
- **Concrete operations** (7 to 11 years)—At this age thought becomes increasingly logical and coherent. Children are able to classify, sort, order, and otherwise organize facts about the world to use in problem solving. They develop a new concept of permanence—**conservation** (see Cognitive Development [Piaget], Chapter 34) (i.e., they realize that physical factors such as volume, weight, and number remain the same even though outward appearances are changed). They are able to deal with a number of different aspects of a situation simultaneously. They do not have the capacity to deal in abstraction; they solve problems in a concrete, systematic fashion based on what they can perceive. Reasoning is inductive. Through progressive changes in thought processes and relationships with others, thought becomes less self-centered. They can consider points of view other than their own. Thinking has become socialized.
- **Formal operations** (11 to 15 years)—Formal operational thought is characterized by adaptability and flexibility. Adolescents can think in abstract terms, use abstract symbols, and draw logical conclusions from a set of observations. For example, they can solve the following question: If *A* is larger than *B* and *B* is larger than *C*, which symbol is the largest? (The answer is *A*.) They can make hypotheses and test them; they can consider abstract, theoretic, and philosophic matters. Although they may confuse the ideal with the practical, most contradictions in the world can be dealt with and resolved.

Language Development

Children are born with the mechanism and capacity to develop speech and language skills. However, they do not speak spontaneously. The environment must provide a means for them to acquire these skills. Speech requires intact physiologic structure and function (including respiratory, auditory, and cerebral) plus intelligence, a need to communicate, and stimulation.

The rate of speech development varies from child to child and is directly related to neurologic competence and cognitive development. Gesture precedes speech, and in this way a small child communicates satisfactorily. As speech develops gesture recedes but never disappears entirely. Research suggests that infants can learn sign language before vocal language and that it may enhance the development of vocal language (Thompson, Cotner-Bichelman, McKerchar, et al., 2007). At all stages of language development, children's comprehension vocabulary (what they understand) is greater than their expressed vocabulary (what they can say), and this development reflects a continuing process of modification that involves both the acquisition of new words and the expanding and refining of word meanings previously learned. By the time they begin to walk, children are able to attach names to objects and persons.

The first parts of speech used are nouns, sometimes verbs (e.g., "go"), and combination words (e.g., "bye-bye"). Responses are usually structurally incomplete during the toddler period, although the meaning is clear. Next they begin to use adjectives and adverbs to qualify nouns, followed by adverbs to qualify nouns and verbs. Later pronouns and gender words are added (e.g., "he" and "she"). By the time children enter school, they are able to use simple, structurally complete sentences that average five to seven words.

Moral Development (Kohlberg)

Children also acquire moral reasoning in a developmental sequence. Moral development, as described by Kohlberg (1968), is based on cognitive developmental theory and consists of the following three major levels, each of which has two stages:

- **Preconventional level**—The preconventional level of moral development parallels the preoperational level of cognitive development and intuitive thought. Culturally oriented to the labels of good/bad and right/wrong, children integrate these in terms of the physical or pleasurable consequences of their actions. At first children determine the goodness or badness of an action in terms of its consequences. They avoid punishment and obey without question those who have the power to determine and enforce the rules and labels. They have no concept of the basic moral order that supports these consequences. Later children determine that the right behavior consists of that which satisfies their own needs (and sometimes the needs of others). Although elements of fairness, give and take, and equal sharing are evident, they are interpreted in a practical, concrete manner without loyalty, gratitude, or justice.
- **Conventional level**—At the conventional stage children are concerned with conformity and loyalty. They value the maintenance of family, group, or national expectations regardless of consequences. Behavior that meets with approval and pleases or helps others is considered good. One earns approval by being "nice." Obeying the rules, doing one's duty, showing respect for authority, and maintaining the social order are the correct behaviors. This level is correlated with the stage of concrete operations in cognitive development.
- **Postconventional, autonomous, or principled level**—At the postconventional level the individual has reached the cognitive stage of formal operations. Correct behavior tends to be defined in terms of general individual rights and standards that have been examined and agreed on by the entire society. Although procedural rules for reaching consensus become important, with emphasis on the legal point of view, there is also emphasis on the possibility for changing law in terms of societal needs and rational considerations.

The most advanced level of moral development is one in which self-chosen ethical principles guide decisions of conscience. These are abstract and ethical but universal principles of justice and human rights with respect for the dignity of people as individuals. It is believed that few people reach this stage of moral reasoning.

Spiritual Development (Fowler)

Spiritual beliefs are closely related to the moral and ethical portion of the child's self-concept and as such must be considered as part of his or her basic needs assessment. Children need to have meaning, purpose, and hope in their lives. In addition, the need for confession and forgiveness is present, even in very young children. Extending beyond religion (an organized set of beliefs and practices), spirituality affects the whole person, including the mind, body, and spirit. Fowler (1981) has identified seven stages in the development of faith, four of which are closely associated with and parallel cognitive and psychosocial development in childhood:

- **Stage 0: Undifferentiated**—This stage of development encompasses the period of infancy during which children have no concept of right or wrong, no beliefs, and no convictions to guide their behavior. However, the beginnings of a faith are established with the development of basic trust through their relationships with the primary caregiver.
- **Stage 1: Intuitive-projective**—Toddlerhood is primarily a time of imitating the behavior of others. Children imitate the religious gestures and behaviors of others without comprehending any meaning of or significance to the activities. During the preschool years they assimilate some of the values and beliefs of their parents. Parental attitudes toward moral codes and religious beliefs convey to children what they consider to be good and bad. Children still imitate behavior at this age and follow parental beliefs as part of their daily lives rather than through an understanding of their basic concepts.
- **Stage 2: Mythical-literal**—Through the school-age years spiritual development parallels cognitive development and is closely related to children's experiences and social interaction. Most children have a strong interest in religion during the school-age years. They accept the existence of a deity, and petitions to an omnipotent being are important and expected to be answered; good behavior is rewarded, and bad behavior is punished. Their developing conscience bothers them when they disobey. They have a reverence for thoughts and matters and are able to articulate their faith. They may even question the validity of their faith.
- **Stage 3: Synthetic-convention**—As children approach adolescence they become increasingly aware of spiritual disappointments. They recognize that prayers are not always answered (at least on their own terms) and may begin to abandon or modify some religious practices. They begin to reason, to question some of the established parental religious standards, and to drop or modify some religious practices.
- **Stage 4: Individuating-reflexive**—Adolescents become more skeptical and begin to compare the religious standards of their parents with those of others. They attempt to determine

which standards to adopt and incorporate into their own set of values. They also begin to compare religious standards with the scientific viewpoint. It is a time of searching rather than reaching. Adolescents are uncertain about many religious ideas but do not achieve profound insights until late adolescence or early adulthood.

Development of Self-Concept

Self-concept is how an individual describes himself or herself. The term *self-concept* includes all of the notions, beliefs, and convictions that constitute an individual's self-knowledge and influence his or her relationships with others. It is not present at birth but develops gradually as a result of unique experiences within the self, significant others, and the realities of the world. However, an individual's self-concept may or may not reflect reality.

In infancy the self-concept is primarily an awareness of one's independent existence learned in part as a result of social contacts and experiences with others. The process becomes more active during toddlerhood as children explore the limits of their capacities and the nature of their impact on others. School-age children are more aware of differences among people, are more sensitive to social pressures, and become more preoccupied with issues of self-criticism and self-evaluation. During early adolescence children focus more on physical and emotional changes taking place and on peer acceptance. Self-concept is crystallized during later adolescence as young people organize their self-concept around a set of values, goals, and competencies acquired throughout childhood.

Body Image

A vital component of self-concept, body image refers to the subjective concepts and attitudes that individuals have toward their own bodies. It consists of the physiologic (the perception of one's physical characteristics), psychologic (values and attitudes toward the body, abilities, and ideals), and social nature of one's image of self (the self in relation to others). All three of the components interrelate with one another. Body image is a complex phenomenon that evolves and changes during the process of growth and development. Any actual or perceived deviation from the "norm" (no matter how this is interpreted) is cause for concern. The extent to which a characteristic, defect, or disease affects children's body image is influenced by the attitudes and behavior of those around them.

The significant others in their lives exert the most important and meaningful impact on children's body image. Labels that are attached to them (e.g., "skinny," "pretty," or "fat") or body parts (e.g., "ugly mole," "bug eyes," or "yucky skin") are incorporated into the body image. Because they lack the understanding of deviations from the physical standard or norm, children notice prominent differences in others and unwittingly make rude or cruel remarks about such minor deviations as large or widely spaced front teeth, large or small eyes, moles, or extreme variations in height.

Infants receive input about their bodies through self-exploration and sensory stimulation from others. As they begin to manipulate their environment, they become aware of their bodies as separate from others. Toddlers learn to identify the various parts of their bodies and are able to use symbols to represent objects. Preschoolers become aware of the wholeness of their bodies and discover the genitalia. Exploration of the genitalia and the discovery of differences between the sexes become important.

School-age children begin to learn about internal body structure and function and become aware of differences in body size and configuration. They are highly influenced by the cultural norms of society and current fads. Children whose bodies deviate from the norm are often criticized or ridiculed. Adolescence is the age when children become most concerned about the physical self. The unfamiliar body changes and the new physical self must be integrated into the self-concept. Adolescents face conflicts over what they see and what they visualize as the ideal body structure. Body image formation during adolescence is a crucial element in the shaping of identity, the psychosocial crisis of adolescence.

Self-Esteem

Self-esteem is the value that an individual places on oneself and refers to an overall evaluation of oneself (Willoughby, King, and Polatajko, 1996). Whereas self-esteem is described as the affective component of the self, self-concept is the cognitive component; however, the two terms are almost indistinguishable and are often used interchangeably.

The term *self-esteem* refers to a personal, subjective judgment of one's worthiness derived from and influenced by the social groups in the immediate environment and individuals' perceptions of how they are valued by others. It changes with development. Highly egocentric toddlers are unaware of any difference between competence and social approval. On the other hand, preschool and early school-age children are increasingly aware of the discrepancy between their competencies and the abilities of more advanced children. Being accepted by adults and peers outside the family group becomes more important to them. Positive feedback enhances their self-esteem; they are vulnerable to feelings of worthlessness and anxious about failure.

As children's competencies increase and they develop meaningful relationships, their self-esteem rises. It is again at risk during early adolescence when they are defining an identity and sense of self in the context of their peer group. Unless children are continually made to feel incompetent and of little worth, a decrease in self-esteem during vulnerable times is only temporary. Children assess the following aspects of themselves in forming an overall evaluation of their self-esteem (Sieving and Zirbel-Donisch, 1990):

- **Competence**—How adequate are my cognitive, physical, and social skills?
- **Sense of control**—How well can I complete tasks needed to produce desired actions? Is someone or something specific versus luck or chance responsible for my successes and failures?
- **Moral worth**—How closely do my actions and behaviors meet moral standards that have been set?
- **Worthiness of love and acceptance**—How worthy am I of love and acceptance from parents, other significant adults, siblings, and peers?

Factors that influence the formation of a child's self-esteem include (1) the child's temperament and personality, (2) abilities and opportunities available to accomplish age-appropriate developmental tasks, (3) how significant others interact with the child, and (4) social roles assumed and the expectations of these roles (see also Psychosocial History, Chapter 29).

ROLE OF PLAY IN DEVELOPMENT

Through the universal medium of play children learn what no one can teach them. They learn about their world and how to deal with this environment of objects, time, space, structure, and people. They learn about themselves operating within that environment (i.e., what they can do, how to relate to things and situations, and how to adapt themselves to the demands society makes on them). Play is the *work* of children. In play they continually practice the

FIG 28-5 Children derive pleasure from handling raw materials. (Paints in this picture are nontoxic.)

FIG 28-6 After infants develop new skills to grasp and manipulate, they begin to conquer new abilities such as putting paper in and taking it out of a toy car.

complicated, stressful processes of living, communicating, and achieving satisfactory relationships with other people.

Classification of Play

From a developmental point of view, patterns of children's play can be categorized according to content and social character. In both there is an additive effect; each builds on past accomplishments, and some element of each is maintained throughout life. At each stage in development the new predominates.

Content of Play

The content of play involves primarily the physical aspects of play, although social relationships cannot be ignored. The content of play follows the directional trend of the simple to the complex:

- **Social-affective play**—Play begins with social-affective play, wherein infants take pleasure in relationships with people. As adults talk, touch, nuzzle, and in various ways elicit responses from an infant, the infant soon learns to provoke parental emotions and responses with such behaviors as smiling, cooing, or initiating games and activities. The type and intensity of the adult behavior with children vary among cultures.
- **Sense-pleasure play**—Sense-pleasure play is a nonsocial stimulating experience that originates from without. Objects in the environment (e.g., light and color, tastes and odors, textures and consistencies) attract children's attention, stimulate their senses, and give pleasure. Pleasurable experiences are derived from handling raw materials (water, sand, food), body motion (swinging, bouncing, rocking), and other uses of senses and abilities (smelling, humming) (Fig. 28-5).
- **Skill play**—After infants have developed the ability to grasp and manipulate, they persistently demonstrate and exercise their newly acquired abilities through skill play, repeating an action over and over again. The element of sense-pleasure play is often evident in the practicing of a new ability, but all too frequently the determination to conquer the elusive skill produces pain and frustration (e.g., putting paper in and taking it out of a toy car) (Fig. 28-6).
- **Unoccupied behavior**—In unoccupied behavior children are not playful but focusing their attention momentarily on anything that strikes their interest. They daydream, fiddle with clothes or other objects, or walk aimlessly. This role differs from that of onlookers, who actively observe the activity of others.
- **Dramatic, or pretend, play**—One of the vital elements in children's process of identification is **dramatic play,** also known as *symbolic* or *pretend play*. It begins in late infancy (11 to 13 months) and is the predominant form of play in preschool children. After children begin to invest situations and people with meanings and attribute affective significance to the world, they can pretend and fantasize almost anything. By acting out events of daily life, they learn and practice the roles and identities modeled by the members of their family and society. Children's toys, replicas of the tools of society, provide a medium for learning about adult roles and activities that may be puzzling and frustrating to them. Interacting with the world is one way children get to know it. The simple, imitative, dramatic play of toddlers such as using the telephone, driving a car, or rocking a doll evolves into more complex, sustained dramas of preschoolers, which extend beyond common domestic matters to the wider aspects of the world and the society such as playing police officer, storekeeper, teacher, or nurse. Older children work out elaborate themes, act out stories, and compose plays.
- **Games**—Children in all cultures engage in games alone and with others. Solitary activity involving games begins as very small children participate in repetitive activities and progress to more complicated games that challenge their independent skills such as puzzles, solitaire, and computer or video games. Very young children participate in simple, imitative games such as pat-a-cake and peek-a-boo. Preschool children learn and enjoy formal games, beginning with ritualistic, self-sustaining games such as ring-around-a-rosy and London Bridge. With the exception of some simple board games, preschool children do not engage in competitive games. Preschoolers hate to lose and try to cheat, want to change rules, or demand exceptions and opportunities to change their moves. School-age children and adolescents enjoy competitive games, including cards, checkers, and chess, and physically active games such as baseball.

Social Character of Play

The play interactions of infancy are between the child and an adult. Children continue to enjoy the company of adults but are increasingly able to play alone. As age advances interaction with age-mates increases in importance and becomes an essential part of the

FIG 28-7 Parallel play at the beach.

socialization process. Through interaction highly egocentric infants, unable to tolerate delay or interference, ultimately acquire concern for others and the ability to delay gratification or even to reject it at the expense of another. A pair of toddlers will engage in considerable combat because their personal needs cannot tolerate delay or compromise. By the time they reach age 5 or 6 years, children are able to arrive at compromises or make use of arbitration, usually after they have attempted but failed to gain their own way. Through continued interaction with peers and the growth of conceptual abilities and social skills, children are able to increase participation with others in the following types of play:

- **Onlooker play**—During onlooker play children watch what other children are doing but make no attempt to enter into the play activity. There is an active interest in observing the interaction of others but no movement toward participating. Watching an older sibling bounce a ball is a common example of the onlooker role.
- **Solitary play**—During solitary play children play alone with toys different from those used by other children in the same area. They enjoy the presence of other children but make no effort to get close to or speak to them. Their interest is centered on their own activity, which they pursue with no reference to the activities of the others.
- **Parallel play**—During parallel activities children play independently but among other children. They play with toys similar to those that the children around them are using but as each child sees fit, neither influencing nor being influenced by the other children. Each plays beside, but not with, other children (Fig. 28-7). There is no group association. Parallel play is the characteristic play of toddlers, but it may also occur in other groups of any age. Individuals who are involved in a creative craft with each person separately working on an individual project are engaged in parallel play.
- **Associative play**—In associative play children play together and are engaged in a similar or even identical activity, but there is no organization, division of labor, leadership assignment, or mutual goal. Children borrow and lend play materials, follow each other with wagons and tricycles, and sometimes attempt to control who may or may not play in the group. Each child acts according to his or her own wishes; there is no group goal (Fig. 28-8). For example, two children play with dolls, borrowing articles of clothing from one another and engaging in similar conversation, but neither directs the other's actions or establishes rules regarding the limits of the play session. There is a great deal of behavioral contagion: when one child initiates an activity, the entire group follows the example.

FIG 28-8 Associative play.

FIG 28-9 Cooperative play.

- **Cooperative play**—Cooperative play is organized, and children play in a group *with* other children (Fig. 28-9). They discuss and plan activities with the purpose of accomplishing an end (e.g., to make something, attain a competitive goal, dramatize situations of adult or group life, or play formal games). The group is loosely formed, but there is a marked sense of belonging or not belonging. The goal and its attainment require organization of activities, division of labor, and role playing. The leader-follower relationship is definitely established, and the activity is controlled by one or two members who assign roles and direct the activity of the others. The activity is organized to allow one child to supplement another's function to complete the goal.

Functions of Play

Sensorimotor Development

Sensorimotor activity is a major component of play at all ages and the predominant form of play in infancy. Active play is essential for muscle development and serves a useful purpose as a release for surplus energy. Through sensorimotor play, children explore the nature of the physical world. Infants gain impressions of themselves and their world through tactile, auditory, visual, and kinesthetic stimulation. Toddlers and preschoolers revel in body movement and exploration of objects in space. With increasing maturity sensorimotor play becomes more differentiated and involved. Whereas very young children run for the sheer joy of body movement, older

children incorporate or modify the motions into increasingly complex and coordinated activities such as races, games, roller skating, and bicycle riding.

Intellectual Development

Through exploration and manipulation children learn colors, shapes, sizes, textures, and the significance of objects. They learn the significance of numbers and how to use them; they learn to associate words with objects; and they develop an understanding of abstract concepts and spatial relationships such as *up, down, under,* and *over.* Activities such as puzzles and games help them develop problem-solving skills. Books, stories, films, and collections expand knowledge and provide enjoyment as well. Play provides a means to practice and expand language skills. Through play children continually rehearse past experiences to assimilate them into new perceptions and relationships. Play helps children comprehend the world in which they live and distinguish between fantasy and reality.

Socialization

From very early infancy children show interest and pleasure in the company of others. Their initial social contact is with the mothering person, but through play with other children they learn to establish social relationships and solve the problems associated with these relationships. They learn to give and take, which is more readily learned from critical peers than from more tolerant adults. They learn the sex role that society expects them to fulfill and approved patterns of behavior and deportment. Closely associated with socialization is development of moral values and ethics. Children learn right from wrong, the standards of the society, and to assume responsibility for their actions.

Creativity

In no other situation is there more opportunity to be creative than in play. Children can experiment and try out their ideas in play through every medium at their disposal, including raw materials, fantasy, and exploration. Creativity is stifled by pressure toward conformity; therefore striving for peer approval may inhibit creative endeavors in school-age or adolescent children. Creativity is primarily a product of solitary activity; however, creative thinking is often enhanced in group settings where listening to others' ideas stimulates further exploration of one's own ideas. After children feel the satisfaction of creating something new and different, they transfer this creative interest to situations outside the world of play.

Self-Awareness

Beginning with active explorations of their bodies and awareness of themselves as separate from their mothers, the process of developing a self-identity is facilitated through play activities. Children learn who they are and their place in the world. They become increasingly able to regulate their own behavior, learn what their abilities are, and compare their abilities with those of others. Through play children are able to test their abilities, assume and try out various roles, and learn the effects that their behavior has on others. They learn the sex role that society expects them to fulfill and approved patterns of behavior and deportment.

Therapeutic Value

Play is therapeutic at any age (Fig. 28-10). In play children can express emotions and release unacceptable impulses in a socially acceptable fashion. They are able to experiment and test fearful situations and can assume and vicariously master the roles and positions that they are unable to perform in the world of reality. Children reveal much about themselves in play. Through play they are able to communicate to the alert observer the needs, fears, and desires that they are unable to express with their limited language skills. Throughout their play children need the acceptance of adults and their presence to help them control aggression and channel their destructive tendencies.

FIG 28-10 Play is therapeutic at any age and provides a means for release of tension and stress.

Morality

Although children learn at home and at school the behaviors considered right and wrong in the culture, the interaction with peers during play contributes significantly to their moral training. Nowhere is the enforcement of moral standards as rigid as in the play situation. If they are to be acceptable members of the group, children must adhere to the accepted codes of behavior of the culture (e.g., fairness, honesty, self-control, consideration for others). Children soon learn that their peers are less tolerant of violations than are adults and that, to maintain a place in the play group, they must conform to the standards of the group (Fig. 28-11).

Toys

The type of toys chosen by or provided for children can support and enhance their development in the areas just described. Although no scientific evidence shows that any toy is necessary for optimal learning, toys offer an opportunity to bring children and parents together. Research has indicated that a positive parent-child interaction can enhance early childhood brain development (AAP, 2003). Toys that are small replicas of the culture and its tools help children assimilate into their culture. Toys that require pushing, pulling, rolling, and manipulating teach them about physical properties of the items and help develop muscles and coordination. Rules and the basic elements of cooperation and organization are learned through board games.

FIG 28-11 Peers become increasingly important as children develop friendships outside the family group.

Because they can be used in a variety of ways, raw materials with which children can exercise their own creativity and imaginations are sometimes superior to ready-made items. For example, building blocks can be used to construct a variety of structures, count, and learn shapes and sizes.

DEVELOPMENTAL ASSESSMENT

One of the most essential components of a complete health appraisal is assessment of developmental function. Screening procedures are designed to identify quickly and reliably children whose developmental level is below normal for their age and who therefore require further investigation. They also provide a means of recording objective measurements of present developmental function for future reference. Since the passage of Public Law 99-457, the Education of the Handicapped Act Amendments of 1986, much greater emphasis is placed on developmental assessment of children with disabilities, and nurses can play a vital role in providing this service. All the procedures discussed in this section can be administered in a variety of settings: home, school, day care center, hospital, practitioner's office, or clinic.

In the past, the most widely used developmental screening tests for young children were the series of tests known as the Denver Developmental Screening Test (DDST) and its revision, the DDST-R, which was revised, restandardized, and renamed the Denver II. The American Academy of Neurology (AAN) and the Child Neurology Society (CNS) state that research has found the Denver II to be insensitive and lacking in specificity; therefore neither the AAN nor the CNS recommends use of the Denver II for primary care developmental screening (Filipek, Accardo, Ashwal, et al., 2000). A complete list of child development assessment tools has been developed by the National Early Childhood Technical Assistance Center (NECTAC) as part of its cooperative agreement with the U.S. Office of Special Education Programs.* The pediatric health promotion chapters include detailed information on development and assessment that is unique to the age and stage of the child.

*Developmental screening and Assessment Instruments is available at http://www.nectac.org/%7Epdfs/pubs/screening.pdf

BOX 28-4 AGES AND STAGES QUESTIONNAIRES AT A GLANCE

- Type of screening: Developmental (ASQ-3™) and social-emotional (ASQ:SE)
- Age range: 1-66 months for ASQ-3™, 3-66 months for ASQ:SE
- Number of questionnaires: 21 for ASQ-3™, 8 for ASQ:SE
- Number of items: About 30 per questionnaire
- Online components: Data management and questionnaire completion
- Reading level of items: 4th to 6th grade
- Who completes it: Parents
- Time to complete: 10-15 minutes
- Who scores it: Professionals
- Time to score: 2-3 minutes
- Languages: English and Spanish (for other languages, visit www.agesandstages.com)

Ages and Stages

Ages and stages is a term used to broadly outline key periods in the human development timeline. During each stage, growth and development occur in primary developmental domains that include physical, intellectual, language, and social-emotional (Box 28-4). The Ages & Stages Questionnaires (ASQ)* are high-quality screening tools that include 19 age-specific surveys that ask parents about developmental skills common in daily life for children 1 month to 5½ years. Parents or other caregivers answer questions regarding their child's abilities (e.g., Does your child climb on an object such as a chair to reach something he wants? When your child wants something, does she tell you by pointing to it?). Children whose development appears to fall significantly below results of other children their age are flagged for further evaluation The ASQ can be used as a universal screening tool in pediatric clinics to identify children at risk for social-emotional developmental delays (Briggs, Stettler, Silver, et al., 2012).

GENETIC FACTORS THAT INFLUENCE DEVELOPMENT

Genes, Genetics, and Genomics

Nurses and other health care providers are increasingly faced with incorporating genetic and genomic information into their practice. In response to this need, the Consensus Panel on Genetic/Genomic Nursing Competencies was established in 2006. This independent panel of nurse leaders from clinical, research, and academic settings established essential minimal competencies necessary for nurses to deliver competent genetic- and genomic-focused nursing care. Subsequently the American Association of Colleges of Nursing published the revised *The Essentials of Baccalaureate Education for Professional Nursing Practice* (2008, www.aacn.nche.edu/education/pdf/BaccEssentials08.pdf) and *The Essentials of Master's Education in Nursing* (2011, www.aacn.nche.edu/education/pdf/MastersEssentials11.pdf), both of which identified genetics and genomics as strong forces influencing the role of nurses in patient care. This brief overview identifies key terms and concepts and highlights

*The ASQ can be found at www.agesandstages.com

essential genetics and genomics competencies for all nurses (2008, www.genome.gov/Pages/Careers/HealthProfessionalEducation/geneticscompetency.pdf).

Genes are segments of deoxyribonucleic acid (DNA) that specify for proteins, segments of proteins, or strands of ribonucleic acid (RNA) necessary to control physiologic functions or characteristics. These segments are often referred to as *sites* or *loci,* indicating a physical or "geographic" location on a chromosome. Variant forms of a gene commonly occur within a population. When referring to a particular form of a gene, the term *allele* is used. Specific differences within a gene are called *mutations* if they are rare within a population or are **polymorphisms** if they are found within more than 1% of a particular population. Mutations and polymorphisms can be inherited or acquired. Variant alleles caused by mutations or polymorphisms may lead to no measureable or observable differences, cause the person to be susceptible to clinically recognizable pathology within specific environmental contexts, cause a clinically recognized disease or disorder, or prove advantageous within a particular environmental context. Whereas genetics is the study of individual genes and the impact of their variant forms on relatively rare single gene disorders, genomics is the study of combinations of multiple genes, their interactions with one another, the environment, and other psychosocial and cultural factors (Guttmacher and Collins, 2002).

In earlier times human diseases were thought to be either clearly genetic or typically environmental. However, the observation that some genetic disorders are congenital (present at birth) but others are expressed later in life has led scientists to conclude that many, if not most, diseases are caused by a genetic predisposition that can be activated by an environmental trigger. Examples of such interactions are found in single-gene disorders such as phenylketonuria (PKU) and sickle cell disease and multifactorial conditions such as cancer and neural tube defects (NTDs). PKU is a disorder resulting from the (genetically determined) absence of an enzyme that metabolizes the amino acid phenylalanine. However, the deleterious effects in the infant are expressed only after sufficient ingestion of phenylalanine-containing substances such as milk (environmental trigger). Even in the case of a "classic" genetic condition such as sickle cell disease, its acute symptoms are precipitated by certain conditions such as lowered oxygen tension, infection, or dehydration.

Cancer is another example of genetic-environment interplay and explains the difference between inherited conditions and somatic cell genetic disorders. A normal somatic cell (any body cell other than the ova and sperm) may become a cancer cell after acquiring a series of gene changes. This process is the typical "genetic" cause of cancer. In a small subset of families a mutation in a gene normally involved in regulation of cell growth, DNA repair, or cell death (apoptosis) is transmitted through the germ cells (ova and sperm). Children who inherit the genetic mutation have it in all of their somatic cells, making them more susceptible to subsequent genetic changes in one or more cells that may transform into cancer cells. Beyond the genetic component of cancer, there is little dispute that environmental insult such as tobacco smoking, sun exposure, and radiation can be carcinogenic. Such environmental triggers are capable of spontaneously creating noninherited mutations in genes that regulate cell growth and cell response to cell abnormalities that can eventually lead to malignant transformation.

Evidence is growing that genes play an important role in human susceptibility and resistance to infection, even in cases with a clear environmental cause of the infectious disease. Evidence for this genetic element in resistance gained heightened recognition during the first decade of the acquired immunodeficiency (AIDS) epidemic. Researchers discovered that adults with a specific deletion in both copies of their *CCR5* genes did not become infected with human immunodeficiency virus (HIV) despite repeated exposure. Later it was found that children exposed in utero to HIV typically had a significantly delayed onset of disease if at least one of their *CCR5* genes had the specific mutation (Romiti, Colognesi, Cancrini, et al., 2000).

Congenital Anomalies

Embryogenesis and fetal development are an intricate and precisely timed series of events in which all parts must be properly integrated to ensure a coordinated whole. Insults during development or abnormalities in differentiation or in the proper timing of organogenesis may result in a variety of congenital anomalies. Congenital anomalies, or birth defects, occur in 2% to 4% of all live-born children and are often classified as deformations, disruptions, dysplasias, or malformations. Deformations are often caused by extrinsic mechanical forces on normally developing tissue. Clubfoot is an example of a deformation often caused by uterine constraint. Disruptions result from the breakdown of previously normal tissue. Congenital amputations caused by amniotic bands (fibrous strands of amnion that wrap around different body parts during development) are examples of disruption anomalies. Dysplasias result from abnormal organization of cells into a particular tissue type. Congenital abnormalities of the teeth, hair, nails, or sweat glands may be manifestations of one of the more than 150 different ectodermal dysplasia syndromes (Ectodermal Dysplasia Society, 2013). Malformations are abnormal formations of organs or body parts resulting from an abnormal developmental process. Most malformations occur before 12 weeks of gestation. Cleft lip, an example of a malformation, occurs at approximately 5 weeks of gestation when the developing embryo naturally has two clefts in the area. Normally between 5 and 7 weeks cells rapidly divide and migrate to fill in these clefts. If there is an abnormality in this developmental process, the embryo is left with either a unilateral or bilateral cleft lip that may also involve the palate.

The types of anomalies that can result from genetic or prenatal environmental causes can be major structural abnormalities with serious medical, surgical, or quality-of-life consequences; or they can be minor anomalies or normal variants with no serious consequences such as a sacral dimple, an extra nipple, or a café-au-lait spot. Congenital anomalies can occur in isolation such as congenital heart defect, or multiple anomalies may be present. A recognized pattern of anomalies resulting from a single specific cause is called a syndrome (e.g., Down syndrome, fetal alcohol syndrome). A nonrandom pattern of malformations for which a cause has not been determined is called an association (e.g., VACTERL [vertebral defects, anal atresia, cardiac defect, tracheoesophageal fistula, and renal and limb defects] association). When a single anomaly leads to a cascade of additional anomalies, the pattern of defects is referred to as a sequence. Pierre Robin sequence begins with the abnormal development of the mandible, resulting in abnormal placement of the tongue during development. The normal developmental process for the palate is prevented because the tongue obstructs the migration of the palatal shelves toward the midline, and a cleft palate remains. Consequently infants born with Pierre Robin sequence have a recessed mandible and an abnormally placed tongue and are at risk for obstructive apnea. NTDs, cleft lip and palate, deafness, congenital heart defects, and cognitive impairment are examples of congenital malformations that can occur in isolation or as part of a syndrome, association, or sequence and can have different causes such as single-gene or chromosome abnormalities, prenatal exposures, or multifactorial causes.

Disorders of the Intrauterine Environment

The intrauterine environment can have a profound and permanent effect on developing fetuses with or without chromosome or single-gene abnormalities. For example, intrauterine growth restriction can occur with many genetic syndromes such as Down, Russell-Silver, Prader-Willi, and Turner syndromes (Rimoin, Connor, Pyeritz, et al., 2002); or it can be caused by nongenetic factors such as maternal alcohol ingestion. Placental abnormalities are increasingly being found to be the etiologic factor in neurodevelopmental disorders (e.g., cerebral palsy and cognitive impairment) that were previously attributed to asphyxia during delivery (Bos, Einspieler, Prechtl, et al., 2001). Teratogens, agents that cause birth defects when present in the prenatal environment, account for most adverse intrauterine effects not attributable to genetic factors. Types of teratogens include drugs (phenytoin [Dilantin], warfarin [Coumadin], isotretinoin [Accutane]), chemicals (ethyl alcohol, cocaine, lead), infectious agents (rubella, cytomegalovirus), physical agents (maternal ionizing radiation, hyperthermia), and metabolic agents (maternal PKU). Many of these teratogenic exposures and the resulting effects are completely preventable such as ingestion of alcohol resulting in fetal alcohol syndrome or fetal alcohol effects, which causes severe birth defects, including cognitive impairment.

Genetic Disorders

Genetic disorders can be caused by chromosome abnormalities as seen in Turner syndrome, Down syndrome, or velocardiofacial syndrome (VCFS); single-gene mutations as seen in sickle cell anemia, neurofibromatosis, or Duchenne muscular dystrophy; a combination of genetic and environmental factors as seen in NTDs or maturity-onset diabetes in the young; and mitochondrial DNA (mtDNA) mutations as seen in nonsyndromic deafness susceptibility caused by aminoglycoside sensitivity.

Both numeric and large structural abnormalities of autosomes (all chromosomes except the X and Y chromosomes) account for a variety of syndromes usually characterized by cognitive deficiencies. Nurses often note dysmorphic facial features, behavioral characteristics such as an unusual cry and poor feeding behavior, and other neurologic manifestations such as hypotonia or abnormal reflex responses, which may alert them to these and other chromosome abnormalities.

Somatic cells contain 44 autosomes (the 22 pairs of chromosomes that do not greatly influence sex determination at conception) and two sex chromosomes, XX in females and XY in males. For the purpose of cytogenetic studies, chromosomes are usually displayed in a karyotype, the laboratory-made arrangement of specially prepared chromosomes according to their size and centromere position. Numeric chromosome abnormalities occur whenever entire chromosomes are added or deleted. Down syndrome is an example of a condition caused by having an extra autosome, chromosome 21. Turner syndrome is the only example of a condition compatible with life that is caused by the absence of a chromosome. Children with Turner syndrome have one X chromosome. Chromosomes are subject to structural alterations resulting from breakage and rearrangement. A chromosome deletion occurs when chromosome breakage results in loss of the broken fragment at the terminal end of a chromosome or within the chromosome. Some structural chromosome abnormalities are too small to visualize reliably under a light microscope but are still clinically relevant. Fragile, or weak, sites associated with expanded triplet repeats have been identified on both the autosomes and the X chromosome. A classic example is fragile X syndrome. Contiguous gene syndromes are disorders characterized by a microdeletion or microduplication of smaller chromosome segments, which may require special analysis techniques or molecular testing to detect (Bar-Shira, Rosner, Rosner, et al., 2006).

Chromosome anomalies typically affect large numbers of genes; however, a single-gene disorder is caused by an abnormality within a gene or in the regulatory region of a gene. Single-gene disorders can affect all body systems and may have mild-to-severe expressions. They display a Mendelian pattern of dominant or recessive inheritance that was first delineated in the mid-nineteenth century by Gregor Mendel's experiments with plants.

Mendelian inheritance laws allow for risk prediction in single-gene disorders; however, phenotypic expression may be altered by incomplete penetrance or variable expressivity of the responsible allele. An allele is said to have reduced or incomplete penetrance in a population when a proportion of people who possess that allele do not express the phenotype. An allele is said to have variable expressivity when individuals possessing that allele display the features of the syndrome in various degrees from mild to severe. If a person expresses even the mildest possible phenotype, the allele is penetrant in that individual.

Role of Nurses in Genetics

All nurses need to be prepared to use genetic and genomic information and technology when providing care. Nearly 50 nursing organizations endorsed essential minimum competencies necessary for nurses to deliver competent genetic- and genomic-focused nursing care (Consensus Panel on Genetic/Genomic Nursing Competencies, 2006). The professional practice domains include applying and integrating genetic knowledge into nursing assessment; identifying and referring patients who may benefit from genetic information or services; identifying genetics resources and services to meet patients' needs; and providing care and support before, during, and after providing genetic information and services. Often a nurse is the first one to recognize the need for genetic evaluation by identifying an inherited disorder in a family history or noting physical, cognitive, or behavioral abnormalities when performing a nursing assessment (Box 28-5).

Applying and Integrating Genetic and Genomic Knowledge into Nursing Assessment

Family health history is an important tool to identify individuals and families at increased risk for disease, risk factors for disease (e.g., obesity), and inheritance patterns of diseases. Because of its importance, all nurses need to be able to elicit family history information and document the collected information in pedigree format.

When eliciting a family health history, nurses should collect information about all family members within a minimum of three generations. This process usually takes 20 to 30 minutes. When possible, it is best to include both parents in the interview to elicit information about relatives on both sides of the family. Medical records, birth and death records, family Bibles, and photograph albums are helpful resources; and people being interviewed should be instructed to bring such items if they are available. It may be necessary to consult other members of the family. The level of education and degree of understanding vary widely among informants and influence their reliability. The informants may be reticent, particularly if they view the disorder as something for which they should be ashamed or that is in some way threatening. Sometimes true relationships may be concealed such as adoption or misattributed paternity.

In addition to family history, nurses caring for children and families need to collect pregnancy, labor and delivery, perinatal,

BOX 28-5 PEDIATRIC INDICATIONS FOR GENETIC CONSULTATION

- Family history
  - Family history of hereditary diseases, birth defects, or developmental problems
  - Family history of sudden cardiac death or early-onset cancer
  - Family history of mental illness
- Medical history
  - Abnormal newborn screen
  - Abnormal genetic test result ordered by a nongenetics professional who lacks the knowledge and experience to discuss the implications of results
  - Excessive bleeding or excessive clotting
  - Progressive neurologic condition
  - Recurrent infection or immunodeficiency
- Developmental history
  - Behavioral disorders
  - Cognitive impairment or autism
  - Development and speech delays or loss of developmental milestones
- Physical assessment
  - Major congenital anomaly
  - Minor anomalies and dysmorphic features
  - Growth abnormalities
  - Skeletal abnormalities
  - Visual or hearing problems
  - Metabolic disorder (unusual odor of breath, urine, or stool)
  - Sexual development abnormalities or delayed puberty
  - Skin disorders or abnormalities
- Parental requests that child be evaluated by a genetics professional

Adapted from Pletcher BA, Toriello HV, Noblin SJ, et al: Indications for genetic referral: a guide for healthcare providers, *Genet Med* 9(6):385–389, 2007.

medical, and developmental histories. Although it is common for genetics nurses to obtain all of these histories before or during an initial genetics consultation, not all nurses are expected to obtain all of these assessment data from each patient during a pediatric visit. Electronic medical records are making it more practical to construct a comprehensive set of histories even when many health care professionals contribute only a portion of the total history.

All nurses are taught to perform physical assessments, but they are seldom taught to recognize minor anomalies and dysmorphology that may suggest a genetic disorder. Yet nurses are keen in recognizing delays in development, behavior differences, and global appearances that raise concern that a newborn, infant, child, or adolescent needs further evaluation. Although dysmorphology is beyond the scope of this chapter, readers are encouraged to review the January 2009 issue of *American Journal of Medical Genetics* (Carey, Cohen, Curry, et al., 2009). Drawings and photographs of normal and abnormal morphologic characteristics are provided for the head, face, and extremities together with accepted dysmorphology terminology. Nurses knowledgeable in dysmorphology are able to articulate specific concerns about a child's appearance rather than rely on the outdated and offensive phrase, "funny looking kid." When a major anomaly is identified, nurses should raise suspicion that the child could have additional congenital anomalies. When three or more minor anomalies are identified, nurses should suspect the possibility of an underlying syndrome. However, it is important to consider the biologic parents' physical appearance, development, and behavior when considering the relevance of the child's combination of minor anomalies.

Identifying and Referring

It is nurses' responsibility to learn basic genetic principles, be alert to situations in which families could benefit from genetic evaluation and counseling, know about special services that can help manage and support affected children, and be familiar with facilities in their areas where these services are available. In this way they are able to direct individuals and families to needed services and be active participants in the genetic evaluation and counseling process. A regularly updated resource for locating genetics clinics can be found at www.genetests.org (click on Clinic Directory tab). Contact information for specific genetics professionals can be found at the following websites: geneticists, www.acmg.net (click on Find a Geneticist); genetics nurses, www.isong.org (call or e-mail office); and genetic counselors, www.nsgc.org (click on Find a Counselor). In addition, state health departments either offer services or can help identify health professionals with specialty training in genetics.

Early identification of a genetic disorder allows anticipation of associated conditions and implementation of available preventive measures and therapy to avoid potential complications and enhance the child's health. It may also prevent the unexpected birth of another affected child in the immediate or extended family. Nurses have an important role in identifying patients and families who have or are at risk for developing or transmitting a genetic condition (see Box 28-5). When facilitating genetics consultations, nurses should share with the genetics professional the findings in the histories they collected that triggered the consultation. Nurses can also help the referral process by determining and communicating the family's initial concerns, their state of knowledge about the reason for referral, and their attitudes and beliefs concerning genetics.

Genetic evaluation for diagnostic purposes may occur at any point in the life span. In the newborn period birth defects and abnormal newborn screen results are obvious reasons for referral. Beyond the newborn period indicators for referral include metabolic disorders, developmental delays, growth delays, behavioral problems, cognitive delays, abnormal or delayed sexual development, and medical problems known to be associated with genetic diseases. For example, a preschooler with hyperactivity and autistic-like behaviors may need evaluation for fragile X syndrome, and a 17-year-old girl with primary amenorrhea and short stature should be evaluated for Turner syndrome.

With so many recent advances in genetic testing, it is not unusual for a child or adult with long-standing medical problems, including cognitive impairment, to be referred for reevaluation of his or her condition as a possible genetic disorder that might not have been diagnosable a few years earlier such as microdeletion disorders or single-gene mutations. If a genetic diagnosis is made, the patient is usually referred back to the primary care physician with recommendations for routine management.

Providing Education, Care, and Support

Maintaining contact with the family or making a referral to a health care practice or an agency that can provide a sustained relationship is critical. It is becoming more common for genetics health care professionals to provide regular follow-up and management, particularly for children with rare genetic disorders. However, some families choose not to have follow-up visits.

Regardless of whether families choose to receive continued care with a genetics center, clinic, or professional, nurses can help patients

and families process and clarify the information they receive during a genetics visit. Misunderstanding of this information can have many causes, including cultural differences, the disparity of knowledge between the counselor and the family, and the heightened emotion surrounding genetic counseling. Family members have difficulty absorbing all of the information presented during a genetics evaluation and counseling session. Knowing this, genetics professionals write and send clinic summary letters to families. The nurse may need to help the family understand terminology in the letter, help them identify and articulate remaining questions or areas of clarification, and coach them through the process of accessing genetics health professionals to have remaining questions and concerns answered. Information often needs to be repeated several times before the family understands the content and its implications.

Nurses must assess for and address parents' feelings of guilt about carrying "bad genes" or having "made my child sick." Depending on the type of cytogenetic disorder, the nurse may be able to absolve the parents of guilt by explaining the random nature of segregation during both gamete formation and fertilization and that these errors in cell division unique to the pregnancy in question are not likely to happen again and are not inherited. If the condition is a Mendelian-inherited or mitochondrial disorder, it is important to assess parents' understanding of recurrence risk, help them understand the chances that a subsequent pregnancy will not be affected, and ensure they have been given information about their options for future children (preimplantation diagnosis, use of donor egg or sperm, prenatal diagnosis, or adoption). Families often try to reason that some unrelated event caused the abnormality (e.g., a fall, a urinary tract infection, or "one glass of wine") before the mother was aware that she was pregnant. These misconceptions need to be assessed and dispelled.

After, and sometimes before, a genetics visit, parents often use the Internet to find answers to their questions. During the initial genetics evaluation a diagnosis may not be possible. Instead findings in medical, developmental, and family histories lead the professional to order genetic tests and other diagnostic procedures. Diagnoses under consideration are discussed briefly with the parents. Some parents are satisfied with the brief information and do not care to find out more until the actual diagnosis is established. Others seek as much information as they can about the diagnoses under consideration. The information they find can be terrifying and overwhelming and inaccurate or misleading. Nurses can play an important role in helping parents identify reliable, accurate resources for information at whatever time they desire it. It is also important to stress that everything that is described for a genetic condition may not be relevant to their child. Before the follow-up genetics visit when test and procedure results are discussed, nurses can help parents identify and write down the questions and concerns they need addressed before leaving the clinic.

After a genetics diagnosis is made or a genetic predisposition to a delayed-onset disorder is identified, nurses need to have frequent contact with patients and families as they attempt to incorporate recommended therapies or disease-prevention strategies into their daily lives. For example, a disorder such as PKU requires conscientious diet management; therefore it is important to make certain that the family understands and follows instructions and is able to navigate the health care system to access the essential formula and low-phenylalanine food products. An infant evaluated for cleft palate and cardiac defect and subsequently found to have VCFS requires surgical intervention for the congenital malformations. Such an infant also benefits from early intervention services and eventually an individualized education plan in school because developmental delays and eventual learning problems are common.

Initial and ongoing assessment of the family's coping abilities, resources, and support systems is vital to determine their need for additional assistance and support. As with any family who has a child with chronic health care needs, nurses must teach them to become the child's advocate. Nurses can help families locate agencies and clinics specializing in a specific disorder or its consequences that can provide services (e.g., equipment, medication, and rehabilitation), educational programs, and parent support groups. Referral to local and national support groups or contact with a local family that has a child with the same condition can be helpful for new parents. Privacy and confidentiality are imperative, and both families must give permission before their contact information is given. Nurses can also be instrumental in helping parents start a support group when none is available.

Parental attachment and adjustment to the baby can be supported and facilitated by nursing interventions. Assessing the parents' understanding of the child's disorder and providing simple and truthful explanations can help them begin to understand their child's health issues. Guiding the parents in recognizing their child's cues, responses, and strengths can be helpful even for experienced parents. A caring attitude conveys the value of their child and by extension their value as parents. The nurse can help the parents identify their strengths as a family and support that is available to them.

Giving birth to and raising a child with a genetic disorder is not necessarily a lifetime burden. It is important for nurses to ask parents to describe their experience raising their child with a particular genetic condition. What has been the impact on their family? Although parents may initially experience negative outcomes such as shock, emotional distress, and grief, families can adapt and thrive. Resources for managing stress and restoring balance in the lives of families affected by a genetic condition can help. Van Riper's research (2007) has identified nursing interventions that can promote resilience and adaptation in families of children with Down syndrome. His recommendations are useful for families of children with any type of genetic disorder:

- Recognize multiple stressors, strains, and transitions in their lives (e.g., unmet family needs).
- Discuss and implement strategies for reducing family demands (e.g., setting priorities and reducing the number of outside activities family members in which are involved).
- Identify and use individual, family, and community resources (e.g., humor, family flexibility, supportive extended family, respite care, local support groups, and Internet resources).
- Expand the range and efficacy of their coping strategies (e.g., increase the use of active strategies such as reframing, mobilize their ability to acquire and accept help, and decrease the use of passive appraisal).
- Encourage the use of an affirming style of family problem-solving communication (e.g., one that conveys support and caring and exerts a calming influence).

Some families struggle after learning that their child has a genetic disorder. They may feel ashamed of a hereditary disorder and seek to blame their partner for transmitting a faulty gene or chromosome. Intrafamilial strife, hostility, and marital or couple disharmony, sometimes to the point of family disintegration, can occur. Nurses should be alert for evidence of risk factors that indicate poor adjustment (e.g., child abuse, divorce, or other maladaptive behaviors). Referral to psychosocial professionals for crisis intervention may be necessary.

KEY POINTS

- Growth is a change in quantity and occurs when cells divide and synthesize new proteins.
- Maturation, a qualitative change, is the aging process or an increase in competence and adaptability.
- Differentiation is a biologic description of the processes by which early cells and structures are modified and altered to achieve specific and characteristic physical and chemical properties.
- Development involves change from a lower to a more advanced stage of complexity.
- The five major developmental periods are prenatal, infancy, early childhood, middle childhood, and later childhood (pubescence and adolescence).
- Growth and development proceed in predictable patterns of direction, sequence, and pace.
- The directional trends in growth and development are cephalocaudal, proximodistal, and mass to specific.
- Physical development includes increase in height and weight and changes in body proportion, dentition, and some body tissues.
- The three broad classifications of child temperament are the easy child, the difficult child, and the slow-to-warm-up child.
- The developmental theories most widely used in explaining child growth and development are Freud's psychosexual stages, Erikson's stages of psychosocial development, Piaget's stages of cognitive development, Kohlberg's stages of moral development, and Fowler's stages of spiritual development.
- To develop a positive self-concept, children need recognition for their achievements and the approval of others.
- Through play children learn about their world and how to relate to objects, people, and situations.
- Play provides a means of development in the areas of sensorimotor and intellectual progress, socialization, creativity, self-awareness, and moral behavior; it serves as a means for release of tension and expression of emotions.
- Growth and development are affected by a variety of conditions and circumstances, including heredity, physiologic function, gender, disease, physical environment, nutrition, and interpersonal relationships.
- Children's vulnerability and reaction to stress depend to a large extent on their age, coping behaviors, and support systems.
- Developmental screening tools are valuable in identifying infants and children who are at risk for developmental delays.
- Genetic mutations and polymorphisms can be inherited or acquired. Mutations are rare, whereas polymorphisms occur in greater than 1% of a population.
- All nurses should be familiar with genetic or genomic information as it relates to the care of their patient.

CHAPTER

29

Communication, History, and Physical Assessment

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify communication strategies for interviewing parents.
- Formulate guidelines for using an interpreter.
- Identify communication strategies for communicating with children of different age-groups.
- Describe four communication techniques that are useful with children.
- State the components of a complete health history.
- List three areas that are evaluated as part of nutritional assessment.
- Prepare a child for a physical examination based on his or her developmental needs.
- Perform a comprehensive physical examination in a sequence appropriate to the child's age.
- Recognize expected normal findings for children at various ages.
- Record the physical examination according to the head-to-toe format.

GUIDELINES FOR COMMUNICATION AND INTERVIEWING

The most widely used method of communicating with parents on a professional basis is the interview process. Unlike social conversation, interviewing is a specific form of goal-directed communication. As nurses converse with children and adults, they focus on the individuals to determine the kind of persons they are, their usual mode of handling problems, whether they need help, and the way they react to counseling. Developing interviewing skills requires time and practice, but following some guiding principles can facilitate this process. An organized approach is most effective when using interviewing skills in patient teaching.

Establishing a Setting for Communication

Appropriate Introduction

Introduce yourself, and ask the name of each family member who is present. Address parents or other adults by their appropriate titles, such as "Mr." and "Mrs.," unless they specify a preferred name. Record the preferred name on the medical record. Using formal address or their preferred names, rather than using first names or "mother" or "father," conveys respect and regard for the parents or other caregivers (Seidel, Ball, Dains, et al., 2011).

At the beginning of the visit, include children in the interaction by asking them their name, age, and other information. Nurses often direct all questions to adults, even when children are old enough to speak for themselves. This only terminates one extremely valuable source of information: the patient. When including the child, follow the general rules for communicating with children given in the Guidelines box on p. 775.

Assurance of Privacy and Confidentiality

The place where the nurse conducts the interview is almost as important as the interview itself. The physical environment should allow for as much privacy as possible, with distractions, such as interruptions, noise, or other visible activity, kept to a minimum. At times it is necessary to turn off a television, radio, or cellular telephone. The environment should also have some play provision for young children to keep them occupied during the parent-nurse interview (Fig. 29-1). Parents who are constantly interrupted by their children are unable to concentrate fully and tend to give brief answers to finish the interview as quickly as possible.

Confidentiality is another essential component of the initial phase of the interview. Because the interview is usually shared with other members of the health care team or the teacher (in the case of students), be certain to inform the family of the limits regarding

FIG 29-1 Child plays while nurse interviews parents.

confidentiality. If confidentiality is a concern in a particular situation, such as when talking to a parent suspected of child abuse or a teenager contemplating suicide, deal with this directly and inform the person that in such instances confidentiality cannot be ensured. However, the nurse judiciously protects information of a confidential nature.

Computer Privacy and Applications in Nursing

The use of computer technology to store and retrieve health information has become widespread. The health care community is increasingly concerned about the privacy and security of this health information. Any person accessing confidential health information is charged with managing safeguards for disclosure, since violations might incur civil damages.

Many institutions use computer and information applications in nursing (nursing informatics), such as electronic medical records, to record care and access information. Two important health care applications are (1) record transmission, including online access, fax, and e-mail; and (2) telemedicine. The telemedicine application is capable of two-way video conferencing, transmission of radiographs, and clinical consultation between remote sites and centralized resources.*

Telephone Triage and Counseling

Nurses are increasingly responsible for assessing children's symptoms and applying clinical judgment for further medical care (triage) via telephone report. Most often, health problems are assessed and prioritized according to urgency and nurses provide treatment via telephone services. A well-designed telephone triage program is essential for safe, prompt, and consistent quality health care (Beaulieu and Humphreys, 2008; Marklund, Ström, Månsson, et al., 2007). Telephone triage is more than "just a phone call," since a child's life is a high price to pay for poorly managed or incompetent telephone assessment skills. Typically, guidelines for telephone triage include asking screening questions; determining when to immediately refer to emergency medical services (dial 911); and determining when to refer to same-day appointments, appointments in 24 to 72 hours, appointments in 4 days or more, or home care (Box 29-1). Successful outcomes are based on the consistency and accuracy of the information provided. Telephone triage care management has increased access to high-quality health care services and empowered parents to participate in their child's medical care. Consequently, patient satisfaction has significantly improved. Unnecessary emergency department and clinic visits have decreased, saving medical costs and time (with less absence from work) for families in need of health care.

COMMUNICATING WITH FAMILIES

Communicating with Parents

Although the parent and the child are separate and distinct individuals, the nurse's relationship with the child is frequently mediated by the parent, particularly with younger children. For the most part, nurses acquire information about the child by direct observation or through communication with the parents. Usually it can be assumed that, because of the close contact with the child, the parent gives reliable information. Assessing the child requires input from the child (verbal and nonverbal), information from the parent, and the nurse's own observations of the child and interpretation of the relationship between the child and the parent. When children are old enough to be active participants in their own health maintenance, the parent becomes a collaborator in health care.

Encouraging the Parents to Talk

Interviewing parents not only offers the opportunity to determine the child's health and developmental status but also offers information about factors that influence the child's life. Whatever the parent sees as a problem should be a concern of the nurse. These problems

are not always easy to identify. Nurses need to be alert for clues and signals by which a parent communicates worries and anxieties. Careful phrasing with broad, open-ended questions such as "What is Jimmy eating now?" provides more information than several single-answer questions, such as "Is Jimmy eating what the rest of the family eats?"

Sometimes the parent will take the lead without prompting. At other times it may be necessary to direct another question on the basis of an observation, such as "Connie seems unhappy today" or "How do you feel when David cries?" If the parent appears to be tired or distraught, consider asking "What do you do to relax?" or "What help do you have with the children?" A comment such as "You handle the baby very well. What kind of experience have you had with babies?" to new parents who appear comfortable with their first child gives positive reinforcement and provides an opening for questions they might have on the infant's care. Often all that is required to keep parents talking is a nod or saying "yes" or "uh-huh."

Directing the Focus

Directing the focus of the interview while allowing maximum freedom of expression is one of the most difficult goals in effective communication. One approach is the use of open-ended or broad questions, followed by guiding statements. For example, if the parent proceeds to list the other children by name, say, "Tell me their ages, too." If the parent continues to describe each child in depth, which is not the purpose of the interview, redirect the focus by stating, "Let's talk about the other children later. You were beginning to tell me about Paul's activities at school." This approach conveys interest in the other children but focuses the assessment on the patient.

Listening and Cultural Awareness

Listening is the most important component of effective communication. When the purpose of listening is to understand the person being interviewed, it is an active process that requires concentration and attention to all aspects of the conversation—verbal, nonverbal, and abstract. Major blocks to listening are environmental distraction and premature judgment.

Although it is necessary to make some preliminary judgments, listen with as much objectivity as possible by clarifying meanings and attempting to see the situation from the parent's point of view. Effective interviewers consciously control their reactions, responses, and the techniques they use (see Cultural Competence box).

Careful listening relies on the use of clues, verbal leads, or signals from the interviewee to move the interview along. Frequent references to an area of concern, repetition of certain key words, or a special emphasis on something or someone serves as a cue to the interviewer for the direction of inquiry. Concerns and anxieties are often mentioned in a casual, offhand manner. Even though they are casual, they are important and deserve careful scrutiny to identify problem areas. For example, a parent who is concerned about a child's habit of bed-wetting may casually mention that the child's bed was "wet this morning."

Using Silence

Silence as a response is often one of the most difficult interviewing techniques to learn. The interviewer requires a sense of confidence and comfort to allow the interviewee space in which to think without interruptions. Silence permits the interviewee to sort out thoughts and feelings and search for responses to questions. Silence can also be a cue for the interviewer to go more slowly, reexamine the approach, and not push too hard (Seidel, Ball, Dains, et al., 2011).

Sometimes it is necessary to break the silence and reopen communication. Do this in a way that encourages the person to continue talking about what is considered important. Breaking a silence by introducing a new topic or by prolonged talking essentially terminates the interviewee's opportunity to use the silence. Suggestions for breaking the silence include statements such as "Is there anything else you wish to say?" "I see you find it difficult to continue; how may I help?" or "I don't know what this silence means. Perhaps there is something you would like to put into words but find difficult to say."

Being Empathic

Empathy is the capacity to understand what another person is experiencing from within that person's frame of reference; it is often described as the ability to put oneself in another's shoes. The essence of empathic interaction is accurate understanding of another's feelings (Mathiasen, 2006). Empathy differs from sympathy, which is *having* feelings or emotions similar to those of another person, rather than *understanding* those feelings (Mathiasen, 2006).

Providing Anticipatory Guidance

The ideal way to handle a situation is to deal with it *before* it becomes a problem. The best preventive measure is anticipatory guidance. Traditionally, anticipatory guidance focused on providing families information on normal growth and development and nurturing childrearing practices. For example, one of the most significant areas in pediatrics is injury prevention. Beginning prenatally, parents need specific instructions on home safety. Because of the child's maturing developmental skills, parents must implement home safety changes early to minimize risks to the child.

Unprepared parents can be disturbed by many normal developmental changes, such as a toddler's diminished appetite, negativism, altered sleeping patterns, and anxiety toward strangers. The chapters on health promotion provide the nurse information for counseling parents. However, anticipatory guidance should extend beyond giving general information during brief visits to empowering families to use the information as a means of building competence in their parenting abilities (Magar, Dabova-Missova, and Gjerdingen, 2006). To achieve this level of anticipatory guidance, the nurse should:

- Base interventions on needs identified by the family, not by the professional
- View the family as competent or as having the ability to be competent
- Provide opportunities for the family to achieve competence

CULTURAL COMPETENCE

Interviewing Without Judgment

It is easy to inject one's own attitudes and feelings into an interview. Often nurses' own prejudices and assumptions, which may include racial, religious, and cultural stereotypes, influence their perceptions of a parent's behavior. What the nurse may interpret as a parent's passive hostility or lack of interest may be shyness or an expression of anxiety. For example, in Western cultures, eye contact and directness are signs of paying attention. However, in many non-Western cultures, including that of Native Americans, directness (e.g., looking someone in the eye) is considered rude. Children are taught to avert their gaze and to look down when being addressed by an adult, especially one with authority (Seidel, Ball, Dains, et al., 2011). Therefore nurses must make judgments about "listening," as well as verbal interactions, with an appreciation of cultural differences.

BOX 29-2 BLOCKS TO COMMUNICATION

Communication Barriers (Nurse)

- Socializing
- Giving unrestricted and sometimes unasked for advice
- Offering premature or inappropriate reassurance
- Giving overready encouragement
- Defending a situation or opinion
- Using stereotyped comments or clichés
- Limiting expression of emotion by asking directed, closed-ended questions
- Interrupting and finishing the person's sentence
- Talking more than the interviewee
- Forming prejudged conclusions
- Deliberately changing the focus

Signs of Information Overload (Patient)

- Long periods of silence
- Wide eyes and fixed facial expression
- Constant fidgeting or attempting to move away
- Nervous habits (e.g., tapping, playing with hair)
- Sudden interruptions (e.g., asking to go to the bathroom)
- Looking around
- Yawning, eyes drooping
- Frequently looking at a watch or clock
- Attempting to change topic of discussion

Avoiding Blocks to Communication

A number of blocks to communication can adversely affect the quality of the helping relationship. The interviewer introduces many of these blocks, such as giving unrestricted advice or forming prejudged conclusions. Another type of block occurs primarily with the interviewees and concerns information overload. When individuals receive too much information or information that is overwhelming, they often demonstrate signs of increasing anxiety or decreasing attention. Such signals should alert the interviewer to give less information or to clarify what has been said. Box 29-2 lists some of the more common blocks to communication, including signs of information overload.

The nurse can correct communication blocks by careful analysis of the interview process. One of the best methods for improving interviewing skills is audiotape or videotape feedback. With supervision and guidance, the interviewer can recognize the blocks and consciously avoid them.

Communicating with Families Through an Interpreter

Sometimes communication is impossible because two people speak different languages. In this case it is necessary to obtain information through a third party, the interpreter. When using an interpreter, the nurse follows the same interviewing guidelines. Specific guidelines for using an adult interpreter are given in the Guidelines box.

Communicating with families through an interpreter requires sensitivity to cultural, legal, and ethical considerations (see Cultural Competence box). For example, in some cultures, using a child as an interpreter is considered an insult to an adult because children are expected to show respect by not questioning their elders. In some cultures, class differences between the interpreter and the family may cause the family to feel intimidated and less inclined to offer information. Therefore it is important to choose the translator carefully and provide time for the interpreter and family to establish rapport.

Legal and ethical concerns may also arise. For example, in obtaining informed consent through an interpreter, the nurse should fully inform the family of all aspects of the particular procedure to which they are consenting. Issues of confidentiality may arise when family members related to another patient are asked to interpret for the family, thus revealing sensitive information that may be shared with other families on the unit. With increased sensitivity toward patient rights and confidentiality, many institutions now require consent forms produced in the patient's primary language.

GUIDELINES

Using an Interpreter

- Explain to interpreter the reason for the interview and the type of questions that will be asked.
- Clarify whether a detailed or brief answer is required and whether the translated response can be general or literal.
- Introduce the interpreter to family, and allow some time before the interview for them to become acquainted.
- Communicate directly with family members when asking questions to reinforce interest in them and to observe nonverbal expressions, but do not ignore interpreter.
- Pose questions to elicit only one answer at a time, such as "Do you have pain?" rather than "Do you have any pain, tiredness, or loss of appetite?"
- Refrain from interrupting family member and interpreter while they are conversing.
- Avoid commenting to interpreter about family members, since they may understand some English.
- Be aware that some medical words, such as *allergy,* may have no similar word in another language; avoid medical jargon whenever possible.
- Be aware that cultural differences may exist regarding views on sex, marriage, or pregnancy.
- Allow time after the interview for interpreter to share something that he or she thought could not be said earlier; ask about the interpreter's impression of nonverbal clues to communication and family members' reliability or ease in revealing information.
- Arrange for family to speak with the same interpreter on subsequent visits whenever possible.

CULTURAL COMPETENCE

Using Children as Translators

When no one else is available to translate, children within the family are often asked to assume this role. In this situation it is important to stress *literal* translation of parent responses. To ensure correct translations, it may be necessary to interrupt the parent and ask the child to translate every few sentences. When using children as interpreters, ask questions directed at specific answers and assess the interpreted translation in terms of nonverbal expressions of communication. Note that some institutions prohibit or discourage the use of children as interpreters; check institution policy for compliance.

! NURSING ALERT

When using translated materials, such as a health history form, be certain the informant is literate in the foreign language.

GUIDELINES

Communicating with Children

- Allow children time to feel comfortable.
- Avoid sudden or rapid advances, broad smiles, extended eye contact, or other gestures that may be seen as threatening.
- Talk to the parent if child is initially shy.
- Communicate through transition objects such as dolls, puppets, and stuffed animals before questioning a young child directly.
- Give older children the opportunity to talk without the parents present.
- Assume a position that is at eye level with child (Fig. 29-2).
- Speak in a quiet, unhurried, and confident voice.
- Speak clearly, be specific, and use simple words and short sentences.
- State directions and suggestions positively.
- Offer a choice only when one exists.
- Be honest with children.
- Allow them to express their concerns and fears.
- Use a variety of communication techniques.

Communicating with Children

Although the greatest amount of verbal communication is usually carried out with the parent, do not exclude the child during the interview. Pay attention to infants and younger children through play or by occasionally directing questions or remarks to them. Include older children as active participants.

In communication with children of all ages, the nonverbal components of the communication process convey the most significant messages. It is difficult to disguise feelings, attitudes, and anxiety when relating to children. They are alert to surroundings and attach meaning to every gesture and move that is made; this is particularly true of very young children.

Active attempts to make friends with children before they have had an opportunity to evaluate an unfamiliar person tend to increase their anxiety. Continue to talk to the child and parent but go about activities that do not involve the child directly, thus allowing the child to observe from a safe position. If the child has a special toy or doll, "talk" to the doll first. Ask simple questions such as "Does your teddy bear have a name?" to ease the child into conversation. Other guidelines for communicating with children are in the Guidelines box. Specific guidelines for preparing children for procedures, a common nursing function, are in Chapter 39.

Communication Related to Development of Thought Processes

The normal development of language and thought offers a frame of reference for communicating with children. Thought processes progress from sensorimotor to perceptual to concrete and finally to abstract, formal operations. An understanding of the typical characteristics of these stages provides the nurse with a framework to facilitate social communication (Box 29-3).

Infancy. Because they are unable to use words, infants primarily use and understand nonverbal communication. Infants communicate their needs and feelings through nonverbal behaviors and vocalizations that can be interpreted by someone who is around them for a sufficient time. Infants smile and coo when content and cry when distressed. Crying is provoked by unpleasant stimuli from inside or outside, such as hunger, pain, body restraint, or loneliness. Adults interpret this to mean that an infant needs something and consequently try to alleviate the discomfort and reduce tension. Crying (or the desire to cry) persists as a part of everyone's communication repertoire.

FIG 29-2 Nurse assumes position at child's level.

BOX 29-3 CHARACTERISTICS OF COMMUNICATIVE DEVELOPMENT IN YOUNG CHILDREN

Perlocutionary Stage (0 to 8-9 Months)
- Child is reflexive to stimuli.
- Child shows increasing purpose in action.

Emerging Illocutionary Stage (8-9 to 12-15 Months)
- Child communicates intentionally with signals and gestures.

Conventional Illocutionary–Emerging Locutionary Stage (12-15 to 18-24 Months)
- Child communicates intentionally with gestures, vocalizations, and verbalizations.

Adapted from Hoge DR, Parette HP: Facilitating communicative development in young children with disabilities, *Transdisc J* 5(2):113–130, 1995.

Infants respond to adults' nonverbal behaviors. They become quiet when they are cuddled, patted, or receive other forms of gentle physical contact. They receive comfort from the sound of a voice, even though they do not understand the words that are spoken. Until infants reach the age at which they experience stranger anxiety, they readily respond to any firm, gentle handling and quiet, calm speech. Loud, harsh sounds and sudden movements are frightening.

Early Childhood. Children younger than 5 years are egocentric. They see things only in relation to themselves and from their point of view. Therefore focus communication on them. Tell them what they can do or how they will feel. Experiences of others are of no interest to them. It is futile to use another child's experience in an attempt to gain the cooperation of small children. Allow them to touch and examine articles they will come in contact with. A stethoscope bell will feel cold; palpating a neck might tickle. Although they have not yet acquired sufficient language skills to express their feelings and wants, toddlers can effectively use their hands to communicate ideas without words. They push an unwanted object away,

pull another person to show them something, point, and cover the mouth that is saying something they do not wish to hear.

Everything is direct and concrete to small children. They are unable to work with abstractions and interpret words literally. Analogies escape them because they are unable to separate fact from fantasy. For example, they attach literal meaning to such common phrases as "two-faced," "sticky fingers," or "coughing your head off." Children who are told they will get "a little stick in the arm" may not be able to envision an injection (Fig. 29-3). Therefore avoid using a phrase that might be misinterpreted by a small child.

School-Age Years. Younger school-age children rely less on what they see and more on what they know when faced with new problems. They want explanations and reasons for everything but require no verification beyond that. They are interested in the functional aspect of all procedures, objects, and activities. They want to know why an object exists, why it is used, how it works, and the intent and purpose of its user. They need to know what is going to take place and why it is being done to them specifically. For example, to explain a procedure such as taking blood pressure, show the child how squeezing the bulb pushes air into the cuff and makes the "silver" in the tube go up. Let the child operate the bulb. An explanation for the procedure might be as simple as "I want to see how far the silver goes up when the cuff squeezes your arm." Consequently, the child becomes an enthusiastic participant.

School-age children have a heightened concern about body integrity. Because of the special importance they place on their body, they are sensitive to anything that constitutes a threat or suggestion of injury to it. This concern extends to their possessions, so they may appear to overreact to loss or threatened loss of treasured objects. Helping children voice their concerns enables the nurse to provide reassurance and to implement activities that reduce their anxiety. For example, if a shy child dislikes being the center of attention, ignore that particular child by talking and relating to other children in the family or group. When children feel more comfortable, they will usually interject personal ideas, feelings, and interpretations of events.

Adolescence. As children move into adolescence, they fluctuate between child and adult thinking and behavior. They are riding a current that is moving them rapidly toward a maturity that may be beyond their coping ability. Therefore when tensions rise, they may seek the security of the more familiar and comfortable expectations of childhood. Anticipating these shifts in identity allows the nurse to adjust the course of interaction to meet the needs of the moment. No single approach can be relied on consistently, and encountering cooperation, hostility, anger, bravado, and a variety of other behaviors and attitudes is common. It is as much a mistake to regard the adolescent as an adult with an adult's wisdom and control as it is to assume that the teenager has the concerns and expectations of a child.

FIG 29-3 A young child may take the expression "a little stick in the arm" literally.

Interviewing the adolescent presents some special issues. The first may be whether to talk with the adolescent alone or with the adolescent and parents together. Of course, if the parent is not there, the only question is whether to suggest to the teenager that the parents be interviewed at another time. If the parents and teenager are together, talking with the adolescent first has the advantage of immediately identifying with the young person, thus fostering the interpersonal relationship. However, talking with the parents initially may provide insight into the family relationship. In either case, give both parties an opportunity to be included in the interview. If time is limited, such as during history taking, clarify this at the onset to avoid appearing to "take sides" by talking more with one person than with the other.

Confidentiality is of great importance when interviewing adolescents. Explain to parents and teenagers the limits of confidentiality, specifically that young persons' disclosures will not be shared unless they indicate a need for intervention, as in the case of suicidal behavior.

Another dilemma in interviewing adolescents is that two views of a problem frequently exist—the teenager's and the parents'. Clarification of the problem is a major task. However, providing both parties an opportunity to discuss their perceptions in an open and unbiased atmosphere can, by itself, be therapeutic. Demonstrating positive communication skills can help families communicate more effectively (see Guidelines box).

Communication Techniques

Nurses use a variety of verbal techniques to encourage communication. Some of these techniques are useful to pose questions or explore concerns in a less threatening manner. Others can be presented as word games, which are often well received by children.

GUIDELINES

Communicating with Adolescents

Build a Foundation

- Spend time together.
- Encourage expression of ideas and feelings.
- Respect their views.
- Tolerate differences.
- Praise good points.
- Respect their privacy.
- Set a good example.

Communicate Effectively

- Give undivided attention.
- Listen, listen, listen.
- Be courteous, calm, and open minded.
- Try not to overreact. If you do, take a break.
- Avoid judging or criticizing.
- Avoid the "third degree" of continuous questioning.
- Choose important issues when taking a stand.
- After taking a stand:
  - Think through all options.
  - Make expectations clear.

However, for many children and adults, talking about feelings is difficult and verbal communication may be more stressful than supportive. In such instances, use several nonverbal techniques to encourage communication.

Box 29-4 describes both verbal and nonverbal techniques. Because of the importance of play in communicating with children, play is discussed more extensively in the section that follows. Any of the verbal or nonverbal techniques can give rise to strong feelings that surface unexpectedly. Be prepared to handle them or to recognize when issues go beyond your ability to deal with them. At that point, consider an appropriate referral.

Play. Play is a universal language of children. It is one of the most important forms of communication and can be an effective technique in relating to them. The nurse can often pick up on clues about physical, intellectual, and social developmental progress from the form and complexity of a child's play behaviors. Play requires minimum equipment or none at all. Many providers use therapeutic play to reduce the trauma of illness and hospitalization (see Chapter 39) and to prepare children for therapeutic procedures (see Chapter 39).

Because their ability to perceive precedes their ability to transmit, infants respond to activities that register on their physical senses. Patting, stroking, and other skin play convey messages. Repetitive actions, such as stretching infants' arms out to the side while they are lying on their back and then folding the arms across the chest or raising and revolving the legs in a bicycling motion, will elicit pleasurable sounds. Colorful items to catch the eye or interesting sounds, such as a ticking clock, chimes, bells, or singing, can be used to attract children's attention.

Older infants respond to simple games. The old game of peek-a-boo is an excellent means of initiating communication with infants while maintaining a "safe," nonthreatening distance. After this intermittent eye contact, the nurse is no longer viewed as a stranger but as a friend. This can be followed by touch games. Clapping an infant's hands together for pat-a-cake or wiggling the toes for "this little piggy" delights an infant or small child. Talking to a

BOX 29-4 CREATIVE COMMUNICATION TECHNIQUES WITH CHILDREN

Verbal Techniques

"I" Messages

- Relate a feeling about a behavior in terms of "I."
- Describe effect behavior had on the person.
- Avoid use of "you."
- "You" messages are judgmental and provoke defensiveness.

  Example—"You" message: "You are being uncooperative about doing your treatments."

  Example—"I" message: "I am concerned about how the treatments are going because I want to see you get better."

Third-Person Technique

- Express a feeling in terms of a third person ("he," "she," "they"). This is less threatening than directly asking children how they feel because it gives them an opportunity to agree or disagree without being defensive.

  Example—"Sometimes when a person is sick a lot, he feels angry and sad because he cannot do what others can." Either wait silently for a response or encourage a reply with a statement such as "Did you ever feel that way?"
- This approach allows children three choices: (1) to agree and, one hopes, express how they feel; (2) to disagree; or (3) to remain silent, which means they probably have such feelings but are unable to express them at this time.

Facilitative Response

- Listen carefully and reflect back to patients the feelings and content of their statements.
- Responses are empathic and nonjudgmental and legitimize the person's feelings.
- Formula for facilitative responses: "You feel _____ because _____."

  Example—If child states, "I hate coming to the hospital and getting needles," a facilitative response is, "You feel unhappy because of all the things that are done to you."

Storytelling

- Use the language of children to probe into areas of their thinking while bypassing conscious inhibitions or fears.
- The simplest technique is asking children to relate a story about an event, such as "being in the hospital."
- Other approaches:
  - Show children a picture of a particular event, such as a child in a hospital with other people in the room, and ask them to describe the scene.
  - Cut out comic strips, remove words, and have child add statements for scenes.

Mutual Storytelling

- Reveal child's thinking and attempt to change child's perceptions or fears by retelling a somewhat different story (more therapeutic approach than storytelling).
- Begin by asking child to tell a story about something, and then tell another story that is similar to child's tale but with differences that help child in problem areas.

  Example—Child's story is about going to the hospital and never seeing his or her parents again. Nurse's story is also about a child (using different names but similar circumstances) in a hospital whose parents visit every day, but in the evening after work, until the child is better and goes home with them.

Bibliotherapy

- Use books in a therapeutic and supportive process.
- Provide children with an opportunity to explore an event that is similar to their own but sufficiently different to allow them to distance themselves from it and remain in control.
- General guidelines for using bibliotherapy are:
  1. Assess child's emotional and cognitive development in terms of readiness to understand the book's message.
  2. Be familiar with the book's content (intended message or purpose) and the age for which it is written.
  3. Read the book to the child if child is unable to read.
  4. Explore the meaning of the book with the child by having child:
     - Retell the story
     - Read a special section with the nurse or parent
     - Draw a picture related to the story and discuss the drawing
     - Talk about the characters
     - Summarize the moral or meaning of the story

Continued

BOX 29-4 CREATIVE COMMUNICATION TECHNIQUES WITH CHILDREN—cont'd

Dreams
- Dreams often reveal unconscious and repressed thoughts and feelings.
- Ask child to talk about a dream or nightmare.
- Explore with child what meaning the dream could have.

"What If" Questions
- Encourage child to explore potential situations and to consider different problem-solving options.
  Example—"What if you got sick and had to go the hospital?" Children's responses reveal what they know already and what they are curious about, providing an opportunity for them to learn coping skills, especially in potentially dangerous situations.

Three Wishes
- Ask, "If you could have any three things in the world, what would they be?"
- If child answers, "That all my wishes come true," ask child for specific wishes.

Rating Game
- Use some type of rating scale (numbers, sad to happy faces) to have child rate an event or feeling.
  Example—Instead of asking youngsters how they feel, ask how their day has been "on a scale of 1 to 10, with 10 being the best."

Word Association Game
- State key words and ask children to say the first word they think of when they hear the word.
- Start with neutral words and then introduce more anxiety-producing words, such as "illness," "needles," "hospitals," and "operation."
- Select key words that relate to some relevant event in the child's life.

Sentence Completion
- Present a partial statement and have the child complete it. Some sample statements are:
  The thing I like best (least) about school is _____.
  The best (worst) age to be is _____.
  The most (least) fun thing I ever did was _____.
  The thing I like most (least) about my parents is _____.
  The one thing I would change about my family is _____.
  If I could be anything I wanted, I would be _____.
  The thing I like most (least) about myself is _____.

Pros and Cons
- Select a topic, such as "being in the hospital," and have child list "five good things and five bad things" about it.
- This is an exceptionally valuable technique when applied to relationships, such as things family members like and dislike about each other.

Nonverbal Techniques
Writing
- Writing is an alternative communication approach for older children and adults.
- Specific suggestions include:
  - Keep a journal or diary.
  - Write down feelings or thoughts that are difficult to express.
  - Write "letters" that are never mailed (a variation is making up a "pen pal" to write to).
- Keep an account of child's progress from both a physical and an emotional viewpoint.

Drawing
- Drawing is one of the most valuable forms of communication—both nonverbal (from looking at the drawing) and verbal (from child's story of the picture).
- Children's drawings tell a great deal about them because they are projections of their inner selves.
- Spontaneous drawing involves giving child a variety of art supplies and providing the opportunity to draw.
- Directed drawing involves a more specific direction, such as "draw a person" or the "three themes" approach (state three things about child and ask child to choose one and draw a picture).

Guidelines for Evaluating Drawings
- Use spontaneous drawings and evaluate more than one drawing whenever possible.
- Interpret drawings in light of other available information about child and family, including the child's age and stage of development.
- Interpret drawings as a whole rather than focusing on specific details of the drawing.
- Consider individual elements of the drawing that may be significant:
  - Sex of figure drawn first—Usually relates to child's perception of own gender role
  - Size of individual figures—Expresses importance, power, or authority
  - Order in which figures are drawn—Expresses priority in terms of importance
  - Child's position in relation to other family members—Expresses feelings of status or alliance
  - Exclusion of a member—May denote feeling of not belonging or desire to eliminate
  - Accentuated parts—Usually express concern for areas of special importance (e.g., large hands may be a sign of aggression)
  - Absence of or rudimentary arms and hands—Suggest timidity, passivity, or intellectual immaturity; tiny, unstable feet may express insecurity, and hidden hands may mean guilt feelings
  - Placement of drawing on the page and type of stroke—Free use of paper and firm, continuous strokes express security, whereas drawings restricted to a small area and lightly drawn in broken or wavering lines may be a sign of insecurity
  - Erasures, shading, or cross-hatching—Expresses ambivalence, concern, or anxiety with a particular area

Magic
- Use simple magic tricks to help establish rapport with child, encourage compliance with health interventions, and provide effective distraction during painful procedures.
- Although the "magician" talks, no verbal response from child is required.

Play
- Play is the universal language and "work" of children.
- It tells a great deal about children because they project their inner selves through the activity.
- Spontaneous play involves giving child a variety of play materials and providing the opportunity to play.
- Directed play involves a more specific direction, such as providing medical equipment or a dollhouse for focused reasons, such as exploring child's fear of injections or exploring family relationships.

foot or other part of the child's body is another effective tactic. Much of the nursing assessment can be carried out with the use of games and simple play equipment while the infant remains in the safety of the parent's arms or lap.

The nurse can capitalize on the natural curiosity of small children by playing games such as "Which hand do you take?" and "Guess what I have in my hand" or by manipulating items such as a flashlight or stethoscope. Finger games are useful. More elaborate materials, such as puppets and replicas of familiar or unfamiliar items, serve as excellent means of communicating with small children. The variety and extent are limited only by the nurse's imagination.

Through play, children reveal their perceptions of interpersonal relationships with their family, friends, or hospital personnel. Children may also reveal the wide scope of knowledge they have acquired from listening to others around them. For example, through needle play, children may reveal how carefully they have watched each procedure by precisely duplicating the technical skills. They may also reveal how well they remember those who performed procedures. In one example, a child painstakingly reenacted every detail of a tedious medical procedure, including the role of the physician who had repeatedly shouted at her to be still for the long ordeal. Her anger at him was most evident during the play session and revealed the cause for her abrupt withdrawal and passive hostility toward the medical and nursing staff after the test.

HISTORY TAKING

Performing a Health History

The format used for history taking may be (1) direct, in which the nurse asks for information via direct interview with the informant; or (2) indirect, in which the informant supplies the information by completing some type of questionnaire. The direct method is superior to the indirect approach or a combination of both. However, because time is limited, the direct approach is not always practical. If the nurse cannot use the direct approach, he or she should review parents' written responses and question them regarding any unusual answers. The categories listed in Box 29-5 encompass children's current and past health status and information about their psychosocial environment.

Identifying Information

Much of the identifying information may already be available from other recorded sources. However, if the parent and youngster seem anxious, use this opportunity to ask about such information to help them feel more comfortable.

Informant. One of the important elements of identifying information is the informant, the person(s) who furnishes the information. Record (1) who the person is (child, parent, or other), (2) an impression of reliability and willingness to communicate, and (3) any special circumstances such as the use of an interpreter or conflicting answers by more than one person.

Chief Complaint

The chief complaint is the specific reason for the child's visit to the clinic, office, or hospital. It may be the theme, with the present illness viewed as the description of the problem. Elicit the chief complaint by asking open-ended, neutral questions such as "What seems to be the matter?" "How may I help you?" or "Why did you come here today?" Avoid labeling-type questions such as "How are you sick?" or "What is the problem?" It is possible that the reason for the visit is not an illness or problem.

BOX 29-5 OUTLINE OF A PEDIATRIC HEALTH HISTORY

Identifying Information
- Name
- Address
- Telephone
- Birth date and place
- Race or ethnic group
- Sex
- Religion
- Date of interview
- Informant

Chief complaint (CC)—To establish the major specific reason for the child's and parents' seeking professional health attention

Present illness (PI)—To obtain all details related to the chief complaint

Past history (PH)—To elicit a profile of the child's previous illnesses, injuries, or operations
- Birth history (pregnancy, labor and birth, perinatal history)
- Previous illnesses, injuries, or operations
- Allergies
- Current medications
- Immunizations
- Growth and development
- Habits

Review of systems (ROS)—To elicit information concerning any potential health problem
- General
- Integument
- Head
- Eyes
- Ears
- Nose
- Mouth
- Throat
- Neck
- Chest
- Respiratory
- Cardiovascular
- Gastrointestinal
- Genitourinary
- Gynecologic
- Musculoskeletal
- Neurologic
- Endocrine

Family medical history—To identify genetic traits or diseases that have familial tendencies and to assess exposure to a communicable disease in a family member and family habits that may affect the child's health, such as smoking and chemical use

Psychosocial history—To elicit information about the child's self-concept

Sexual history—To elicit information concerning the child's sexual concerns or activities and any pertinent data regarding adults' sexual activity that influences the child

Family history—To develop an understanding of the child as an individual and as a member of a family and a community
- Family composition
- Home and community environment
- Occupation and education of family members
- Cultural and religious traditions
- Family function and relationships

Nutritional assessment—To elicit information on the adequacy of the child's nutritional intake and needs
- Dietary intake
- Clinical examination

GUIDELINES

Analyzing the Symptom: Pain

Type

Be as specific as possible. With young children, asking the parents how they know the child is in pain may help describe its type, location, and severity. For example, a parent may state, "My child must have a severe earache because she pulls at her ears, rolls her head on the floor, and screams. Nothing seems to help." Help older children describe the "hurt" by asking them if it is sharp, throbbing, dull, or stabbing. Record whatever words they use in quotes.

Location

Be specific. "Stomach pains" is too general a description. Children can better localize the pain if they are asked to "point with one finger to where it hurts" or to "point to where Mommy or Daddy would put a Band-Aid." Determine if the pain radiates by asking, "Does the pain stay there or move? Show me with your finger where the pain goes."

Severity

Severity is best determined by finding out how it affects the child's usual behavior. Pain that prevents a child from playing, interacting with others, sleeping, and eating is most often severe. Assess pain intensity using a rating scale, such as a numeric or FACES scale (see Chapter 30).

Duration

Include the duration, onset, and frequency. Describe this in terms of activity and behavior, such as "pain reported to last all night, child refused to sleep and cried intermittently."

Influencing Factors

Include anything that causes a change in the type, location, severity, or duration of the pain: (1) precipitating events (those that cause or increase the pain), (2) relieving events (those that lessen the pain, such as medications), (3) temporal events (times when the pain is relieved or increased), (4) positional events (standing, sitting, lying down), and (5) associated events (meals, stress, coughing).

Occasionally it is difficult to isolate one symptom or problem as the chief complaint because the parent may identify many. In this situation, be as specific as possible when asking questions. For example, asking informants to state which *one* problem or symptom prompted them to seek help now may help them focus on the most immediate concern.

Present Illness

The history of the present illness* is a narrative of the chief complaint from its earliest onset through its progression to the present. Its four major components are (1) the details of **onset,** (2) a complete **interval** history, (3) the **present** status, and (4) the reason for seeking help **now.** The focus of the present illness is on all factors relevant to the main problem, even if they have disappeared or changed during the onset, interval, and present.

Analyzing a Symptom. Because pain is often the most characteristic symptom denoting the onset of a physical problem, it is used as an example for analysis of a symptom. Assessment includes (1) type, (2) location, (3) severity, (4) duration, and (5) influencing factors (see Guidelines box; see also Pain Assessment, Chapter 30).

*The term *illness* is used in its broadest sense to denote any problem of a physical, emotional, or psychosocial nature. It is actually a history of the chief complaint.

Past History

The history contains information relating to all previous aspects of the child's health status and concentrates on several areas that are ordinarily passed over in the history of an adult, such as birth history, detailed feeding history, immunizations, and growth and development. Because this section includes a great deal of information, use a combination of open-ended and fact-finding questions. For example, begin interviewing for each section with an open-ended statement such as "Tell me about your child's birth" to provide the informants the opportunity to relate what they think is most important. Ask fact-finding questions related to specific details whenever necessary to focus the interview on certain topics.

Birth History. The birth history includes all data concerning (1) the mother's health during pregnancy, (2) the labor and birth, and (3) the infant's condition immediately after birth. Because prenatal influences have significant effects on a child's physical and emotional development, a thorough investigation of the birth history is essential. Because parents may question what relevance pregnancy and birth have on the child's present condition, particularly if the child is past infancy, explain why such questions are included. An appropriate statement may be "I will be asking you some questions about your pregnancy and ____'s [refer to child by name] birth. Your answers will give me a more complete picture of his [or her] overall health."

Because emotional factors also affect the outcome of pregnancy and the subsequent parent-child relationship, investigate (1) concurrent crises during pregnancy and (2) prenatal attitudes toward the fetus. It is best to approach the topic of parental acceptance of pregnancy through indirect questioning. Asking parents if the pregnancy was planned is a leading question because they may respond affirmatively for fear of criticism if the pregnancy was unexpected. Rather, encourage parents to state their true reactions by referring to specific facts relating to the pregnancy, such as the spacing between offspring, an extended or short interval between marriage and conception, or a pregnancy during adolescence. The parent can choose to explore such statements with further explanations or, for the moment, may not be able to reveal such feelings. If the parent remains silent, return to this topic later in the interview.

Dietary History. Because parental concerns are common and nursing interventions are important in ensuring optimum nutrition, the dietary history is discussed in detail later in this chapter in the Nutritional Assessment section.

Previous Illnesses, Injuries, and Operations. When inquiring about past illnesses, begin with a general statement such as "What other illnesses has your child had?" Because parents are most likely to recall serious health problems, ask specifically about colds; earaches; and childhood diseases such as measles, rubella (German measles), chickenpox, mumps, pertussis (whooping cough), diphtheria, tuberculosis, scarlet fever, strep throat, recurrent ear infections, gastroesophageal reflux, tonsillitis, or allergic manifestations.

In addition to illnesses, ask about injuries that required medical intervention, operations, and any other reason for hospitalization, including the dates of each incident. Focus on injuries such as accidental falls, poisoning, choking, or burns, since these may be potential areas for parental guidance.

Allergies. Ask about commonly known allergic disorders such as hay fever and asthma; unusual reactions to drugs, food, or latex products; and reactions to other contact agents such as poisonous plants, animals, household products, or fabrics. If asked appropriate questions, most people can give reliable information about drug reactions (see Guidelines box).

GUIDELINES

Taking an Allergy History

- Has your child ever taken any drugs or tablets that have disagreed with him or her or caused an allergic reaction? If yes, can you remember the name(s) of these drugs?
- Can you describe the reaction?
- Was the drug taken by mouth (as a tablet or syrup), or was it an injection?
- How soon after starting the drug did the reaction happen?
- How long ago did this happen?
- Did anyone tell you it was an allergic reaction, or did you decide for yourself?
- Has your child ever taken this drug, or a similar one, again? If yes, did your child experience the same problems?
- Have you told the doctors or nurses about your child's reaction or allergy?

! NURSING ALERT

Information about allergic reactions to drugs or other products is essential. Failure to document a serious reaction places the child at risk if the agent is given.

Current Medications. Inquire about current drug regimens, including vitamins, antipyretics (especially aspirin), antibiotics, antihistamines, decongestants, or herbs and homeopathic medications. List all medications, including name, dose, schedule, duration, and reason for administration. Often parents are unaware of the drug's actual name. Whenever possible, ask parents to bring the containers with them to the next visit, or ask for the name of the pharmacy and call for a list of all the child's recent prescription medications. However, this list will not include over-the-counter medications, which are important to know.

Immunizations. A record of all immunizations is essential. Because many parents are unaware of the exact name and date of each immunization, the most reliable source of information is a hospital, clinic, or private practitioner's record. All immunizations and "boosters" are listed, stating (1) the name of the specific disease, (2) the number of injections, (3) the dosage (sometimes lesser amounts are given if a reaction is anticipated), (4) the ages when administered, and (5) the occurrence of any reaction after the immunization.

! NURSING ALERT

Inquire about previous administration of any horse or other foreign serum. Inquire about recent administration of immune gamma globulin or blood transfusion because these necessitate a delay in giving live vaccines. And ask about anaphylactic reactions to neomycin, eggs, or any other component of a vaccine.

Growth and Development. The most important previous growth patterns to record are:

- Approximate weight at 6 months, 1 year, 2 years, and 5 years of age
- Approximate length at ages 1 and 4 years
- Dentition, including age of onset, number of teeth, and symptoms during teething

BOX 29-6 HABITS TO EXPLORE DURING HEALTH INTERVIEW

- Behavior patterns such as nail biting, thumb sucking, pica (habitual ingestion of nonfood substances), rituals ("security" blanket or toy), and unusual movements (head banging, rocking, overt masturbation, walking on toes)
- Activities of daily living, such as hour of sleep and arising, duration of nighttime sleep and naps, type and duration of exercise, regularity of stools and urination, age of toilet training, and daytime or nighttime bed-wetting
- Unusual disposition; response to frustration
- Use or abuse of alcohol, drugs, coffee, or tobacco

Developmental milestones include:

- Age of holding up head steadily
- Age of sitting alone without support
- Age of walking without assistance
- Age of saying first words with meaning
- Present grade in school
- Scholastic performance
- If the child has a best friend
- Interactions with other children, peers, and adults

Use specific and detailed questions when inquiring about each developmental milestone. For example, "sitting up" can mean many different activities, such as sitting propped up, sitting in someone's lap, sitting with support, sitting up alone but in a hyperflexed position for assisted balance, or sitting up unsupported with the back slightly rounded. A clue to misunderstanding of the requested activity may be an unusually early age of achievement.

Habits. Habits are an important area to explore (Box 29-6). Parents frequently express concerns during this part of the history. Encourage their input by saying, "Please tell me any concerns you have about your child's habits, activities, or development." Investigate further any concerns that parents express.

One of the most common concerns relates to sleep. Many children develop a normal sleep pattern, and all that is required during the assessment is a general overview of nighttime sleep and nap schedules. However, a number of children develop sleep problems (see Sleep Problems, Chapters 31 and 32). When sleep problems occur, the nurse needs a more detailed sleep history to guide appropriate interventions.*

Habits related to use of chemicals apply primarily to older children and adolescents. If a youngster admits to smoking, drinking, or using drugs, ask about the quantity and frequency. Questions such as "Many kids your age are experimenting with drugs and alcohol; have you ever had any drugs or alcohol?" may give more reliable data than questions such as "How much do you drink?" or "How often do you drink or take drugs?" Clarify that "drinking" includes all types of alcohol, including beer and wine. When quantities such as a "glass" of wine or a "can" of beer are given, ask about the size of the container.

If older children deny use of chemical substances, inquire about past experimentation. Asking "You mean you never tried to smoke or drink?" implies that the nurse expects some such activity, and the youngster may be more inclined to answer truthfully. Be aware of

*A sleep history and a sleep chart for the family to record the child's daily sleep and wake activities is available in Wilson D, Hockenberry M: *Wong's clinical manual of pediatric nursing,* ed 8, St Louis, 2011, Mosby.

the confidential nature of such questioning, the adverse effect that the parents' presence may have on the adolescent's willingness to answer, and the fact that self-reporting may not be an accurate account of chemical abuse.

Sexual History

The sexual history is an essential component of adolescents' health assessment. The history uncovers areas of concern related to sexual activity; alerts the nurse to circumstances that may indicate screening for sexually transmitted infections or testing for pregnancy; and provides information related to the need for sexual counseling, such as safer sex practices. Box 29-7 gives guidelines for anticipatory guidance topics for parents and adolescents.

One approach to initiating a conversation about sexual concerns is to begin with a history of peer interactions. Open-ended statements or questions such as "Tell me about your social life" or "Who are your closest friends?" generally lead into a discussion of dating and sexual issues. To probe further, include questions about the adolescent's attitudes on such topics as sex education, "going steady," "living together," and premarital sex. Phrase questions to reflect concern rather than judgment or criticism of sexual practices.

In any conversation regarding sexual history, be aware of the language that is used in either eliciting or conveying sexual information. For example, avoid asking whether the adolescent is "sexually active," since this term is broadly defined. "Are you having sex with anyone?" is probably the most direct and best understood question. Since same-sex experimentation may occur, refer to all sexual contacts in nongender terms, such as "anyone" or "partners," rather than "girlfriends" or "boyfriends."

BOX 29-7 ANTICIPATORY GUIDANCE—SEXUALITY

Ages 12 to 14 Years

- Have adolescent identify supportive adult to discuss sexuality issues and concerns with.
- Discuss advantages of delaying sexual activity.
- Discuss making responsible decisions regarding normal sexual feelings.
- Discuss role of gender, peer pressure, and the media in sexual decision making.
- Discuss contraceptive options (advantages and disadvantages).
- Provide education regarding sexually transmitted infections (STIs), including human immunodeficiency virus (HIV) infection; clarify risks, and discuss condoms.
- Discuss abuse prevention: avoiding dangerous situations, role of drugs and alcohol, and use of self-defense.
- Have adolescent clarify values, needs, and ability to be assertive.
- If adolescent is sexually active, discuss limiting partners, use of condoms, and contraceptive options.
- Have confidential interview with adolescent (including a sexual history).
- Discuss the evolution of sexual identity and expression.
- Discuss breast examination or testicular examination.

Ages 15 to 18 Years

- Support delaying sexual activity.
- Discuss alternatives to intercourse.
- Discuss "When are you ready for sex?"
- Clarify values; encourage responsible decision making.
- Discuss consequences of unprotected sex: early pregnancy, STIs, including HIV infection.
- Discuss negotiating with partner and barriers to safer sex.
- If adolescent is sexually active, discuss limiting partners, use of condoms, and contraceptive options.
- Emphasize that sex should be safe and pleasurable for both partners.
- Have confidential interview with adolescent.
- Discuss concerns about sexual expression and identity.

Data from Fonseca H, Greydanus D: Sexuality in the child, teen and young adult: concepts for the clinician, *Prim Care Clin Office Pract* 34:275–292, 2007; Wright K: Anticipatory guidance: developing a healthy sexuality, *Pediatr Ann* 26(Suppl 2):S142–S144, C3, 1997.

Family Medical History

The family medical history is used primarily to discover any hereditary or familial diseases in the parents and child. In general, it is confined to first-degree relatives (parents, siblings, grandparents, and immediate aunts and uncles). Information for each family member includes age; marital status; state of health if living; cause of death if deceased; and any evidence of conditions such as early heart disease, sudden death from unknown cause, hypercholesterolemia, hypertension, cancer, diabetes mellitus, obesity, congenital anomalies, allergies, asthma, seizures, tuberculosis, sickle cell disease, cognitive impairment, hearing or visual deficits, psychiatric disorders such as depression or psychosis, and emotional problems. Confirm the accuracy of the reported disorders by inquiring about the symptoms, course, treatment, and sequelae of each diagnosis.

Geographic Location. One of the important areas to explore when assessing the family health history is geographic location, including the birthplace and travel to different areas in or outside of the country, for identification of possible exposure to endemic diseases. Although the primary interest is the child's temporary residence in various localities, also inquire about close family members' travel, especially during tours of military service or business trips. Children are especially susceptible to parasitic infestation in areas of poor sanitary conditions and to vector-borne diseases, such as those from mosquitoes or ticks in warm and humid or heavily wooded regions.

Family Structure

Assessment of the family, both its structure and function, is an important component of the history-taking process. Because the quality of the functional relationship between the child and family members is a major factor in emotional and physical health, family assessment is discussed separately and in greater detail apart from the more traditional health history.

Family assessment is the collection of data about the composition of the family and the relationships among its members. In its broadest sense, family refers to all those individuals who are considered by the family member to be significant to the nuclear unit, including relatives, friends, and social groups such as the school and church. Although family assessment is not family therapy, it can and frequently is therapeutic. Involving family members in discussing family characteristics and activities can provide insight into family dynamics and relationships.

Because of the time involved in performing an in-depth family assessment as presented here, be selective in deciding when knowledge of family function may facilitate nursing care (see Guidelines box). During brief contacts with families, a full assessment is not appropriate and screening with one or two questions from each category may reflect the health of the family system or the need for additional assessment.

The most common method of eliciting information on the family structure is to interview family members. The principal areas of concern are (1) family composition, (2) home and community environment, (3) occupation and education of family members, and (4) cultural and religious traditions (Box 29-8).

Psychosocial History

The traditional medical history includes a personal and social section that concentrates on children's personal status, such as school adjustment and any unusual habits, and the family and home environment. Because several personal aspects are covered under development and habits, only those issues related to children's ability to cope and their self-concept are presented here.

Through observation, obtain a general idea of how children handle themselves in terms of confidence in dealing with others, answering questions, and coping with new situations. Observe the parent-child relationship for the types of messages sent to children about their coping skills and self-worth. Do the parents treat the child with respect, focusing on strengths, or is the interaction one of constant reprimands, with emphasis on weaknesses and faults? Do the parents help the child learn new coping strategies or support the ones the child uses?

Parent-child interactions also convey messages about body image. Do the parents label the child and body parts, such as "bad boy," "skinny legs," or "ugly scar"? Do the parents handle the child gently, using soothing touch to calm an anxious child, or do they treat the child roughly, using slaps or restraint to make the child obey? If the child touches certain parts of the body, such as the genitalia, do the parents make comments that suggest a negative connotation?

With older children, many of the communication strategies discussed earlier in the chapter are useful in eliciting more definitive information about their coping and self-concept. Children can write down five things they like and dislike about themselves. The nurse can use sentence completion statements, such as "The thing I like best (or worst) about myself is _____"; "If I could change one thing about myself, it would be _____"; or "When I am scared, I _____."

Review of Systems

The review of systems is a specific review of each body system, following an order similar to that of the physical examination (see Guidelines box). Often the history of the present illness provides a complete review of the system involved in the chief complaint. Because asking questions about other body systems may appear irrelevant to the parents or child, precede the questioning with an explanation of why the data are necessary (similar to the explanation concerning the relevance of the birth history) and reassure the parents that the child's main problem has not been forgotten.

Begin the review of a specific system with a broad statement such as "How has your child's general health been?" or "Has your child had any problems with his eyes?" If the parent states that the child has had problems with some body function, pursue this with an encouraging statement such as "Tell me more about that." If the parent denies any problems, query for specific symptoms (e.g., "No headaches, bumping into objects, or squinting?"). If the parent reconfirms the absence of such symptoms, record positive statements in the history, such as "Mother denies headaches, bumping into objects, or squinting." In this way, anyone who reviews the health history is aware of exactly what symptoms were investigated.

GUIDELINES

Initiating a Comprehensive Family Assessment

Perform a comprehensive assessment on:

- Children receiving comprehensive well-child care
- Children experiencing major stressful life events (e.g., chronic illness, disability, parental divorce, death of a family member)
- Children requiring extensive home care
- Children with developmental delays
- Children with repeated accidental injuries and those with suspected child abuse
- Children with behavioral or physical problems that could be caused by family dysfunction

Performing a Nutritional Assessment

Dietary Intake

Knowledge of the child's dietary intake is an essential component of a nutritional assessment. However, it is also one of the most difficult factors to assess. Individuals' recall of food consumption, especially amounts eaten, is frequently unreliable. The food intake history of children and adolescents is prone to reporting error, mostly in the form of under-reporting. People from different cultures may have difficulty adequately describing the types of food they eat. Despite

BOX 29-8 FAMILY ASSESSMENT INTERVIEW

General Guidelines

- Schedule the interview with the family at a time that is most convenient for all parties; include as many family members as possible; clearly state the purpose of the interview.
- Begin the interview by asking each person's name and their relationship to one another.
- Restate the purpose of the interview and the objective.
- Keep the initial conversation general to put members at ease and to learn the "big picture" of the family.
- Identify major concerns and reflect these back to the family to be certain that all parties receive the same message.
- Terminate the interview with a summary of what was discussed and a plan for additional sessions if needed.

Structural Assessment Areas

Family Composition

- Immediate members of the household (names, ages, and relationships)
- Significant extended family members
- Previous marriages, separations, death of spouses, or divorces

Home and Community Environment

- Type of dwelling, number of rooms, occupants
- Sleeping arrangements
- Number of floors, accessibility of stairs and elevators
- Adequacy of utilities
- Safety features (fire escape, smoke and carbon monoxide detectors, guardrails on windows, use of car restraint)

Continued

BOX 29-8 FAMILY ASSESSMENT INTERVIEW—cont'd

- Environmental hazards (e.g., chipped paint, poor sanitation, pollution, heavy street traffic)
- Availability and location of health care facilities, schools, play areas
- Relationship with neighbors
- Recent crises or changes in home
- Child's reaction and adjustment to recent stresses

Occupation and Education of Family Members

- Types of employment
- Work schedules
- Work satisfaction
- Exposure to environmental or industrial hazards
- Sources of income and adequacy
- Effect of illness on financial status
- Highest degree or grade level attained

Cultural and Religious Traditions

- Religious beliefs and practices
- Cultural and ethnic beliefs and practices
- Language spoken in home
- Assessment questions include:
  - Does the family identify with a particular religious or ethnic group? Are both parents from that group?
  - How is religious or ethnic background part of family life?
  - What special religious or cultural traditions are practiced in the home (e.g., food choices and preparation)?
  - Where were family members born, and how long have they lived in this country?
  - What language does the family speak most frequently?
  - Do they speak and understand English?
  - What do they believe causes health or illness?
  - What religious or ethnic beliefs influence the family's perception of illness and its treatment?
  - What methods are used to prevent or treat illness?
  - How does the family know when a health problem needs medical attention?
  - Whom does the family contact when a member is ill?
  - Does the family rely on cultural or religious healers or remedies? If so, ask them to describe the type of healer or remedy.
  - Whom does the family go to for support (clergy, medical healer, relatives)?
  - Does the family experience discrimination because of their race, beliefs, or practices? Ask them to describe.

Functional Assessment Areas

Family Interactions and Roles

- *Interactions* refer to ways family members relate to each other. Chief concern is the amount of intimacy and closeness among the members, especially spouses.
- *Roles* refer to behaviors of people as they assume a different status or position.
- Observations include:
  - Family members' responses to each other (cordial, hostile, cool, loving, patient, short-tempered)
  - Obvious roles of leadership versus submission
  - Support and attention shown to various members
- Assessment questions include:
  - What activities does the family perform together?
  - Whom do family members talk to when something is bothering them?
  - What are members' household chores?
  - Who usually oversees what is happening with the children, such as at school or health care?
  - How easy or difficult is it for the family to change or accept new responsibilities for household tasks?

Power, Decision Making, and Problem Solving

- *Power* refers to individual member's control over others in family; it is manifested through family decision making and problem solving.
- Chief concern is clarity of boundaries of power between parents and children.
- One method of assessment involves offering a hypothetical conflict or problem, such as a child failing school, and asking family how they would handle this situation.
- Assessment questions include:
  - Who usually makes the decisions in the family?
  - If one parent makes a decision, can the child appeal to the other parent to change it?
  - What input do children have in making decisions or discussing rules?
  - Who makes and enforces the rules?
  - What happens when a rule is broken?

Communication

- Communication is concerned with clarity and directness of communication patterns.
- Further assessment includes periodically asking family members if they understood what was just said and to repeat the message.
- Observations include:
  - Who speaks to whom
  - If one person speaks for another or interrupts
  - If members appear uninterested when certain individuals speak
  - If there is agreement between verbal and nonverbal messages
- Assessment questions include:
  - How often do family members wait until others are through talking before "having their say"?
  - Do parents or older siblings tend to lecture and preach?
  - Do parents tend to "talk down" to the children?

Expression of Feelings and Individuality

- Expressions are concerned with personal space and freedom to grow, with limits and structure needed for guidance.
- Observing patterns of communication offers clues to how freely feelings are expressed.
- Assessment questions include:
  - Is it OK for family members to get angry or sad?
  - Who gets angry most of the time? What do they do?
  - If someone is upset, how do other family members try to comfort this person?
  - Who comforts specific family members?
  - When someone wants to do something, such as try out for a new sport or get a job, what is the family's response (offer assistance, discouragement, or no advice)?

GUIDELINES

Review of Systems

General—Overall state of health, fatigue, recent or unexplained weight gain or loss (period of time for either), contributing factors (change of diet, illness, altered appetite), exercise tolerance, fevers (time of day), chills, night sweats (unrelated to climatic conditions), frequent infections, general ability to carry out activities of daily living

Integument—Pruritus, pigment or other color changes, acne, eruptions, rashes (location), tendency for bruising, petechiae, excessive dryness, general texture, disorders or deformities of nails, hair growth or loss, hair color change (for adolescent, use of hair dyes or other potentially toxic substances, such as hair straighteners)

Head—Headaches, dizziness, injury (specific details)

Eyes—Visual problems (behaviors indicative of blurred vision, such as bumping into objects, clumsiness, sitting close to television, holding a book close to face, writing with head near desk, squinting, rubbing the eyes, bending head in an awkward position), cross-eyes (strabismus), eye infections, edema of lids, excessive tearing, use of glasses or contact lenses, date of last optic examination

Ears—Earaches, discharge, evidence of hearing loss (ask about behaviors, such as need to repeat requests, loud speech, inattentive behavior), results of any previous auditory testing

Nose—Nosebleeds (epistaxis), constant or frequent runny or stuffy nose, nasal obstruction (difficulty breathing), alteration or loss of sense of smell

Mouth—Mouth breathing, gum bleeding, toothaches, toothbrushing, use of fluoride, difficulty with teething (symptoms), last visit to dentist (especially if temporary dentition is complete), response to dentist

Throat—Sore throats, difficulty swallowing, choking (especially when chewing food; may be from poor chewing habits), hoarseness or other voice irregularities

Neck—Pain, limitation of movement, stiffness, difficulty holding head straight (torticollis), thyroid enlargement, enlarged nodes or other masses

Chest—Breast enlargement, discharge, masses, enlarged axillary nodes (for adolescent girl, ask about breast self-examination)

Respiratory—Chronic cough, frequent colds (number per year), wheezing, shortness of breath at rest or on exertion, difficulty breathing, sputum production, infections (pneumonia, tuberculosis), date of last chest x-ray examination, skin reaction from tuberculin testing

Cardiovascular—Cyanosis or fatigue on exertion, history of heart murmur or rheumatic fever, anemia, date of last blood count, blood type, recent transfusion

Gastrointestinal (questions in regard to appetite, food tolerance, and elimination habits are asked elsewhere)—Nausea, vomiting (not associated with eating, may be indicative of brain tumor or increased intracranial pressure), jaundice or yellowing skin or sclera, belching, flatulence, recent change in bowel habits (blood in stools, change of color, diarrhea or constipation)

Genitourinary—Pain on urination, frequency, hesitancy, urgency, hematuria, nocturia, polyuria, unpleasant odor to urine, force of stream, discharge, change in size of scrotum, date of last urinalysis (for adolescent, sexually transmitted infection, type of treatment; for male adolescent, ask about testicular self-examination)

Gynecologic—Menarche, date of last menstrual period, regularity or problems with menstruation, vaginal discharge, pruritus, date and result of last Papanicolaou (Pap) test (include obstetric history, as discussed under birth history, when applicable); if sexually active, type of contraception, sexually transmitted infection and type of treatment

Musculoskeletal—Weakness, clumsiness, lack of coordination, unusual movements, back or joint stiffness, muscle pains or cramps, abnormal gait, deformity, fractures, serious sprains, activity level

Neurologic—Seizures, tremors, dizziness, loss of memory, general affect, fears, nightmares, speech problems, any unusual habits

Endocrine—Intolerance to weather changes, excessive thirst or urination, excessive sweating, salty taste to skin, signs of early puberty

these obstacles, a dietary evaluation is an important component of the child's assessment.

The dietary reference intakes (DRIs) are a set of four nutrient-based reference values that provide quantitative estimates of nutrient intake for use in assessing and planning dietary intake (American Academy of Pediatrics, 2009). The specific DRIs are:

- **Estimated average requirement (EAR)**—Nutrient intake estimated to meet the requirement of half the healthy individuals (50%) for a specific age and gender group.
- **Recommended dietary allowance (RDA)**—Average daily dietary intake sufficient to meet the nutrient requirement of nearly all (97% to 98%) of healthy individuals for a specific age and gender group.
- **Adequate intake (AI)**—Recommended intake level based on estimates of nutrient intake by healthy groups of individuals.
- **Tolerable upper intake level (UL)**—Highest average daily nutrient intake level likely to pose no risk for adverse health effects. As intake increases above the UL, risk for adverse effects increases.

Fig. 29-4 contains MyPlate, which describes the **recommended dietary allowance.** Specific questions used to conduct a nutritional assessment are given in Box 29-9. Every nutritional assessment should begin with a dietary history. The exact questions used to elicit

CULTURAL COMPETENCE

Food Practices

Because cultural practices are prevalent in food preparation, consider carefully the kinds of questions that are asked and the judgments made during counseling. For example, some cultures, such as Hispanic, African-American, and Native-American, include many vegetables, legumes, and starches in their diet that together provide sufficient essential amino acids, even though the actual amount of meat or dairy protein is low. (See Table 27-1.)

a dietary history vary with the child's age. In general, the younger the child, the more specific and detailed the history should be. The overview elicited from the dietary history can be helpful in evaluating food frequency records. The history is also concerned with financial and cultural factors that influence food selection and preparation (see Cultural Competence box).

The most common and probably easiest method of assessing daily intake is the 24-hour recall. The child or parent recalls every item eaten in the past 24 hours and the approximate amounts. The 24-hour recall is most beneficial when it represents a typical day's intake. Some of the difficulties with a daily recall are the family's inability to remember exactly what was eaten and inaccurate

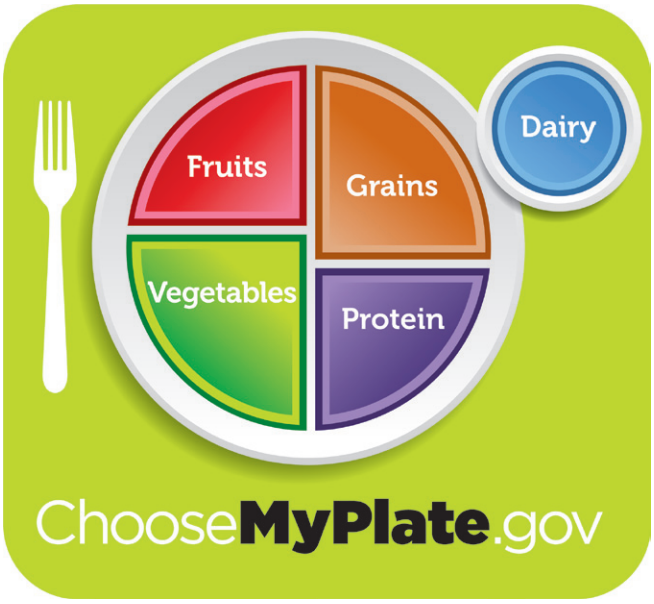

FIG 29-4 MyPlate. MyPlate advocates building a healthy plate by making half of your plate fruits and vegetables and the other half grains and protein. Avoiding oversized portions, making half your grains whole grains, and drinking fat-free or low-fat (1%) milk are additional recommendations for a healthy diet. (From U.S. Department of Agriculture: *MyPlate,* Washington, DC, June 2011, Author, www.choosemyplate.gov.)

estimation of portion size. To increase accuracy of reporting portion sizes, the use of food models and additional questions are recommended. In general, this method is most useful in providing *qualitative* information about the child's diet.

To improve the reliability of the daily recall, the family can complete a food diary by recording every food and liquid consumed for a certain number of days. A 3-day record consisting of 2 weekdays and 1 weekend day is representative for most people. Providing specific charts to record intake can improve compliance. The family should record items immediately after eating.

Clinical Examination of Nutrition

A significant amount of information regarding nutritional deficiencies comes from a clinical examination, especially from assessing the skin, hair, teeth, gums, lips, tongue, and eyes. Hair, skin, and mouth are vulnerable because of the rapid turnover of epithelial and mucosal tissue. Table 29-1 summarizes clinical signs of possible nutritional deficiency or excess. Few are diagnostic for a specific nutrient, and if suspicious signs are found, they must be confirmed with dietary and biochemical data. Generally, the clinical examination does not reveal children *at risk* for a deficiency or excess.

Anthropometry, an essential parameter of nutritional status, is the measurement of height, weight, head circumference, proportions, skinfold thickness, and arm circumference in young children. Height and head circumference reflect past nutrition, whereas weight, skinfold thickness, and arm circumference reflect present nutritional status, especially of protein and fat reserves. Skinfold

BOX 29-9 DIETARY REFERENCE INTAKES FOR AN INDIVIDUAL

Estimated average requirement (EAR)—Used to examine the possibility of inadequacy.

Recommended dietary allowance (RDA)—Dietary intake at or above this level usually has a low probability of inadequacy.

Adequate intake (AI)—Dietary intake at or above this level usually has a low probability of inadequacy.

Tolerable upper intake level (UL)—Dietary intake above this level usually places an individual at risk for adverse effects from excessive nutrient intake.

Dietary History

- What are the family's usual mealtimes?
- Do family members eat together or at separate times?
- Who does the family grocery shopping and meal preparation?
- How much money is spent to buy food each week?
- How are most foods prepared—baked, broiled, fried, other?
- How often does the family or your child eat out?
  - What kinds of restaurants do you go to?
  - What kinds of food does your child typically eat at restaurants?
- Does your child eat breakfast regularly?
- Where does your child eat lunch?
- What are your child's favorite foods, beverages, and snacks?
  - What are the average amounts eaten per day?
  - What foods are artificially sweetened?
  - What are your child's snacking habits?
  - When are sweet foods usually eaten?
  - What are your child's toothbrushing habits?
- What special cultural practices are followed? What ethnic foods are eaten?
- What foods and beverages does your child dislike?
- How would you describe your child's usual appetite (hearty eater, picky eater)?
- What are your child's feeding habits (breast, bottle, cup, spoon, eats by self, needs assistance, any special devices)?
- Does your child take vitamins or other supplements? Do they contain iron or fluoride?
- Does your child have any known or suspected food allergies? Is your child on a special diet?
- Has your child lost or gained weight recently?
- Are there any feeding problems (excessive fussiness, spitting up, colic, difficulty sucking or swallowing)? Are there any dental problems or appliances, such as braces, that affect eating?
- What types of exercise does your child do regularly?
- Is there a family history of cancer, diabetes, heart disease, high blood pressure, or obesity?

Additional Questions for Infants

- What was the infant's birth weight? When did it double? Triple?
- Was the infant premature?
- Are you breastfeeding or have you breastfed your infant? For how long?
- If you use a formula, what is the brand?
  - How long has the infant been taking it?
  - How many ounces does the infant drink a day?
- Are you giving the infant cow's milk (whole, low fat, skim)?
  - When did you start?
  - How many ounces does the infant drink a day?
- Do you give your infant extra fluids (water, juice)?

BOX 29-9 DIETARY REFERENCE INTAKES FOR AN INDIVIDUAL—cont'd

- If the infant takes a bottle to bed at nap time or nighttime, what is in the bottle?
- At what age did the child start on cereal, vegetables, meat or other protein sources, fruit or juice, finger food, table food?
- Do you make your own baby food or use commercial foods, such as infant cereal?
- Does the infant take a vitamin or mineral supplement? If so, what type?
- Has the infant had an allergic reaction to any food(s)? If so, list the foods and describe the reaction.
- Does the infant spit up frequently; have unusually loose stools; or have hard, dry stools? If so, how often?
- How often do you feed your infant?
- How would you describe your infant's appetite?

Adapted from Murphy SP, Poos MI: Dietary reference intakes: summary of applications in dietary assessment, *Public Health Nutr* 5(6A): 843–849, 2002.

TABLE 29-1 CLINICAL ASSESSMENT OF NUTRITIONAL STATUS

EVIDENCE OF ADEQUATE NUTRITION	EVIDENCE OF DEFICIENT OR EXCESS NUTRITION	DEFICIENCY OR EXCESS*
General Growth		
Between 5th and 95th percentiles for height, weight, and head circumference	<5th or >95th percentile for growth	Protein, calories, fats, and other essential nutrients, especially vitamin A, pyridoxine, niacin, calcium, iodine, manganese, zinc
Steady gain with expected growth spurts during infancy and adolescence	Absence of or delayed growth spurts; poor weight gain	
Sexual development appropriate for age	Delayed sexual development	Excess vitamins A, D
Skin		
Smooth, slightly dry to touch Elastic and firm Absence of lesions Color appropriate to genetic background	Hardening and scaling	Vitamin A
	Seborrheic dermatitis	Excess niacin
	Dry, rough, petechiae	Riboflavin
	Delayed wound healing	Vitamin C
	Scaly dermatitis on exposed surfaces	Riboflavin, vitamin C, zinc
	Wrinkled, flabby	Niacin
	Crusted lesions around orifices, especially nares	Protein, calories, zinc
	Pruritus	Excess vitamin A, riboflavin, niacin
	Poor turgor	Water, sodium
	Edema	Protein, thiamine Excess sodium
	Yellow tinge (jaundice)	Vitamin B_{12} Excess vitamin A, niacin
	Depigmentation	Protein, calories
	Pallor (anemia)	Pyridoxine, folic acid, vitamins B_{12}, C, E (in premature infants), iron Excess vitamin C, zinc
	Paresthesia	Excess riboflavin
Hair		
Lustrous, silky, strong, elastic	Stringy, friable, dull, dry, thin	Protein, calories
	Alopecia	Protein, calories, zinc
	Depigmentation	Protein, calories, copper
	Raised areas around hair follicles	Vitamin C

Continued

TABLE 29-1 CLINICAL ASSESSMENT OF NUTRITIONAL STATUS—cont'd

EVIDENCE OF ADEQUATE NUTRITION	EVIDENCE OF DEFICIENT OR EXCESS NUTRITION	DEFICIENCY OR EXCESS*
Head		
Even molding, occipital prominence, symmetric facial features Fused sutures after 18 months	Softening of cranial bones, prominence of frontal bones, skull flat and depressed toward middle	Vitamin D
	Delayed fusion of sutures	Vitamin D
	Hard, tender lumps in occiput	Excess vitamin A
	Headache	Excess thiamine
Neck		
Thyroid not visible, palpable in midline	Thyroid enlarged, may be grossly visible	Iodine
Eyes		
Clear, bright	Hardening and scaling of cornea and conjunctiva	Vitamin A
Good night vision	Night blindness	Vitamin A
Conjunctiva—Pink, glossy	Burning, itching, photophobia, cataracts, corneal vascularization	Riboflavin
Ears		
Tympanic membrane—Pliable	Calcified (hearing loss)	Excess vitamin D
Nose		
Smooth, intact nasal angle	Irritation and cracks at nasal angle	Riboflavin Excess vitamin A
Mouth		
Lips—Smooth, moist, darker color than skin	Fissures and inflammation at corners	Riboflavin Excess vitamin A
Gums—Firm, coral pink, stippled	Spongy, friable, swollen, bluish red or black, bleed easily	Vitamin C
Mucous membranes—Bright pink, smooth, moist	Stomatitis	Niacin
Tongue—Rough texture, no lesions, taste sensation	Glossitis	Niacin, riboflavin, folic acid
	Diminished taste sensation	Zinc
Teeth—Uniform white color, smooth, intact	Brown mottling, pits, fissures	Excess fluoride
	Defective enamel	Vitamins A, C, D, calcium, phosphorus
	Caries	Excess carbohydrates
Chest		
In infants, shape almost circular	Depressed lower portion of rib cage	Vitamin D
In children, lateral diameter increased in proportion to anteroposterior diameter	Sharp protrusion of sternum	Vitamin D
Smooth costochondral junctions	Enlarged costochondral junctions	Vitamins C, D
Breast development—Normal for age	Delayed development	See under General Growth; especially zinc

TABLE 29-1 CLINICAL ASSESSMENT OF NUTRITIONAL STATUS—cont'd

EVIDENCE OF ADEQUATE NUTRITION	EVIDENCE OF DEFICIENT OR EXCESS NUTRITION	DEFICIENCY OR EXCESS*
Cardiovascular System		
Pulse and blood pressure (BP) within normal limits	Palpitations	Thiamine
	Rapid pulse	Potassium Excess thiamine
	Dysrhythmias	Magnesium, potassium Excess niacin, potassium
	Increased BP	Excess sodium
	Decreased BP	Thiamine Excess niacin
Abdomen		
In young children, cylindric and prominent	Distended, flabby, poor musculature	Protein, calories
	Prominent, large	Excess calories
In older children, flat	Potbelly, constipation	Vitamin D
Normal bowel habits	Diarrhea	Niacin Excess vitamin C
	Constipation	Excess calcium, potassium
Musculoskeletal System		
Muscles—Firm, well-developed, equal strength bilaterally	Flabby, weak, generalized wasting	Protein, calories
	Weakness, pain, cramps	Thiamine, sodium, chloride, potassium, phosphorus, magnesium Excess thiamine
	Muscle twitching, tremors	Magnesium
	Muscular paralysis	Excess potassium
Spine—Cervical and lumbar curves (double-S curve)	Kyphosis, lordosis, scoliosis	Vitamin D
Extremities—Symmetric; legs straight with minimum bowing	Bowing of extremities, knock-knees	Vitamin D, calcium, phosphorus
	Epiphyseal enlargement	Vitamins A, D
	Bleeding into joints and muscles, joint swelling, pain	Vitamin C
Joints—Flexible, full range of motion, no pain or stiffness	Thickening of cortex of long bones with pain and fragility, hard tender lumps in extremities	Excess vitamin A
	Osteoporosis of long bones	Calcium Excess vitamin D
Neurologic System		
Behavior—Alert, responsive, emotionally stable	Listless, irritable, lethargic, apathetic (sometimes apprehensive, anxious, drowsy, mentally slow, confused)	Thiamine, niacin, pyridoxine, vitamin C, potassium, magnesium, iron, protein, calories Excess vitamins A, D, thiamine, folic acid, calcium
Absence of tetany, convulsions	Masklike facial expression, blurred speech, involuntary laughing	Excess manganese
	Convulsions	Thiamine, pyridoxine, vitamin D, calcium, magnesium Excess phosphorus (in relation to calcium)
Intact peripheral nervous system	Peripheral nervous system toxicity (unsteady gait, numb feet and hands, fine motor clumsiness)	Excess pyridoxine
Intact reflexes	Diminished or absent tendon reflexes	Thiamine, vitamin E

*Nutrients listed are deficient unless specified as excess.

thickness is a measurement of the body's fat content, because approximately half the body's total fat stores are directly beneath the skin. The upper arm muscle circumference is correlated with measurements of total muscle mass. Because muscle serves as the body's major protein reserve, this measurement is considered an index of the body's protein stores. Ideally, growth measurements are recorded over time, and comparisons are made regarding the *velocity* of growth based on previous and present values.

Numerous biochemical tests are available for assessing nutritional status and include analysis of plasma; blood cells; urine; and tissues from liver, bone, hair, and fingernails. Many of these tests are complicated and are not performed routinely. Common laboratory procedures for nutritional status include measurement of hemoglobin, hematocrit, transferrin, albumin, creatinine, and nitrogen. Appendix B provides laboratory values for these tests and more specific nutrient measurements.

Evaluation of Nutritional Assessment

After collecting the data needed for a thorough nutritional assessment, evaluate the findings to plan appropriate counseling. From the data, assess whether the child is (1) malnourished, (2) at risk for becoming malnourished, (3) well nourished with adequate reserves, or (4) overweight or obese.

Analyze the daily food diary for the variety and amounts of foods suggested in MyPlate (see Fig. 29-4). For example, if the list includes no vegetables, inquire about this rather than assume that the child dislikes vegetables, since it is possible that none were served that day. Also, evaluate the information in terms of the family's ethnic practices and financial resources. Encouraging increased protein intake with additional meat is not always feasible for families on a limited budget and may conflict with food practices that use meat sparingly, such as in Asian meal preparation.

PHYSICAL ASSESSMENT

General Approaches Toward Examining the Child

Although the approach to and sequence of the physical examination differ according to the child's age, the following discussion outlines the traditional model for physical assessment. Because the physical examination is a vital part of preventive pediatric care, Fig. 29-5 gives a schedule for periodic health visits.

Sequence of the Examination

Ordinarily, the sequence for examining patients follows a head-to-toe direction. The main function of such a systematic approach is to provide a general guideline for assessment of each body area to

Clinical Preventive Services for Normal-Risk Children*

avoid omitting segments of the examination. The standard recording of data also facilitates exchange of information among different professionals. This orderly sequence is frequently altered to accommodate the child's developmental needs, although the examination is recorded following the head-to-toe model. Using developmental and **chronologic age** as the main criteria for assessing each body system accomplishes several goals:

- Minimizes stress and anxiety associated with assessment of various body parts
- Fosters a trusting nurse-child-parent relationship
- Allows for maximum preparation of the child
- Preserves the essential security of the parent-child relationship, especially with young children
- Maximizes the accuracy and reliability of assessment findings

Preparation of the Child

Although the physical examination consists of painless procedures, for some children the use of a tight arm cuff, probes in the ears and mouth, pressure on the abdomen, and a cold piece of metal to listen to the chest are stressful. Therefore the nurse should use the same considerations discussed in Chapter 39 for preparing children for procedures. In addition to that discussion, general guidelines related to the examining process are given in the Guidelines box.

The physical examination should be as pleasant as possible, as well as educational. The paper-doll technique is a useful approach to teaching children about the body part that is being examined (Fig. 29-6). At the conclusion of the visit, the child can bring home the paper doll as a memento.

Table 29-2 summarizes guidelines for positioning, preparing, and examining children at various ages. Because no child fits precisely into one age category, it may be necessary to vary the approach after a preliminary assessment of the child's developmental achievements and needs. Even with the best approach, many toddlers are uncooperative and inconsolable for much of the physical examination. However, some seem intrigued by the new surroundings and unusual equipment and respond more like preschoolers than toddlers. Likewise, some early preschoolers may require more of the "security measures" employed with younger children, such as continued parent-child contact, and less of the preparatory measures used with preschoolers, such as playing with the equipment before and during the actual examination (Fig. 29-7).

FIG 29-6 Using paper-doll technique to prepare child for physical examination.

Growth Measurements

Measurement of physical growth in children is a key element in evaluating their health status. Physical growth parameters include weight, height (length), skinfold thickness, arm circumference, and head circumference. Values for these growth parameters are plotted on percentile charts, and the child's measurements in percentiles are compared with those of the general population.

Growth Charts

Growth charts use a series of percentile curves to demonstrate the distribution of body measurements in children. The Centers for Disease Control (CDC) recommends that the World Health Organization (WHO) growth standards be used to monitor growth for infants and children between the ages of 0 and 2 years. The CDC growth charts are used for children age 2 years and older.*

Children whose growth may be questionable include:

- Children whose height and weight percentiles are widely disparate (e.g., height in the 10th percentile and weight in the 90th percentile, especially with above-average skinfold thickness)
- Children who fail to follow the expected growth velocity in height and weight, especially during the rapid growth periods of infancy and adolescence
- Children who show a sudden increase (except during puberty), decrease, or no change in a previously steady growth pattern.

Because growth is a continuous but uneven process, the most reliable evaluation lies in comparing growth measurements over time. It is important to remember that normal growth patterns vary among children of the same age (Fig. 29-8).

Breastfed and Formula-Fed Infants. The WHO growth charts are used because they reflect growth patterns among children who were predominantly breastfed (the recommended standard for

FIG 29-7 Preparing children for physical examination.

*Growth Charts can be found on the Centers for Disease Control and Prevention website at http://www.cdc.gov/growthcharts/who_charts.htm.

GUIDELINES

Performing Pediatric Physical Examination

- Perform the examination in an appropriate, nonthreatening area:
  - Have room well lit and decorated with neutral colors.
  - Have room temperature comfortably warm.
  - Place all strange and potentially frightening equipment out of sight.
  - Have some toys, dolls, stuffed animals, and games available for child.
  - If possible, have rooms decorated and equipped for different-age children.
  - Provide privacy, especially for school-age children and adolescents.
- Provide time for play and becoming acquainted.
- Observe behaviors that signal child's readiness to cooperate:
  - Talking to the nurse
  - Making eye contact
  - Accepting the offered equipment
  - Allowing physical touching
  - Choosing to sit on examining table rather than parent's lap
- If signs of readiness are not observed, use the following techniques:
  - Talk to parent while essentially "ignoring" child; gradually focus on child or a favorite object, such as a doll.
  - Make complimentary remarks about child, such as appearance, dress, or a favorite object.
  - Tell a funny story or play a simple magic trick.
  - Have a nonthreatening "friend" available, such as a hand puppet to "talk" to child for the nurse (see Fig. 29-26, *A*).
- If child refuses to cooperate, use the following techniques:
  - Assess reason for uncooperative behavior; consider that a child who is unduly afraid may have had a traumatic experience.
  - Try to involve child and parent in process.
  - Avoid prolonged explanations about examining procedure.
  - Use a firm, direct approach regarding expected behavior.
  - Perform examination as quickly as possible.
  - Have attendant gently restrain child.
  - Minimize any disruptions or stimulation.
  - Limit number of people in room.
  - Use isolated room.
  - Use quiet, calm, confident voice.
- Begin examination in a nonthreatening manner for young children or children who are fearful:
  - Use activities that can be presented as games, such as test for cranial nerves (see Table 29-13) or parts of developmental screening tests (pp. 825-826).
  - Use approaches such as "Simon Says" to encourage child to make a face, squeeze a hand, stand on one foot, and so on.
  - Use paper-doll technique:
    1. Lay child supine on an examining table or floor that is covered with a large sheet of paper.
    2. Trace around child's body outline.
    3. Use body outline to demonstrate what will be examined, such as drawing a heart and listening with stethoscope before performing activity on child.
- If several children in the family will be examined, begin with most cooperative child to model desired behavior.
- Involve child in examination process:
  - Provide choices, such as sitting on table or in parent's lap.
  - Allow child to handle or hold equipment.
  - Encourage child to use equipment on a doll, family member, or examiner.
  - Explain each step of the procedure in simple language.
- Examine child in a comfortable and secure position:
  - Sitting in parent's lap
  - Sitting upright if in respiratory distress
- Proceed to examine the body in an organized sequence (usually head to toe) with the following exceptions:
  - Alter sequence to accommodate needs of different-age children (see Table 29-2).
  - Examine painful areas last.
  - In emergency situation, examine vital functions (airway, breathing, and circulation) and injured area first.
- Reassure child throughout the examination, especially about bodily concerns that arise during puberty.
- Discuss findings with family at the end of the examination.
- Praise child for cooperation during the examination; give a reward such as a small toy or sticker.

infant feeding) for at least 4 months and still breastfeeding at 12 months.

Length

The term *length* refers to measurements taken when children are supine (also referred to as recumbent length). Until children are 24 months old (or 36 months if using the chart for birth to 36 months), measure recumbent length. Because of the normally flexed position during infancy, fully extend the body by (1) holding the head in midline, (2) grasping the knees together gently, and (3) pushing down on the knees until the legs are fully extended and flat against the table. If using a measuring board, place the head firmly at the top of the board and the heels of the feet firmly against the footboard.

If such a measuring device is not available, measure length by placing the child on a paper-covered surface, marking the endpoints of the top of the head and the heels of the feet, and measuring between these two points (Fig. 29-9). For accurate measurement, hold the writing utensil at a right angle to the table when marking the cephalic point; position the feet with the toes pointing directly to the ceiling when marking the heel point. Regardless of the method used, have someone assist in holding the child's head in midline while you extend the legs and take the measurements.

Height

The term *height* (or stature) refers to the measurement taken when a child is standing upright. Measure height by having the child, with shoes removed, stand as tall and straight as possible, with the head in midline and the line of vision parallel to the ceiling and floor. Be certain the child's back is to the wall or other vertical flat surface, with the heels, buttocks, and back of the shoulders touching the wall and the medial malleoli touching if possible (Fig. 29-10). Check for and correct bending of the knees, slumping of the shoulders, or raising of the heels. Normally, height is less if measured in the afternoon than in the morning. To minimize this variation, apply modest upward pressure under the jaw or the mastoid processes behind the ears.

TABLE 29-2 AGE-SPECIFIC APPROACHES TO PHYSICAL EXAMINATION DURING CHILDHOOD

POSITION	SEQUENCE	PREPARATION
Infant		
Before able to sit alone—Supine or prone, preferably in parent's lap; before 4-6 months, can place on examining table After able to sit alone—Sitting in parent's lap whenever possible; if on table, place with parent in full view	If quiet, auscultate heart, lungs, abdomen. Record heart and respiratory rates. Palpate and percuss same areas. Proceed in usual head-to-toe direction. Perform traumatic procedures last (eyes, ears, mouth [while crying]). Elicit reflexes as body part is examined. Elicit Moro reflex last.	Completely undress if room temperature permits. Leave diaper on male infant. Gain cooperation with distraction, bright objects, rattles, talking. Smile at infant; use soft, gentle voice. Pacify with bottle of sugar water or feeding. Enlist parent's aid for restraining to examine ears, mouth. Avoid abrupt, jerky movements.
Toddler		
Sitting or standing on or by parent Prone or supine in parent's lap	Inspect body area through play: "count fingers," "tickle toes." Use minimum physical contact initially. Introduce equipment slowly. Auscultate, percuss, palpate whenever quiet. Perform traumatic procedures last (same as for infant).	Have parent remove outer clothing. Remove underwear as body part is examined. Allow to inspect equipment; demonstrating use of equipment is usually ineffective. If uncooperative, perform procedures quickly. Use restraint when appropriate; request parent's assistance. Talk about examination if cooperative; use short phrases. Praise for cooperative behavior.
Preschool Child		
Prefer standing or sitting Usually cooperative prone or supine Prefer parent's closeness	If cooperative, proceed in head-to-toe direction. If uncooperative, proceed as with toddler.	Request self-undressing. Allow to wear underpants if shy. Offer equipment for inspection; briefly demonstrate use. Make up story about procedure (e.g., "I'm seeing how strong your muscles are" [blood pressure]). Use paper-doll technique. Give choices when possible. Expect cooperation; use positive statements (e.g., "Open your mouth").
School-Age Child		
Prefer sitting Cooperative in most positions Younger child prefers parent's presence Older child may prefer privacy	Proceed in head-to-toe direction. May examine genitalia last in older child.	Respect need for privacy. Request self-undressing. Allow to wear underpants. Give gown to wear. Explain purpose of equipment and significance of procedure, such as otoscope to see eardrum, which is necessary for hearing. Teach about body function and care.
Adolescent		
Same as for school-age child Offer option of parent's presence	Same as older school-age child. May examine genitalia last.	Allow to undress in private. Give gown. Expose only area to be examined. Respect need for privacy. Explain findings during examination: "Your muscles are firm and strong." Matter-of-factly comment about sexual development: "Your breasts are developing as they should be." Emphasize normalcy of development. Examine genitalia as any other body part; may leave to end.

For the most accurate measurement, use a wall-mounted unit (stadiometer; see Fig. 29-10). The movable measuring rod of platform scales is accurate only if it remains parallel to the floor and rests securely on the topmost part of the head. To improvise a flat surface for measuring length, attach a paper or metal tape or yardstick to the wall, position the child adjacent to the tape, and place a three-dimensional object, such as a thick book or box, on top of the head. Rest the side of the object firmly against the wall to form a right angle. Measure length or stature to the nearest 1 mm or ⅛ inch.

Weight

Weight is measured with an appropriate-size balance beam scale, which measures weight to the nearest 10 g (0.35 oz) for infants and

100 g (0.22 lb) for children. Before weighing the child, balance the scale by setting it at 0 and noting if the balance registers exactly in the middle of the mark. If the end of the balance beam rises to the top or bottom of the mark, more or less weight, respectively, is needed. Some scales are designed to self-correct, but others need to be recalibrated by the manufacturer. Scales vary in their accuracy; infant scales tend to be more accurate than adult platform scales, and newer scales tend to be more accurate than older ones, especially at the upper levels of weight measurement. When precise measurements are necessary, two nurses should take the weight independently; if there is a discrepancy, take a third reading.

Take measurements in a comfortably warm room. When the birth-to-36-month growth charts are used, children should be weighed nude. Older children are usually weighed while wearing their underpants or a light gown. However, always respect the privacy of all children. If the child must be weighed wearing some article of clothing or some type of special device, such as a prosthesis or an armboard for an intravenous device, note this when recording

FIG 29-8 These children of identical age (8 years) are markedly different in size. Child on left, of Asian descent, is at 5th percentile for height and weight. Child on right is above 95th percentile for height and weight. However, both children demonstrate normal growth patterns.

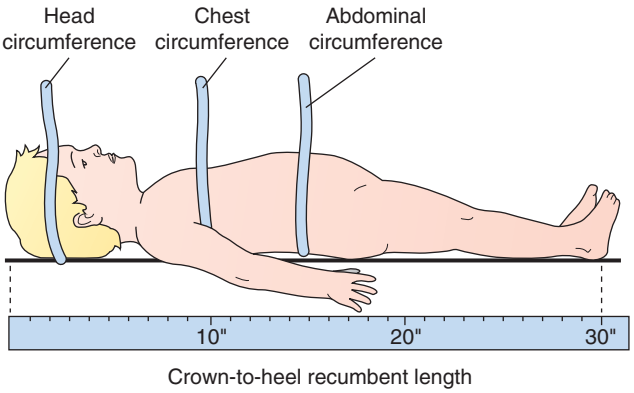

FIG 29-9 Measurement of head, chest, and abdominal circumference and crown-to-heel (recumbent) length. (From Price DL: *Pediatric nursing: an introductory text,* ed 10, St Louis, 2007, Saunders.)

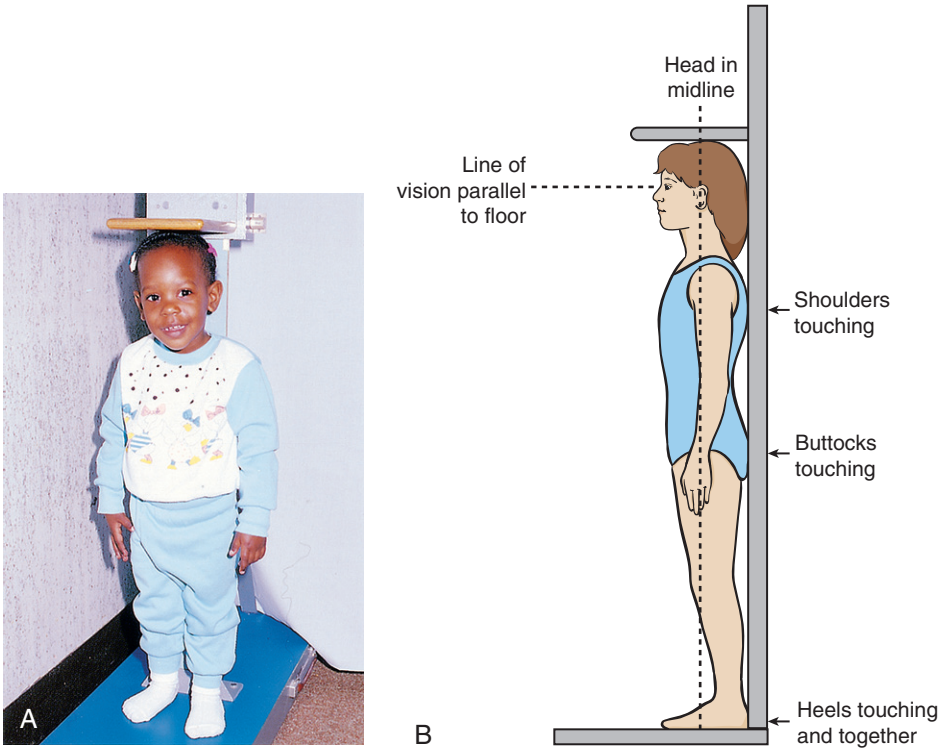

FIG 29-10 **A** and **B,** Measurement of height. (*A,* From Seidel HM, Ball JW, Dains JE, et al: *Mosby's guide to physical examination,* ed 6, St Louis, 2007, Mosby. *B,* From Wilson S: *Health assessment for nursing practice,* ed 5, St Louis, 2013, Mosby.)

the weight. Children who are measured for recumbent length are usually weighed on an infant platform scale and placed in a lying or sitting position. When weighing a child, place your hand lightly above the infant to prevent him or her from accidentally falling off the scale (Fig. 29-11, *A*) or stand close to the toddler, ready to prevent a fall (Fig. 29-11, *B*). For maximum asepsis, cover the scale with a clean sheet of paper between each child's measurement.

Skinfold Thickness and Arm Circumference

Measures of relative weight and stature cannot distinguish between adipose (fat) tissue and muscle. One convenient measure of body fat is skinfold thickness, which is increasingly recommended as a routine measurement. Measure skinfold thickness with special calipers, such as the Lange calipers. The most common sites for measuring skinfold thickness are the triceps (most practical for routine clinical use), subscapula, suprailiac, abdomen, and upper thigh. For greatest reliability, follow the exact procedure for measurement and record the average of at least two measurements of one site.

Arm circumference is an indirect measure of muscle mass. Measurement of arm circumference follows the same procedure as for skinfold thickness except the midpoint is measured with a paper or steel tape. Place the tape vertically, along the posterior aspect of the upper arm to the acromial process and to the olecranon process; half the measured length is the midpoint.

Head Circumference

Measure head circumference in children up to 36 months of age and in any child whose head size is questionable. Measure the head at its greatest circumference, usually slightly above the eyebrows and pinna of the ears and around the occipital prominence at the back of the skull (see Fig. 29-9). Because head shape can affect the location of the maximum circumference, more than one measurement at points above the eyebrows is necessary to obtain the most accurate measure. Use a paper or metal tape, since a cloth tape can stretch and give a falsely small measurement. For greatest accuracy, use devices marked with tenths of a centimeter, since the percentile charts have only 0.5-cm increments.

Plot the head size on the appropriate growth chart under head circumference. Generally, head and chest circumferences are equal at about 1 to 2 years of age. During childhood, chest circumference exceeds head size by about 5 to 7 cm (2 to 2.75 inches).

Physiologic Measurements

Physiologic measurements, key elements in evaluating physical status of vital functions, include temperature, pulse, respiration, and blood pressure. Compare each physiologic recording with normal values for that age-group. In addition, compare the values taken on preceding health visits with present recordings. For example, a falsely elevated blood pressure reading may not indicate hypertension if previous recent readings have been within normal limits. The isolated recording may indicate some stressful event in the child's life.

As in most procedures carried out with children, treat older children and adolescents much the same as adults. However, give special consideration to preschool children (see Atraumatic Care box). For best results in taking vital signs of infants, count respirations first (before the infant is disturbed), take the pulse next, and measure temperature last. If vital signs cannot be taken without disturbing the child, record the child's behavior (e.g., crying) along with the measurement.

Temperature

Temperature is the measure of heat content within an individual's body. The core temperature most closely reflects the temperature of the blood flow through the carotid arteries to the hypothalamus. Core temperature is relatively constant despite wide fluctuations in the external environment. When a child's temperature is altered, receptors in the skin, spinal cord, and brain respond in an attempt to achieve normothermia, a normal temperature state. In pediatrics, there is a lack of consensus regarding what temperature constitutes

ATRAUMATIC CARE

Reducing Young Children's Fears

Young children, especially preschoolers, fear intrusive procedures because of their poorly defined body boundaries. Therefore avoid invasive procedures, such as measuring rectal temperature, whenever possible. Also, avoid using the word "take" when measuring vital signs, since young children interpret words literally and may think that their temperature or other function will be taken away. Instead, say, "I want to know how warm you are."

FIG 29-11 **A,** Infant on scale. **B,** Toddler on scale. Note presence of nurse to prevent falls. (*B,* Courtesy Paul Vincent Kuntz, Texas Children's Hospital, Houston, TX.)

normothermia for every child. For rectal temperatures in children, a value of 37° to 37.5°C (98.6° to 99.5°F) is an acceptable range, where heat loss and heat production are balanced. For neonates, a core body temperature between 36.5° and 37.6°C (97.7° and 99.7°F) is a desirable range. In the neonate, obtain temperature measurements for monitoring adequacy of thermoregulation, not fever; therefore temperature measurements in each infant should be carefully considered in the context of the *purpose* and the environment.

The nurse can measure temperature in healthy children at several body sites via oral, rectal, axillary, ear canal, tympanic membrane, temporal artery, or skin route (Box 29-10). For the ill child, other sites for temperature measurement that have been investigated include the urinary bladder, pulmonary artery, and esophageal and nasopharyngeal sites (El-Radhi and Barry, 2006; Mains, Coxall, and Lloyd, 2008) (Box 29-11). One of the most important influences on the accuracy of temperature is improper temperature-taking technique. Detailed discussion of temperature-taking methods and visual examples of proper techniques are given in Table 29-3. For a critical review of the evidence on temperature-taking methods, see the Evidence-Based Practice box.

The most frequently used temperature measurement devices in infants and children include:

- **Electronic intermittent thermometers**—Measure the patient's temperature at oral, rectal, and axillary sites and are used as primary diagnostic indicators
- **Infrared thermometers**—Measure the patient's temperature by collecting emitted thermal radiation from a particular site (e.g., ear canal)
- **Electronic continuous thermometers**—Measure the patient's temperature during the administration of general anesthesia, treatment of hypothermia or hyperthermia, and other situations that require continuous monitoring

Box 29-12 provides a detailed description of these devices.

BOX 29-10 RECOMMENDED TEMPERATURE SCREENING ROUTES IN INFANTS AND CHILDREN

Birth to 2 Years
- Axillary
- Rectal—if definitive temperature reading is needed for infants older than 1 month

2 to 5 Years
- Axillary
- Tympanic
- Oral—when child can hold thermometer under tongue
- Rectal—if definitive temperature reading is needed

Older than 5 Years
- Oral
- Axillary
- Tympanic

! NURSING ALERT

The belief that core temperature can be estimated by adding 1°C to the temperature taken in the axilla is incorrect. Do not add a degree to the finding obtained by taking a temperature by the axillary route (Craig, Lancaster, Williamson, et al., 2000).

Pulse

A satisfactory pulse can be taken radially in children older than 2 years. However, in infants and young children, the apical impulse (heard through a stethoscope held to the chest at the apex of the heart) is more reliable (see Fig. 29-33 for location of pulses). Count the pulse for 1 full minute in infants and young children because of possible irregularities in rhythm. However, when frequent apical

BOX 29-11 ALTERNATIVE TEMPERATURE MEASUREMENT SITES FOR THE ILL CHILD

Skin
- Probe is placed on the skin to determine heat output in response to changes in the patient's skin temperature.
- Skin temperature sensors are most often used for neonates and infants placed in radiant heat warmers or isolettes (using servo-control feature of the apparatus). In turn, the heater unit warms to a set point to maintain the infant's temperature within a specified range.
- ThermoSpot is an example of a device allowing continuous thermal monitoring in neonates.

Urinary Bladder
- A thermistor or thermocouple is placed within the indwelling bladder catheter. The catheter tip immersed in the bladder provides a continuous temperature read-out on the bedside monitor.
- This is not a true measure of core temperature but responds better than rectal and skin temperatures to core body changes.
- Because of thermistor sizes, this method is unusable with neonates and small infants.

Pulmonary Artery
- A catheter is placed into the heart to obtain a reading in the pulmonary artery.
- It is used in critical care settings or operating rooms only in patients requiring aggressive monitoring.
- Catheter is not available in sizes for neonates or small infants.

Esophageal Site
- Probe is inserted into the lower third of the esophagus at the level of the heart.
- This is used in critical care settings or operating rooms.
- Several companies have esophageal stethoscopes with temperature probe monitors for patients in the operating room that show a continuous temperature reading.

Nasopharyngeal Site
- Probe is inserted into the nasopharynx, posterior to the soft palate, and provides an estimate of hypothalamic temperature.
- This is used in critical care settings or operating rooms.

Data from Kumar PR, Nisarga R, Gowda B: Temperature monitoring in newborns using ThermoSpot, *Indian J Pediatr* 71(9):795–796, 2004; Martin SA, Kline AM: Can there be a standard for temperature measurement in the pediatric intensive care unit? *AACN Clin Issues* 15(2):254–266, 2004; Maxton FJC, Justin L, Gilles D: Estimating core temperature in infants and children after cardiac surgery: a comparison of six methods, *J Adv Nurs* 45(2):214–222, 2004.

rates are necessary, use shorter counting times (e.g., 15- or 30-second intervals). For greater accuracy, measure the apical rate while the child is asleep; record the child's behavior along with the rate. Grade pulses according to the criteria in Table 29-4. Compare radial and femoral pulses at least once during infancy to detect the presence of circulatory impairment, such as coarctation of the aorta. (See Appendix C for normal rates for pediatric age-groups.)

Respiration

Count the respiratory rate in children in the same manner as for the adult patient. However, in infants, observe abdominal movements since respirations are primarily diaphragmatic. Because the movements are irregular, count them for 1 full minute for accuracy (see also pp. 814-815). (See Appendix C for normal respiratory rates in children.)

TABLE 29-3 TEMPERATURE MEASUREMENT LOCATIONS FOR INFANTS AND CHILDREN

TEMPERATURE SITE

Oral

Place tip under tongue in right or left posterior sublingual pocket, not in front of tongue. Have child keep mouth closed, without biting on thermometer.

Pacifier thermometers measure intraoral or supralingual temperature and are available but lack support in the literature.

Several factors affect mouth temperature: eating and mastication, hot or cold beverages, open-mouth breathing, ambient temperature.

Axillary

Place tip under arm in center of axilla and keep close to skin, not clothing. Hold child's arm firmly against side. Temperature may be affected by poor peripheral perfusion (results in lower value), clothing or swaddling, use of radiant warmer, or amount of brown fat in cold-stressed neonate (results in higher value).

Advantage—Avoids intrusive procedure and eliminates risk for rectal perforation.

Ear-Based (Aural)

Insert small infrared probe deeply into canal to allow sensor to obtain measurement. Size of probe (most are 8 mm) may influence accuracy of result. In young children this may be a problem because of small diameter of canal. Proper placement of ear is controversial related to whether the pinna should be pulled in manner similar to that used during otoscopy (see pp. 809-810).

Rectal

Place well-lubricated tip at maximum 2.5 cm (1 in) into rectum for children and 1.5 cm (0.6 in) for infants; securely hold thermometer close to anus.

Child may be placed in side-lying, supine, or prone position (i.e., supine with knees flexed toward abdomen); cover penis, since procedure may stimulate urination. A small child may be placed prone across parent's lap.

Continued

TABLE 29-3 TEMPERATURE MEASUREMENT LOCATIONS FOR INFANTS AND CHILDREN—cont'd

TEMPERATURE SITE

Temporal Artery

An infrared sensor probe scans across forehead, capturing heat from arterial blood flow. Temporal artery is only artery close enough to skin's surface to provide access for accurate temperature measurement.

Data from Falzon A, Grech V, Caruana B, et al: How reliable is axillary temperature measurement? *Acta Paediatr* 92(3):309–313, 2003; Martin SA, Kline AM: Can there be a standard for temperature measurement in the pediatric intensive care unit? *AACN Clin Issues* 15(2):254–266, 2004. EVIDENCE-BASED PRACTICE

Temperature Measurement in Pediatrics

Ask the Question

In infants and children, what is the most accurate method for measuring temperature in febrile children?

Search for the Evidence

Search Strategies

Clinical research studies related to this issue were identified by searching for English publications for infant and child populations; comparisons with gold standard: rectal thermometry.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Joanna Briggs Institute, National Guideline Clearinghouse (AHRQ), TRIP Database Plus, PedsCCM, BestBETs

Critically Analyze the Evidence

- **Rectal temperature**—Rectal measurement remains the clinical gold standard for the precise diagnosis of fever in infants and children compared with other methods (Fortuna, Carney, Macy, et al., 2010; Greenes and Fleisher, 2004; Holzhauer, Reith, Sawin, et al., 2009; Riddell and Eppich, 2003; University of Michigan, 2003). However, this procedure is more invasive and is contraindicated for infants younger than 1 month, children with recent rectal surgery, children with diarrhea or anorectal lesions, and children receiving chemotherapy (cancer treatment usually affects mucosa and causes neutropenia).
- **Oral temperature (OT)**—OT indicates rapid changes in core body temperature, but accuracy may be an issue when compared with the rectal site (Jensen, Jensen, Madsen, et al., 2000). OTs are considered the standard for temperature measurement (Gilbert, Barton, and Counsell, 2002) but are contraindicated in children who have an altered level of consciousness, are receiving oxygen, are mouth breathing, are experiencing mucositis, had recent oral surgery or trauma, or are younger than 5 years (Carroll, 2000; El-Radhi and Barry, 2006). Limitations of OTs include the effects of ambient room temperature and recent oral intake (Carroll, 2000; Martin and Kline, 2004).
- **Axillary temperature**—This is inconsistent and insensitive in infants and children older than 1 month (Falzon, Grech, Caruana, et al., 2003; Jean-Mary, Dicanzio, Shaw, et al., 2002). In neonates with fever, the axillary temperature cannot be used interchangeably with rectal measurement (Hissink Muller, van Berkel, and de Beaufort, 2008).
- **Ear (aural) temperature**—This is not a precise measurement of body temperature. Meta-analysis of 101 studies comparing tympanic membrane temperatures with rectal temperatures in children concluded that the tympanic method demonstrated a wide range of variability, limiting its application in a pediatric setting (Craig, Lancaster, Taylor, et al., 2002). More recently published reviews continue to find poor sensitivity using infrared ear thermometry (Devrim, Kara, Ceyhan, et al., 2007; Dodd, Lancaster, Craig, et al., 2006). Diagnosis of fever without a focus should not be made based on tympanic thermometry, since it is not an accurate measure of core temperature (Craig, Lancaster, Taylor, et al., 2002; Devrim, Kara, Ceyhan, et al., 2007; Dodd, Lancaster, Craig, et al., 2006; Riddell and Eppich, 2003).
- **Temporal artery temperature (TAT)**—TAT is not predictable for fever in young children but can be used as a screening tool for detecting fever less than 38° C (100.4° F) in children 3 months to 4 years of age (Al-Mukhaizeem, Allen, Komar, et al., 2004; Callanan, 2003; Fortuna, Carney, Macy, et al., 2010; Greenes and Fleisher, 2001; Hebbar, Fortenberry, Rogers, et al., 2005; Holzhauer, Reith, Sawin, et al., 2009; Schuh, Komar, Stephens, et al., 2004; Siberry, Diener-West, Schappell, et al., 2002; Titus, Hulsey, Heckman, et al., 2009).

Apply the Evidence: Nursing Implications

- No single site used for temperature assessment provides unequivocal estimates of core body temperature.
- Studies show that the axillary and tympanic measures demonstrate poor agreement when these modes are compared with more accurate core temperature methods. The differences are more evident as temperature increases, regardless of age.
- TAT is not predictable for fever and should be used only as a screening tool in young children.
- When an accurate method for obtaining a correct reflection of core temperature is needed, the rectal temperature is recommended in younger children and the oral route in older children.

EVIDENCE-BASED PRACTICE

Temperature Measurement in Pediatrics—cont'd

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate Clinical Opinion from Research and Evidence-Based Summaries.

Demonstrate understanding of thermometry selection based on the developmental age of the child.

Skills

Base Individualized Care Plan on Patient Values, Clinical Expertise, and Evidence.

Integrate evidence into practice by using the correct type of thermometry to screen for fever compared with measures used for accurate determination of the degree of fever.

Attitudes

Value the Concept of Evidence-Based Practice (EBP) as Integral to Determining Best Clinical Practice.

Recognize strengths and weakness of evidence for the most accurate method for measuring fever in infants and children.

Blood Pressure

Blood pressure (BP) measurement by noninvasive methods is part of a routine vital sign determination. Measure BP annually in children 3 years of age through adolescence and in children with symptoms of hypertension, children in emergency departments and intensive care units, and high risk infants (National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004).

Measurement Devices. Ambulatory BP monitoring in children and adolescents is a valuable method for assessing and managing suspected hypertension. Also measure BP using electronic devices that employ oscillometric or Doppler techniques. In oscillometry, pressure changes are transmitted through the arterial wall to the pressure cuff and the oscillations are detected by a pressure-sensitive indicator. Oscillometers have digital read-outs for systolic, diastolic, and mean arterial pressures (MAPs) and for pulse. The MAP is not the same as the mean BP (arithmetic average of systolic and diastolic pressures). Rather, it is a value somewhat lower than the arithmetic mean. BP readings using oscillometry, such as Dinamap, are generally higher (10 mm Hg higher) than measurements using auscultation (Park, Menard, and Schoolfield, 2005) (Table 29-5). Differences between Dinamap and auscultatory readings prevent the interchange of the readings by the two methods (Midgley, Wardhaugh, Macfarlane, et al., 2009).

Doppler ultrasound translates changes in ultrasound frequency caused by blood movement within the artery to audible sound by

BOX 29-12 TYPES OF THERMOMETERS USED TO MEASURE TEMPERATURE IN INFANTS AND CHILDREN

Electronic Thermometer
- Temperature is sensed with an electronic component called *thermistor* mounted at the tip of a plastic and stainless steel probe, which is connected to an electronic recorder. A disposable plastic cover is used for infection control.
- Temperature measurement appears on digital display within 60 seconds.
- Probe can be placed in mouth, axilla, or rectum.

Infrared Thermometer
- Thermal radiation is measured from axilla, ear canal, or tympanic membrane.
- Temperature measurement appears on digital display in approximately 1 second.
- Three types are available for ear-based use: tympanic, ear canal, and arterial heat balance via the ear canal (AHBE).
- Often these devices are all inappropriately referred to as *tympanic thermometers.*
- Temperatures measured in this way reflect arterial (bloodstream) temperature.

Ear-Based Temperature Sensor
- Although this is frequently used in pediatric settings (especially ambulatory clinics), debate continues on the reliability of ear-based thermometry in screening febrile children.
- Most models use "offsets" for internal calculations that transform ear temperature into supposedly equivalent oral or rectal temperatures.

Ear Sensor (LighTouch LTX)
- This measures the infrared heat energy radiating from canal opening, scans canal for highest temperature reading, and then calculates arterial temperature (correlates highly with core or internal body temperature).
- It is available in two sizes; smaller size of LighTouch Pedi-Q is for infants and toddlers.

Axillary Sensor (LighTouch LTN)
- This measures the infrared heat energy radiating from the axilla.
- It can be used on wet skin; in incubators; or under radiant heaters, warming pads, or other heat sources.

Digital Thermometer
- A probe is connected to a microprocessor chip, which translates signals into degrees and sends temperature measurement to digital display.
- It is used like an oral electronic thermometer and can be used for measuring oral, rectal, and axillary temperature.
- It is more accurate and easier to read but somewhat more expensive than plastic strip thermometer.

Liquid Crystal Skin Contact Thermometer (Chemical Dot Thermometer)
- This single-use, disposable, flexible thermometer has a specific chemical mixture in each circle that changes color to measure temperature increments of $^{7}/_{10}$ of a degree.
- There are two types:
  1. Kept in mouth (1 minute), axilla (3 minutes), or rectum (3 minutes); color change is read 10 to 15 seconds after removing thermometer.
  2. Wearable, continuous-use thermometer, which is placed under axilla; may be read within 2 to 3 minutes after placement and continuously thereafter; discard and replace every 48 hours.

TABLE 29-4 GRADING OF PULSES

GRADE	DESCRIPTION
0	Not palpable
+1	Difficult to palpate, thready, weak, easily obliterated with pressure
+2	Difficult to palpate, may be obliterated with pressure
+3	Easy to palpate, not easily obliterated with pressure (normal)
+4	Strong, bounding, not obliterated with pressure

TABLE 29-5 NORMATIVE DINAMAP BLOOD PRESSURE VALUES (SYSTOLIC/DIASTOLIC; MEAN ARTERIAL PRESSURE IN PARENTHESES)

AGE-GROUP	MEAN	90TH PERCENTILE	95TH PERCENTILE
Newborn (1-3 days)	65/41 (50)	75/49 (59)	78/52 (62)
1 month-2 years	95/58 (72)	106/68 (83)	110/71 (86)
2-5 years	101/57 (74)	112/66 (82)	115/68 (85)

From Park M, Menard S: Normative oscillometric blood pressure values in the first 5 years in an office setting, *Am J Dis Child* 143(7):860–864, 1989.

means of a transducer in the cuff. This technique is useful for systolic pressure measurement but is unreliable for diastolic pressure measurement. Oscillometric and Doppler instruments are useful in measuring BP in infants and have largely replaced the flush method, which reflects only the mean BP, and the auscultatory method.

Selection of Cuff. No matter what type of noninvasive technique is used, the most important factor in accurately measuring BP is the use of an appropriate-size cuff (cuff size refers only to the inner inflatable bladder, not the cloth covering). A technique to establish an appropriate cuff size is to choose a cuff with a bladder width that is approximately 40% of the arm circumference midway between the olecranon and the acromion. This will usually be a cuff bladder that covers 80% to 100% of the circumference of the arm (Fig. 29-12) (Beevers, Lip, and O'Brien, 2001). Cuffs that are either too narrow or too wide affect the accuracy of BP measurements. If the cuff size is too small, the reading on the device is falsely high. If the cuff size is too large, the reading is falsely low (Clark, Kieh-Lai, Sarnaik, et al., 2002).

Using limb circumference for selecting cuff width more accurately reflects direct arterial BP than using limb length, since this method takes into account variations in arm thickness and the amount of pressure required to compress the artery. For measurement on sites other than the upper arms, use the limb circumference, although the shape of the limb (e.g., conical shape of the thigh)

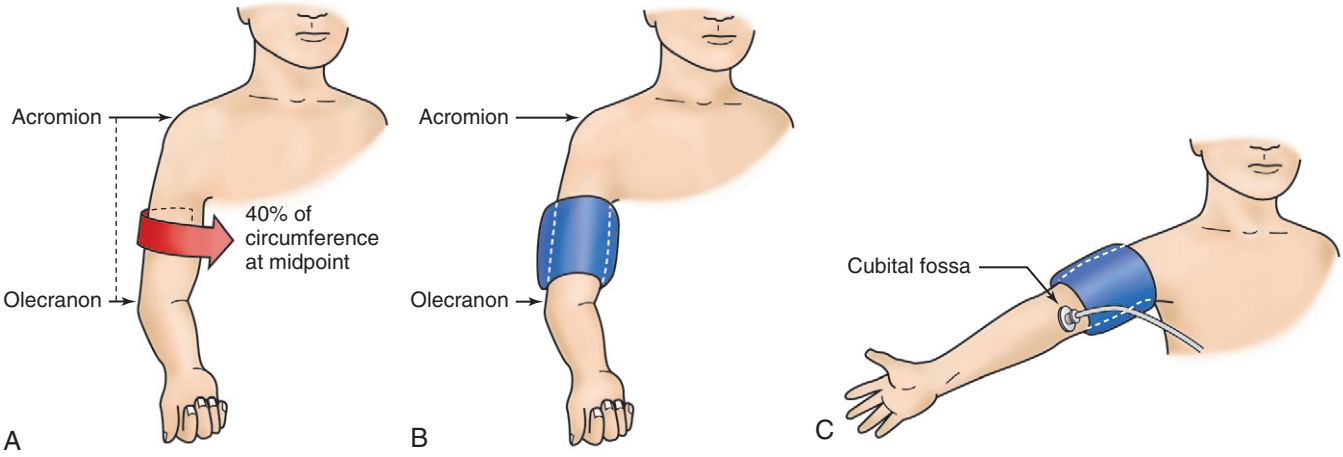

FIG 29-12 Determination of proper cuff size. **A,** Cuff bladder width should be approximately 40% of circumference of arm measured at a point midway between olecranon and acromion. **B,** Cuff bladder length should cover 80% to 100% of circumference of arm. **C,** Blood pressure should be measured with cubital fossa at heart level. Arm should be supported. Stethoscope bell is placed over brachial artery pulse, proximal and medial to cubital fossa and below bottom edge of cuff. (From National Institutes of Health, National Heart, Lung, and Blood Institute: *Update on the Task Force Report [1987] on high blood pressure in children and adolescents: a working group report from the National High Blood Pressure Education Program,* NIH Pub No 96-3790, Bethesda, MD, September 1996, Authors.)

TABLE 29-6 RECOMMENDED DIMENSIONS FOR BLOOD PRESSURE CUFF BLADDERS

AGE	WIDTH (CM)	LENGTH (CM)	MAXIMUM ARM CIRCUMFERENCE (CM)*
Newborn	4	8	10
Infant	6	12	15
Child	9	18	22
Small adult	10	24	26
Adult	13	30	34
Large adult	16	38	44
Thigh	20	42	52

! NURSING ALERT

When taking BP, use an appropriate-size cuff. When the correct size is not available, use an oversize cuff rather than an undersize one or use another site that more appropriately fits the cuff size. Do not choose a cuff based on the name of the cuff (e.g., an "infant" cuff may be too small for some infants).

! NURSING ALERT

Compare BP in the upper and lower extremities to detect abnormalities, such as coarctation of the aorta, in which the lower extremity pressure is less than the upper extremity pressure.

may prevent appropriate placement of the cuff and inaccurately reflect intraarterial BP (Table 29-6).

When using a site other than the arm, BP measurements using noninvasive techniques may differ. Generally, systolic pressure in the lower extremities (thigh or calf) is greater than pressure in the upper extremities and systolic BP in the calf is higher than that in the thigh (Fig. 29-13). Table 29-7 lists these differences that are applied to oscillometric measurements taken on the right extremities with the child supine and the cuff size based on the circumference method.

Measurement and Interpretation. Measuring and interpreting BP in infants and children require attention to correct procedure because (1) limb sizes vary and cuff selection must accommodate the circumference; (2) excessive pressure on the antecubital fossa

TABLE 29-7 DIFFERENCES IN OSCILLOMETRIC SYSTOLIC BLOOD PRESSURE BETWEEN ARM AND LOWER EXTREMITY SITES IN NORMAL CHILDREN

	SYSTOLIC BLOOD PRESSURE × (MEAN ± SD)	
AGE-GROUP (YR)	ARM-THIGH	ARM-CALF
4-8	–7.1 ± 6.8	–9.3 ± 7.4
9-16	–2.4 ± 7.7	–5.0 ± 26.9

affects the Korotkoff sounds; (3) children easily become anxious, which can elevate BP; and (4) BP values change with age and growth. In children and adolescents, determine the normal range of BP by body size and age. BP standards that are based on sex, age, and height provide a more precise classification of BP according to body size. This approach avoids misclassifying children who are very tall or very short. The revised BP tables now include the 50th, 90th, and 95th percentiles (with standard deviations) by sex, age, and height (see Appendix C).

To use the tables in a clinical setting, determine the height percentile by using the newly revised Centers for Disease Control and Prevention (CDC) growth charts (www.cdc.gov/growthcharts). The child's measured systolic BP and diastolic BP are compared with the numbers provided in the table (boys or girls) according to the child's age and height percentile. The child is normotensive if the BP is below the 90th percentile. If the BP is at or above the 90th percentile, repeat the BP measurement at that visit to verify an elevated BP. BP measurements between the 90th and 95th percentiles indicate prehypertension and necessitate reassessment and consideration of other risk factors. In addition, if an adolescent's BP is more than 120/80 mm Hg, consider the patient prehypertensive even if this value is below the 90th percentile. This BP level typically occurs for systolic BP at 12 years old and for diastolic BP at 16 years old. If the child's BP (systolic or diastolic) is at or above the 95th percentile, the child may be hypertensive and the measurement must be repeated on at least two occasions to confirm diagnosis (National High Blood Pressure Education Program, 2004) (see Guidelines box).

Orthostatic Hypotension. Orthostatic hypotension (OH), also called *postural hypotension* or *orthostatic intolerance,* often manifests as syncope (fainting), vertigo (dizziness), or lightheadedness and is caused by decreased blood flow to the brain (cerebral hypoperfusion). Normally blood flow to the brain is maintained at a constant level by a number of compensating mechanisms that regulate systemic BP. When one assumes a sitting or standing position from a supine or recumbent position, peripheral capillary vasoconstriction occurs and blood that was pooling in the lower vasculature is returned to the heart for redistribution to the head and remainder of the body. When this mechanism fails or is slow to respond, the person may experience vertigo or syncope. One of the most common causes of OH is hypovolemia, which may be induced by medications such as diuretics, vasodilator medications, and prolonged immobility or bed rest. Other causes of OH include dehydration, diarrhea, emesis, fluid loss from sweating and exertion, alcohol intake, dysrhythmias, diabetes mellitus, sepsis, and hemorrhage.

BP measurements taken with the child supine and then standing (at least 2 minutes in each position) may demonstrate variability and assist in the diagnosis of OH. The child with a sustained drop in systolic pressure of more than 20 mm Hg or in diastolic pressure of more than 10 mm Hg after standing for 2 minutes without an increase in heart rate of more than 15 beats/min most likely has an autonomic deficit. Nonneurogenic causes of OH have a compensatory increase in pulse of more than 15 beats/min as well as a drop in BP, as noted previously. For the child or adolescent with vertigo, lightheadedness, nausea, syncope, diaphoresis, and pallor, it is important to monitor BP and heart rate to determine the original cause. BP is an important diagnostic measurement in children and adolescents and must be a part of the routine monitoring of vital signs.

GUIDELINES

Using the Blood Pressure Tables

1. Use the standard height charts to determine the height percentile.
2. Measure and record the child's systolic blood pressure (SBP) and diastolic blood pressure (DBP).
3. Use the correct gender table for SBP and DBP.
4. Find the child's age on the left side of the table. Follow the age row horizontally across the table to the intersection of the line for the height percentile (vertical column).
5. There, find the 50th, 90th, 95th, and 99th percentiles for SBP in the left columns and for DBP in the right columns.
   - BP less than 90th percentile is normal.
   - BP between the 90th and 95th percentiles is prehypertension. In adolescents, BP of 120/80 mm Hg or greater is prehypertension, even if this figure is less than the 90th percentile.
   - BP over the 95th percentile may be hypertension.
6. If the BP is over the 90th percentile, the BP should be repeated twice at the same office visit, and an average SBP and DBP should be used.
7. If the BP is over the 95th percentile, BP should be staged. If BP is stage 1 (95th to 99th percentile plus 5 mm Hg), BP measurements should be repeated on two more occasions. If hypertension is confirmed, evaluation should proceed. If BP is stage 2 (>99th percentile plus 5 mm Hg), prompt referral should be made for evaluation and therapy. If the patient is symptomatic, immediate referral and treatment are indicated.

From National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents: The fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents, http://www.nhlbi.nih.gov/health/prof/heart/hbp/hbp_ped.pdf, US Department of Health and Human Services.

NURSING ALERT

Published norms for BP, such as those in Appendix C, are valid only if you use the same method of measurement (auscultation and cuff size determination) in clinical practice.

General Appearance

The child's general appearance is a cumulative, subjective impression of the child's physical appearance, state of nutrition, behavior, personality, interactions with parents and nurse (also siblings if present), posture, development, and speech. Although the nurse records general appearance at the beginning of the physical

TABLE 29-8 DIFFERENCES IN COLOR CHANGES OF RACIAL GROUPS

DESCRIPTION	APPEARANCE IN LIGHT SKIN	APPEARANCE IN DARK SKIN
Cyanosis—Bluish tone through skin; reflects reduced (deoxygenated) hemoglobin	Bluish tinge, especially in palpebral conjunctiva (lower eyelid), nail beds, earlobes, lips, oral membranes, soles, and palms	Ashen gray lips and tongue
Pallor—Paleness; may be sign of anemia, chronic disease, edema, or shock	Loss of rosy glow in skin, especially face	Ashen gray appearance in black skin More yellowish brown color in brown skin
Erythema—Redness; may be result of increased blood flow from climatic conditions, local inflammation, infection, skin irritation, allergy, or other dermatoses or may be caused by increased numbers of red blood cells as compensatory response to chronic hypoxia	Redness easily seen anywhere on body	Much more difficult to assess; rely on palpation for warmth or edema
Ecchymosis—Large, diffuse areas, usually black and blue, caused by hemorrhage of blood into skin; typically result of injuries	Purplish to yellow-green areas; may be seen anywhere on skin	Very difficult to see unless in mouth or conjunctiva
Petechiae—Same as ecchymosis except for size: small, distinct, pinpoint hemorrhages ≤2 mm in size; can denote some type of blood disorder, such as leukemia	Purplish pinpoints most easily seen on buttocks, abdomen, and inner surfaces of arms or legs	Usually invisible except in oral mucosa, conjunctiva of eyelids, and conjunctiva covering eyeball
Jaundice—Yellow staining of skin usually caused by bile pigments	Yellow staining seen in sclerae of eyes, skin, fingernails, soles, palms, and oral mucosa	Most reliably assessed in sclerae, hard palate, palms, and soles

examination, it encompasses all the observations of the child during the interview and physical assessment.

Note the facies, the child's facial expression and appearance. For example, the facies may give clues to children who are in pain; have difficulty breathing; feel frightened, discontented, or unhappy; are mentally delayed; or are acutely ill.

Observe the posture, position, and types of body movement. The child with hearing or vision loss may characteristically tilt the head in an awkward position to hear or see better. The child in pain may favor a body part. The child with low self-esteem or a feeling of rejection may assume a slumped, careless, and apathetic pose. Likewise, a child with confidence, a feeling of self-worth, and a sense of security usually demonstrates a tall, straight, well-balanced posture. While observing such body language, do not interpret too freely but, rather, record objectively.

Note the child's hygiene in terms of cleanliness; unusual body odor; the condition of the hair, neck, nails, teeth, and feet; and the condition of the clothing. Such observations are excellent clues to possible instances of neglect, inadequate financial resources, housing difficulties (e.g., no running water), or lack of knowledge concerning children's needs.

Behavior includes the child's personality, activity level, reaction to stress, requests, frustration, interactions with others (primarily the parent and nurse), degree of alertness, and response to stimuli. Some mental questions that serve as reminders for observing behavior include:

- What is the child's overall personality?
- Does the child have a long attention span, or is he or she easily distracted?
- Can the child follow two or three commands in succession without the need for repetition?
- What is the youngster's response to delayed gratification or frustration?
- Does the child use eye contact during conversation?
- What is the child's reaction to the nurse and family members?
- Is the child quick or slow to grasp explanations?

Skin

Assess skin for color, texture, temperature, moisture, turgor, lesions, and rashes. Examination of the skin and its accessory organs primarily involves inspection and palpation. Touch allows the nurse to assess the texture, turgor, and temperature of the skin. The normal color in light-skinned children varies from a milky white and rose to a deeply hued pink. Dark-skinned children, such as those of Native-American, Hispanic, or African descent, have inherited various brown, red, yellow, olive green, and bluish tones in their skin. Asian persons have skin that is normally of a yellow tone. Several variations in skin color can occur, some of which warrant further investigation. The types of color change and their appearance in children with light or dark skin are summarized in Table 29-8.

Normally the skin texture of young children is smooth, slightly dry, and not oily or clammy. Evaluate skin temperature by symmetrically feeling each part of the body and comparing upper areas with lower ones. Note any difference in temperature.

Determine tissue turgor, or elasticity in the skin, by grasping the skin on the abdomen between the thumb and index finger, pulling it taut, and quickly releasing it. Elastic tissue immediately resumes its normal position without residual marks or creases. In children with poor skin turgor, the skin remains suspended or tented for a few seconds before slowly falling back on the abdomen. Skin turgor is one of the best estimates of adequate hydration and nutrition.

Accessory Structures

Inspection of the accessory structures of the skin may be performed while examining the skin, scalp, or extremities.

Inspect the hair for color, texture, quality, distribution, and elasticity. Children's scalp hair is usually lustrous, silky, strong, and elastic. Genetic factors affect the appearance of hair. For example, the hair of African-American children is usually curlier and coarser than that of Caucasian children. Hair that is stringy, dull, brittle, dry, friable, and depigmented may suggest poor nutrition. Record any bald or thinning spots. Loss of hair in infants may indicate lying in

the same position and may be a cue to counsel parents concerning the child's stimulation needs.

Inspect the hair and scalp for general cleanliness. Persons in some ethnic groups condition their hair with oils or lubricants that, if not thoroughly washed from the scalp, clog the sebaceous glands, causing scalp infections. Also examine the area for lesions; scaliness; evidence of infestation, such as lice or ticks; and signs of trauma, such as ecchymosis, masses, or scars.

In children who are approaching puberty, look for growth of secondary hair as a sign of normally progressing pubertal changes. Note precocious or delayed appearance of hair growth because, although not always suggestive of hormonal dysfunction, it may be of great concern to the early- or late-maturing adolescent.

Inspect the nails for color, shape, texture, and quality. Normally the nails are pink, convex, smooth, and hard but flexible (not brittle). The edges, which are usually white, should extend over the fingers. Dark-skinned individuals may have more deeply pigmented nail beds. Short, ragged nails are typical of habitual biting. Uncut, dirty nails are a sign of poor hygiene.

The palm normally shows three flexion creases (Fig. 29-14, *A*). In some situations such as Down syndrome, the two distal horizontal creases are fused to form a single horizontal crease (the single palmar crease, or transpalmar crease) (Fig. 29-14, *B*). If grossly abnormal lines or folds are observed, sketch a picture to describe them and refer the finding to a specialist for further investigation.

Lymph Nodes

Lymph nodes are usually assessed during examination of the part of the body in which they are located. The body's lymphatic drainage system is extensive. Fig. 29-15 shows the usual sites for palpating accessible lymph nodes.

Palpate nodes using the distal portion of the fingers and gently but firmly pressing in a circular motion along the regions where nodes are normally present. During assessment of the nodes in the head and neck, tilt the child's head upward slightly but without tensing the sternocleidomastoid or trapezius muscles. This position facilitates palpation of the submental, submandibular, tonsillar, and cervical nodes. Palpate the axillary nodes with the child's arms relaxed at the sides but slightly abducted. Assess the inguinal nodes with the child in the supine position. Note size, mobility, temperature, and tenderness, as well as reports by the parents regarding any visible change of enlarged nodes. In children, small, nontender, movable nodes are usually normal. Tender, enlarged,

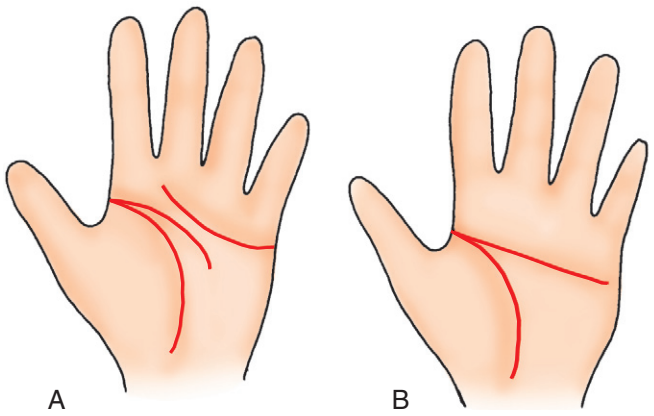

FIG 29-14 Examples of flexion creases on palm. **A,** Normal. **B,** Transpalmar crease.

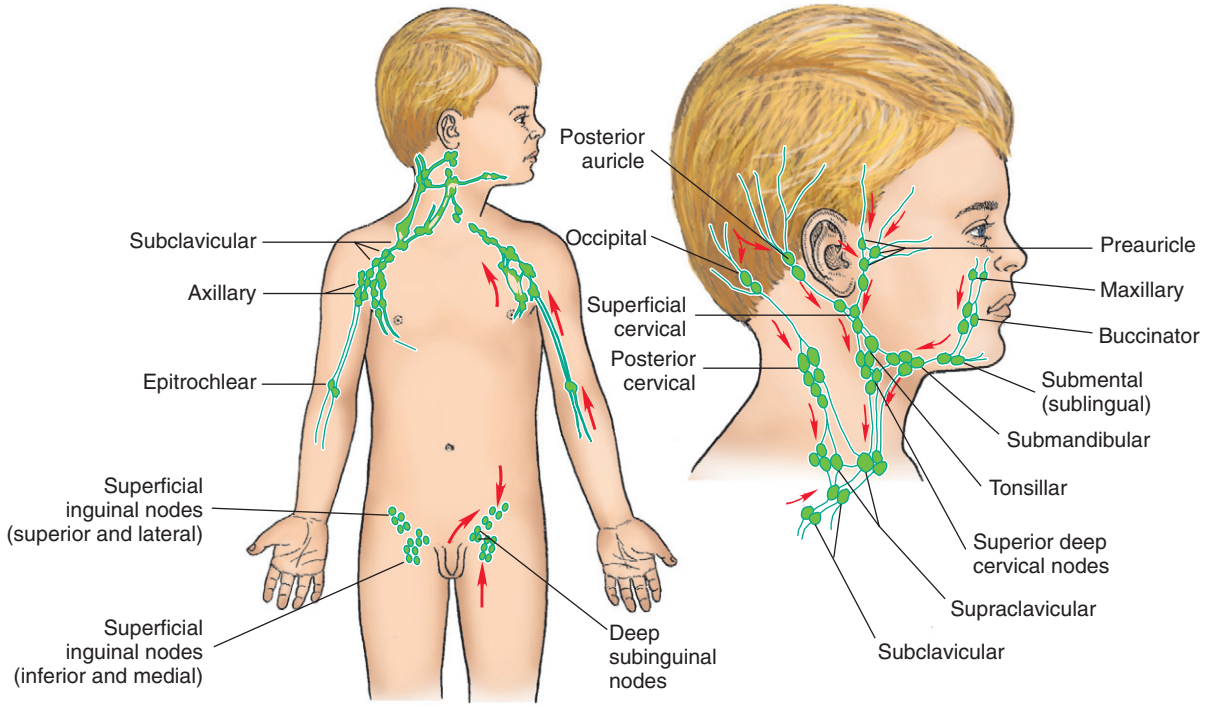

FIG 29-15 Location of superficial lymph nodes. *Arrows* indicate directional flow of lymph.

warm, erythematous lymph nodes generally indicate infection or inflammation close to their location. Report such findings for further investigation.

Head and Neck

Observe the head for general shape and symmetry. A flattening of one part of the head, such as the occiput, may indicate that the child continually lies in this position. Marked asymmetry is usually abnormal and may indicate premature closure of the sutures (craniosynostosis).

! NURSING ALERT

Significant head lag after 6 months of age strongly indicates cerebral injury and is referred for further evaluation.

Note head control in infants and head posture in older children. Most infants by 4 months of age should be able to hold the head erect and in midline when in a vertical position.

Evaluate range of motion by asking the older child to look in each direction (to either side, up, and down) or by manually putting the younger child through each position. Limited range of motion may indicate wryneck, or torticollis, in which the child holds the head to one side with the chin pointing toward the opposite side as a result of injury to the sternocleidomastoid muscle.

! NURSING ALERT

Hyperextension of the head (opisthotonos) with pain on flexion is a serious indication of meningeal irritation and is referred for immediate medical evaluation.

Palpate the skull for patent sutures, fontanels, fractures, and swellings. Normally, the posterior fontanel closes by the second month of life and the anterior fontanel fuses between 12 and 18 months. Early or late closure is noted, since either may be a sign of a pathologic condition. While examining the head, observe the face for symmetry, movement, and general appearance. Ask the child to "make a face" to assess symmetric movement and disclose any degree of paralysis. Note any unusual facial proportion, such as an unusually high or low forehead; wide- or close-set eyes; or a small, receding chin.

In addition to assessment of the head and neck for movement, inspect the neck for size and palpate its associated structures. The neck is normally short, with skinfolds between the head and shoulders during infancy; however, it lengthens during the next 3 to 4 years.

! NURSING ALERT

If any masses are detected in the neck, report them for further investigation. Large masses can block the airway.

Eyes

Inspection of External Structures

Inspect the lids for proper placement on the eye. When the eye is open, the upper lid should fall near the upper iris. When the eyes are closed, the lids should completely cover the cornea and sclera (Fig. 29-16).

Determine the general slant of the palpebral fissures or lids by drawing an imaginary line through the two points of the medial canthus and across the outer orbit of the eyes and aligning each eye on the line. Usually the palpebral fissures lie horizontally. However, in Asians the slant is normally upward.

Also inspect the inside lining of the lids, the palpebral conjunctivae. To examine the lower conjunctival sac, pull the lid down while the patient looks up. To evert the upper lid, hold the upper lashes and gently pull *down* and *forward* as the child looks down. Normally the conjunctiva appears pink and glossy. Vertical yellow striations along the edge are the meibomian glands, or sebaceous glands, near the hair follicle. Located in the inner or medial canthus and situated on the inner edge of the upper and lower lids is a tiny opening, the lacrimal punctum. Note any excessive tearing, discharge, or inflammation of the lacrimal apparatus.

The bulbar conjunctiva, which covers the eye up to the limbus, or junction of the cornea and sclera, should be transparent. The sclera, or white covering of the eyeball, should be clear. Tiny black marks in the sclera of heavily pigmented individuals are normal.

The cornea, or covering of the iris and pupil, should be clear and transparent. Record opacities because they can be signs of scarring or ulceration, which can interfere with vision. The best way to test for opacities is to illuminate the eyeball by shining a light at an angle (obliquely) toward the cornea.

Compare the pupils for size, shape, and movement. They should be round, clear, and equal. Test their reaction to light by quickly shining a light toward the eye and removing it. As the light approaches, the pupils should constrict; as the light fades, the pupils should dilate. Test the pupil for any response of accommodation by having the child look at a bright, shiny object at a distance and quickly moving the object toward the face. The pupils should constrict as the object is brought near the eye. Record normal findings on examination of the pupils as PERRLA, which stands for "**P**upils **E**qual, **R**ound, **R**eact to **L**ight, and **A**ccommodation."

Inspect the iris and pupil for color, size, shape, and clarity. Permanent eye color is usually established by 6 to 12 months of age. While inspecting the iris and pupil, look for the lens. Normally the lens is not visible through the pupil.

Inspection of Internal Structures

The ophthalmoscope permits visualization of the interior of the eyeball with a system of lenses and a high-intensity light. The lenses permit clear visualization of eye structures at different distances from the nurse's eye and correct visual acuity differences in the examiner and child. Use of the ophthalmoscope requires practice to know which lens setting produces the clearest image.

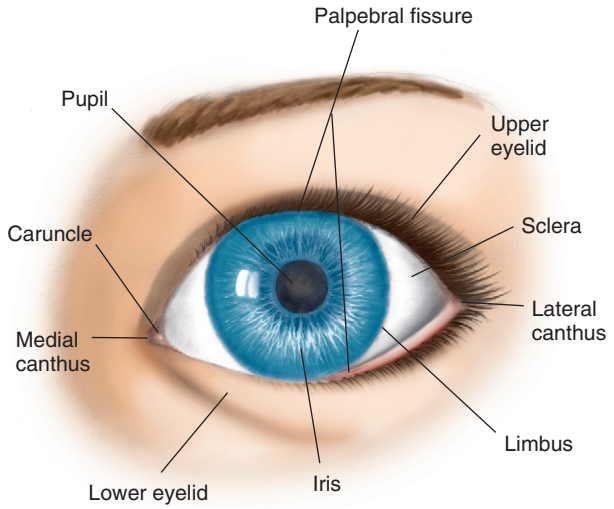

FIG 29-16 External structures of eye.

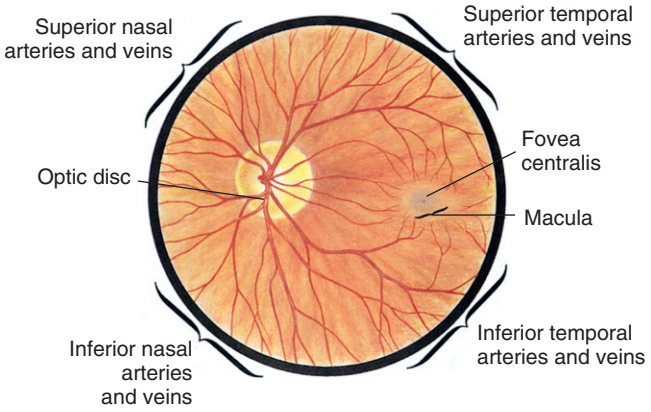

FIG 29-17 Structures of fundus. (From Seidel HM, Ball JW, Dains JE, et al: *Mosby's guide to physical examination,* ed 7, St Louis, 2011, Mosby.)

The ophthalmic and otic heads are usually interchangeable on one "body" or handle, which encloses the power source, either disposable or rechargeable batteries. The nurse should practice changing the heads, which snap on and are secured with a quarter turn, and replacing the batteries and light bulbs. Nurses who are not directly involved in physical assessment are often responsible for ensuring that the equipment functions properly.

Preparing the Child. The nurse can prepare the child for the ophthalmoscopic examination by showing the child the instrument, demonstrating the light source and how it shines in the eye, and explaining the reason for darkening the room. For infants and young children who do not respond to such explanations, it is best to use distraction to encourage them to keep their eyes open. Forcibly parting the lids results in an uncooperative, watery-eyed child and a frustrated nurse. Usually, with some practice, the nurse can elicit a red reflex almost instantly while approaching the child and may also gain a momentary inspection of the blood vessels, macula, or optic disc.

Funduscopic Examination. Fig. 29-17 shows the structures of the back of the eyeball, or the fundus. The fundus is immediately apparent as the red reflex. The intensity of the color increases in darkly pigmented individuals.

! NURSING ALERT

A brilliant, uniform red reflex is an important sign because it rules out many serious defects of the cornea, aqueous chamber, lens, and vitreous chamber. Any dark shadows or opacities are recorded because they indicate some abnormality in any of these structures.

As the ophthalmoscope is brought closer to the eye, the most conspicuous feature of the fundus is the optic disc, the area where the blood vessels and optic nerve fibers enter and exit the eye. The disc is creamy pink and lighter in color than the surrounding fundus. Normally it is round or vertically oval.

After locating the optic disc, inspect the area for blood vessels. The central retinal artery and vein appear in the depths of the disc and emanate outward with visible branching. The veins are darker and about one-fourth larger than the arteries. Normally the branches of the arteries and veins cross each other.

Other structures that are common are the macula, the area of the fundus with the greatest concentration of visual receptors, and, in the center of the macula, a minute glistening spot of reflected light called the fovea centralis; this is the area of most perfect vision.

Vision Testing

Several tests are available for assessing vision. This discussion focuses on four areas: (1) ocular alignment, (2) visual acuity, (3) peripheral vision, and (4) color vision. Vision screening should be performed by age 3 years and annually after that or more often if there are concerns (American Academy of Pediatrics, 2003a; Wall, Marsh-Tootle, Evans, et al., 2002). Chapter 37 discusses behavioral and physical signs of visual impairment.

Ocular Alignment. Normally, by the age of 3 to 4 months, children are able to fixate on one visual field with both eyes simultaneously (binocularity). One of the most important tests for binocularity is alignment of the eyes to detect nonbinocular vision, or **strabismus** (Halle, 2002). In strabismus, or cross-eye, one eye deviates from the point of fixation. If the misalignment is constant, the weak eye becomes "lazy," and the brain eventually suppresses the image produced by that eye. If strabismus is not detected and corrected by age 4 to 6 years, blindness from disuse, known as **amblyopia,** may result.

Tests commonly used to detect misalignment are the corneal light reflex and the cover tests. To perform the corneal light reflex test, or Hirschberg test, shine a flashlight or the light of the ophthalmoscope directly into the patient's eyes from a distance of about 40.5 cm (16 inches). If the eyes are orthophoric, or normal, the light falls symmetrically within each pupil (Fig. 29-18, *A*). If the light falls off center in one eye, the eyes are misaligned. Epicanthal folds, excess folds of skin that extend from the roof of the nose to the inner termination of the eyebrow and that partially or completely overlap the inner canthus of the eye, may give a false impression of misalignment (pseudostrabismus) (Fig. 29-18, *B*). Epicanthal folds are often found in Asian children.

In the cover test, one eye is covered and the movement of the *uncovered* eye is observed while the child looks at a near (33 cm [13 inches]) or distant (6 m [20 feet]) object. If the uncovered eye does not move, it is aligned. If the uncovered eye moves, a misalignment is present because, when the stronger eye is temporarily covered, the misaligned eye attempts to fixate on the object.

In the alternate cover test, occlusion shifts back and forth from one eye to the other and movement of the eye that was *covered* is observed as soon as the occluder is removed while the child focuses on a point in front of him or her (Fig. 29-19). If normal alignment is present, shifting the cover from one eye to the other will not cause the eye to move. If misalignment is present, eye movement will occur when the cover is moved. This test takes more practice than the other cover test because the occluder must be moved back and forth quickly and accurately to see the eye move. Because deviations can occur at different ranges, it is important to perform the cover tests at both close and far distances.

! NURSING ALERT

The cover test is usually easier to perform if the examiner uses his or her hand rather than a card-type occluder (see Fig. 29-19). Attractive occluders fashioned like an ice cream cone or happy-face lollipop cut from cardboard are also well received by young children.

Photoscreening is a technique used to screen for amblyopia, refractive disorders, and media opacities (American Academy of Pediatrics, 2003a). Using a camera, the nurse obtains images of the pupillary reflexes (reflections) and red reflexes (Bruckner test) (American Academy of Pediatrics, 2003a). Photoscreening offers an effective way to screen infants, preverbal children, and those with developmental delays who are difficult to screen.

Visual Acuity Testing in Children Beyond Infancy. The most common test for measuring **visual acuity** is the Snellen letter chart,

FIG 29-18 **A,** Corneal light reflex test demonstrating orthophoric eyes. **B,** Pseudostrabismus. Inner epicanthal folds cause eyes to appear misaligned; however, corneal light reflexes fall perfectly symmetrically.

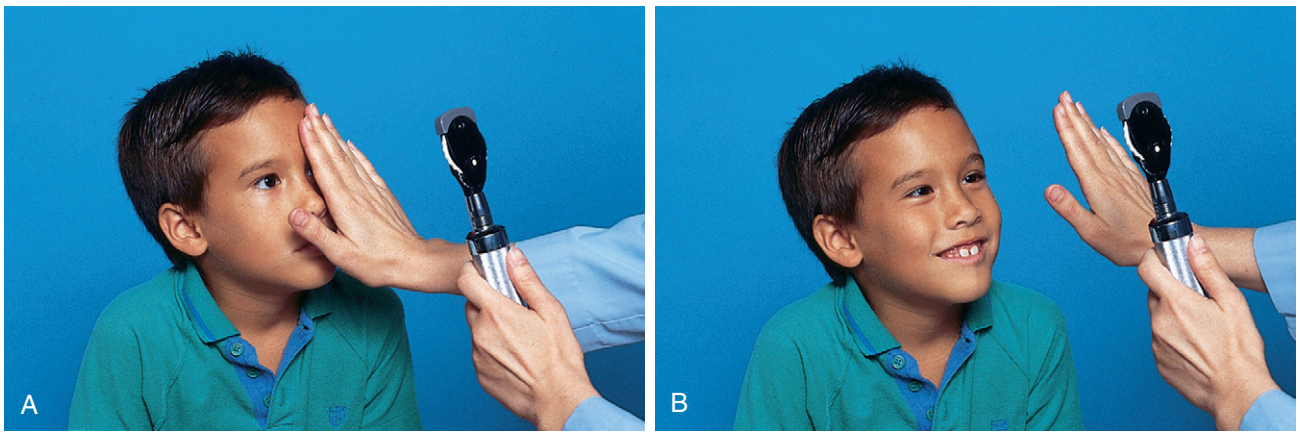

FIG 29-19 Alternate cover test to detect amblyopia in patient with strabismus. **A,** Eye is occluded, and child is fixating on light source. **B,** If eye does not move when uncovered, eyes are aligned.

which consists of lines of letters of decreasing size. The American Academy of Pediatrics (2003a) recommends that children stand 10 feet from the chart with their heels at the 10-foot line during testing. When screening for visual acuity in children, the nurse tests the child's right eye first by covering the left. Children who wear glasses should be screened with them on. Tell the child to keep both eyes open during the examination. If the child fails to read the current line, move up the chart to the next larger line. Continue up the chart until a line is found that the child can pass. Then begin moving down the chart again until the child fails to read the line. To pass each line, the child must correctly identify four of six symbols on the line. Repeat the procedure, covering the right eye. Table 29-9 provides a list of visual screening tests for children and guidelines for referral recommended by the American Academy of Pediatrics (2003a).

For children unable to read letters and numbers, the tumbling E or HOTV test is useful (Coats and Jenkins, 1997). The tumbling E test uses the capital letter E pointing in four different directions. The child is asked to point in the direction the E is facing. The HOTV test consists of a wall chart composed of the letters H, O, T, and V. The child is given a board containing a large H, O, T, and V. The examiner points to a letter on the wall chart, and the child matches the correct letter on the board held in his or her hand. The tumbling E and HOTV are excellent tests for preschool-age children.

Visual Acuity Testing in Infants and Difficult-to-Test Children. In newborns, vision is tested mainly by checking for light perception by shining a light into the eyes and noting responses such as pupillary constriction, blinking, following the light to midline, increased alertness, or refusal to open the eyes after exposure to the light. Although the simple maneuver of checking light perception and eliciting the pupillary light reflex indicates that the anterior half of the visual apparatus is intact, it does not confirm that the infant can see. In other words, this test does not assess whether the brain receives the visual message and interprets the signals.

Another test of visual acuity is the infant's ability to fix on and follow a target. Although any brightly colored or patterned object can be used, the human face is excellent. Hold the infant upright while moving your face slowly from side to side.

! NURSING ALERT

If visual fixation and following are not present by 3 to 4 months of age, further ophthalmologic evaluation is necessary.

Other signs that may indicate visual loss or other serious eye problems include fixed pupils, strabismus, constant nystagmus, the setting-sun sign, and slow lateral movements. Unfortunately, it is difficult to test each eye separately; the presence of such signs in one eye could indicate unilateral blindness.

TABLE 29-9 EYE EXAMINATION GUIDELINES*

FUNCTION	RECOMMENDED TESTS	REFERRAL CRITERIA	COMMENTS
Ages 3-5 Years			
Distance visual acuity	Snellen letters Snellen numbers Tumbling E HOTV Picture test: Allen figures LEA symbols	1. <4 of 6 correct on 20-foot (6-m) line with either eye tested at 10 foot (3 m) monocularly (i.e., <10/20 or 20/40) or 2. Two-line difference between eyes, even within passing range (i.e., 10/12.5 and 10/20 or 20/25 and 20/40)	1. Tests are listed in decreasing order of cognitive difficulty; highest test that child is capable of performing should be used; in general, tumbling E or HOTV test should be used for children 3-5 yr of age and Snellen letters or numbers for children 6 yr and older. 2. Testing distance of 10 feet (3 m) is recommended for all visual acuity tests. 3. Line of figures is preferred over single figures. 4. Nontested eye should be covered by occluder held by examiner or by adhesive occluder patch applied to eye; examiner must ensure that it is not possible to peek with nontested eye.
Ocular alignment	Cross cover test at 10 feet (3 m) Random dot E stereo test at 18 inches (40 cm) Simultaneous red reflex test (Bruckner test)	Any eye movement <4 of 6 correct Any asymmetry of pupil color, size, brightness	Child must be fixing on a target while cross cover test is performed. Use direct ophthalmoscope to view both red reflexes simultaneously in a darkened room from 2-3 feet (0.6 to 0.9 m) away; detects asymmetric refractive errors as well.
Ocular media clarity (cataracts, tumors, etc.)	Red reflex	White pupil, dark spots, absent reflex	Use direct ophthalmoscope in a darkened room. View eyes separately at 12-18 inches (30-45 cm); white reflex indicates possible retinoblastoma.
6 Years and Older			
Distance visual acuity	Snellen letters Snellen numbers Tumbling E HOTV Picture test: Allen figures LEA symbols	1. <4 of 6 correct on 15-foot (4.5-m) line with either eye tested at 10 feet (3 m) monocularly (i.e., <10/15 or 20/30) or 2. Two-line difference between eyes, even within the passing range (i.e., 10/10 and 10/15 or 20/20 and 20/30)	1. Tests are listed in decreasing order of cognitive difficulty; highest test that child is capable of performing should be used; in general, tumbling E or HOTV test should be used for children 3-5 yr of age and Snellen letters or numbers for children 6 yr and older. 2. Testing distance of 10 feet (3 m) is recommended for all visual acuity tests. 3. Line of figures is preferred over single figures. 4. Nontested eye should be covered by occluder held by examiner or by adhesive occluder patch applied to eye; examiner must ensure that it is not possible to peek with nontested eye.
Ocular alignment	Cross cover test at 10 feet (3 m) Random dot E stereo test at 18 inches (40 cm) Simultaneous red reflex test (Bruckner test)	Any eye movement <4 of 6 correct Any asymmetry of pupil color, size, brightness	Child must be fixing on target while cross cover test is performed. Use direct ophthalmoscope to view both red reflexes simultaneously in a darkened room from 2-3 feet (0.6 to 0.9 m) away; detects asymmetric refractive errors as well.
Ocular media clarity (cataracts, tumors, etc.)	Red reflex	White pupil, dark spots, absent reflex	Use direct ophthalmoscope in a darkened room. View eyes separately at 12-18 inches (30-45 cm); white reflex indicates possible retinoblastoma.

From American Academy of Pediatrics, Committee on Practice and Ambulatory Medicine, Section on Ophthalmology: Eye examination in infants, children, and young adults by pediatricians, *Pediatrics* 111(4):902–907, 2003.
*Assessing visual acuity (vision screening) is one of the most sensitive techniques for detection of eye abnormalities in children. The American Academy of Pediatrics Section on Ophthalmology, in cooperation with American Association for Pediatric Ophthalmology and Strabismus and American Academy of Ophthalmology, has developed these guidelines to be used by physicians, nurses, educational institutions, public health departments, and other professionals who perform vision evaluation services.

Special tests are available for testing infants and other difficult-to-test children to assess acuity or confirm blindness. For example, in visually evoked potentials, the eyes are stimulated with a bright light or pattern and electrical activity to the visual cortex is recorded through scalp electrodes. Acuity is assessed by using progressively smaller patterns.

Peripheral Vision. In children who are old enough to cooperate, estimate peripheral vision, or the visual field of each eye, by having the children fixate on a specific point directly in front of them while an object, such as a finger or a pencil, is moved from beyond the field of vision into the range of peripheral vision. As soon as children see the object, have them say "stop." At that point, measure the angle from the anteroposterior axis of the eye (straight line of vision) to the peripheral axis (point at which the object is first seen). Check each eye separately and for each quadrant of vision. Normally children see about 50 degrees upward, 70 degrees downward, 60 degrees

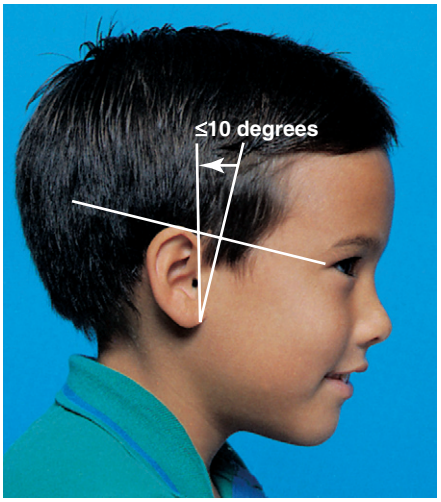

FIG 29-20 Ear alignment.

nasalward, and 90 degrees temporally. Limitations in peripheral vision may indicate blindness from damage to structures within the eye or to any of the visual pathways.

Color Vision. The tests available for color vision include the Ishihara test and the Hardy-Rand-Rittler test. Each consists of a series of cards (pseudoisochromatic) that contain a color field composed of spots of a certain "confusion" color. Against the field is a number or symbol similarly printed in dots but of a color likely to be confused with the field color by the person with a color vision deficit. As a result, the figure or letter is invisible to an affected individual but is clearly seen by a person with normal vision.

Ears

Inspection of External Structures

The entire external earlobe is called the pinna, or auricle; one is located on each side of the head. Measure the height alignment of the pinna by drawing an imaginary line from the outer orbit of the eye to the occiput, or most prominent protuberance of the skull. The top of the pinna should meet or cross this line. Low-set ears are commonly associated with renal anomalies or cognitive impairment. Measure the angle of the pinna by drawing a perpendicular line from the imaginary horizontal line and aligning the pinna next to this mark. Normally the pinna lies within a 10-degree angle of the vertical line (Fig. 29-20). If it falls outside this area, record the deviation and look for other anomalies.

Normally the pinna extends slightly outward from the skull. Except in newborn infants, ears that are flat against the head or protruding away from the scalp may indicate problems. Flattened ears in an infant may suggest a frequent side-lying position and, just as with isolated areas of hair loss, may be a clue to investigate parents' understanding of the child's stimulation needs.

Inspect the skin surface around the ear for small openings, extra tags of skin, or sinuses. If a sinus is found, note this because it may represent a fistula that drains into some area of the neck or ear. Cutaneous tags represent no pathologic process but may cause parents concern in terms of the child's appearance.

Also assess the ear for hygiene. An otoscope is not necessary for looking into the external canal to note the presence of cerumen, a waxy substance produced by the ceruminous glands in the outer portion of the canal. Cerumen is usually yellow-brown and soft. If an otoscope is used and any discharge is visible, note its color and odor. Avoid transmitting potentially infectious material to the other ear or to another child through handwashing and using disposable specula or sterilizing reusable specula between each examination.

ATRAUMATIC CARE

Reducing Distress from Otoscopy in Young Children

Make examining the ear a game by explaining that you are looking for a "big elephant" in the ear. This kind of make-believe is an absorbing distraction and usually elicits cooperation. After examining the ear, clarify that "looking for elephants" was only pretend and thank the child for letting you look in his or her ear. Another great distraction technique is asking the child to put a finger on the opposite ear to keep the light from getting out.

Inspection of Internal Structures

The head of the otoscope permits visualization of the tympanic membrane by use of a bright light, a magnifying glass, and a speculum. Some otoscopes have an attachment for a pneumonic device to insert air into the canal to determine membrane compliance (movement). The speculum, which is inserted into the external canal, comes in a variety of sizes to accommodate different canal widths. The largest speculum that fits comfortably into the ear is used to achieve the greatest area of visualization. The lens, or magnifying glass, is movable, allowing the examiner to insert an object, such as a curette, into the ear canal through the speculum while still viewing the structures through the lens.

Positioning the Child. Before beginning the otoscopic examination, position the child properly and gently restrain (have the child sit on parent's lap and hold parent's hands) if necessary. Older children usually cooperate and do not need restraint. However, prepare them for the procedure by allowing them to play with the instrument, demonstrating how it works, and stressing the importance of remaining still. A helpful suggestion is to let them observe you examining the parent's ear. Restraint is needed for younger children because the ear examination upsets them (see Atraumatic Care box).

As you insert the speculum into the meatus, move it around the outer rim to accustom the child to the feel of something entering the ear. If examining a painful ear, touch a nonpainful part of the affected ear, then examine the unaffected ear, and finally return to the painful ear. By this time the child is usually less fearful of anything causing discomfort to the ear and will cooperate more.

For their protection and safety, restrain infants and toddlers for the otoscopic examination. There are two general positions of restraint. In one, the child is seated sideways in the parent's lap with one arm hugging the parent and the other arm at the side. The ear to be examined is toward the nurse. With one arm the parent holds the child's head firmly against his or her chest and with the other arm hugs the child, thereby securing the child's free arm (Fig. 29-21, *A*). Examine the ear using the same procedure for holding the otoscope as described later.

The other position involves placing the child on the side, back, or abdomen with the arms at the side and the head turned so that the ear to be examined points toward the ceiling. Lean over the child, use the upper part of the body to restrain the arms and upper trunk movements, and use the examining hand to stabilize the head. This position is practical for young infants or for older children who need minimum restraint, but it may not be feasible for other children who protest vigorously. For safety, enlist the parent's or an assistant's help in immobilizing the head by firmly placing one hand above the ear and the other on the child's side, abdomen, or back (Fig. 29-21, *B*).

FIG 29-21 Position for restraining child **(A)** and infant **(B)** during otoscopic examination.

FIG 29-22 Positioning head by tilting it toward opposite shoulder for full view of tympanic membrane.

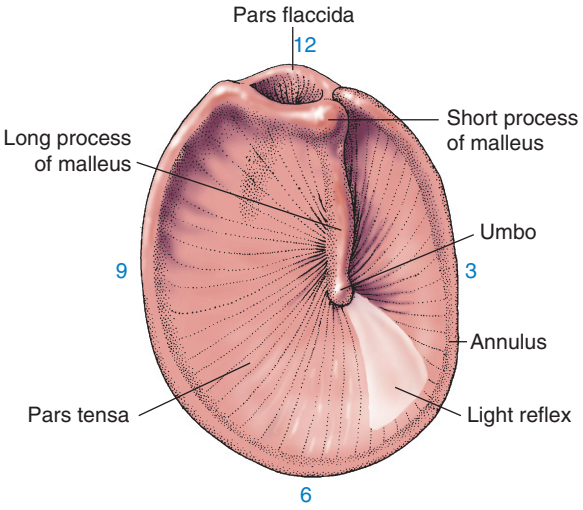

FIG 29-23 Landmarks of tympanic membrane. (From Rothrock JC: *Alexander's care of the patient in surgery,* ed 15, St Louis, 2015, Mosby.)

With cooperative children, examine the ear with the child in a side-lying, sitting, or standing position. One disadvantage to standing is that the child may "walk away" as the otoscope enters the canal. If the child is standing or sitting, tilt the head slightly toward the child's opposite shoulder to achieve a better view of the drum (Fig. 29-22).

With the thumb and forefinger of the free (usually nondominant) hand, grasp the auricle. For the two positions of restraint, hold the otoscope upside down at the junction of its head and handle with the thumb and index finger. Place the other fingers against the skull to allow the otoscope to move with the child in case of sudden movement. In examining a cooperative child, hold the handle with the otic head upright or upside down. Use the dominant hand to examine both ears or reverse hands for each ear, whichever is more comfortable.

Before using the otoscope, visualize the external ear and the tympanic membrane as being superimposed on a clock (Fig. 29-23). The numbers are important geographic landmarks. Introduce the speculum into the meatus between the 3 and 9 o'clock positions in a *downward* and *forward* position. Because the canal is curved, the speculum does not permit a panoramic view of the tympanic membrane unless the canal is straightened. In infants, the canal curves upward. Therefore pull the pinna *down* and *back* to the 6 to 9 o'clock range to straighten the canal (Fig. 29-24, *A*). With older children, usually those older than 3 years, the canal curves downward and forward. Therefore pull the pinna *up* and *back* toward a 10 o'clock position (Fig. 29-24, *B*). If you have difficulty visualizing the membrane, try repositioning the head, introducing the speculum at a different angle, and pulling the pinna in a slightly different direction. Do not insert the speculum past the cartilaginous (outermost) portion of the canal, usually a distance of 0.60 to 1.25 cm (0.23 to 0.5 inch) in older children. Insertion of the speculum into the posterior or bony portion of the canal causes pain.

In neonates and young infants, the walls of the canal are pliable and floppy because of the underdeveloped cartilaginous and bony structures. Therefore the very small 2-mm speculum usually needs to be inserted deeper into the canal than in older children. Exercise great care not to damage the walls or drum. For this reason, only an experienced examiner should insert an otoscope into the ears of very young infants.

Otoscopic Examination. As you introduce the speculum into the external canal, inspect the walls of the canal, the color of the tympanic membrane, the light reflex, and the usual landmarks of the bony prominences of the middle ear. The walls of the external auditory canal are pink, although they are more pigmented in dark-skinned children. Minute hairs are evident in the outermost portion,

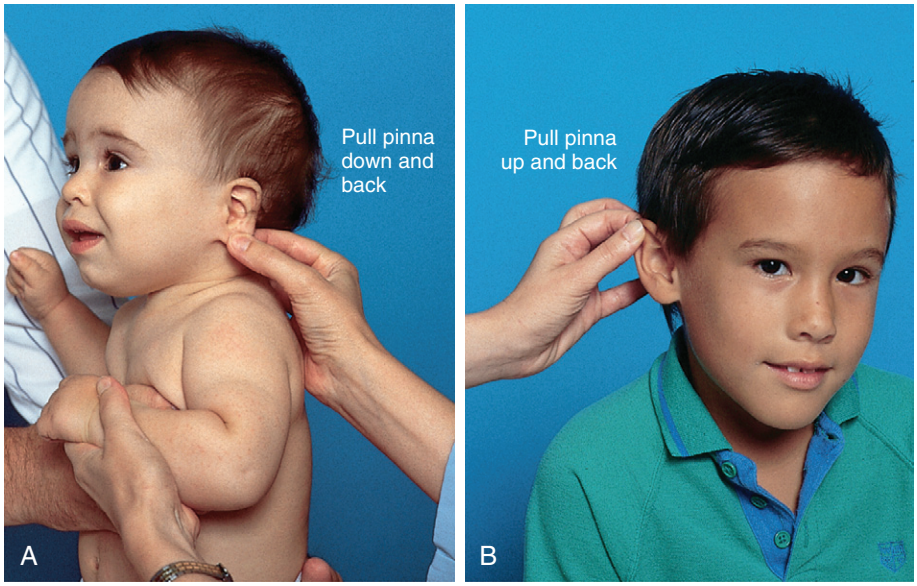

FIG 29-24 Positioning for visualizing eardrum in infant **(A)** and in child older than 3 years **(B).**

TABLE 29-10 AUDITORY TESTS FOR INFANTS AND CHILDREN

AGE	AUDITORY TEST AND AVERAGE TIME	TYPE OF MEASUREMENT	PROCEDURE
All ages	Evoked otoacoustic emissions, 10-min test	Physiologic test specifically measuring cochlear (outer hair cell) response to presentation of stimulus	Small probe containing sensitive microphone is placed in ear canal for stimulus delivery and response detection.
Birth-9 months	Auditory brainstem response, 15-min test	Electrophysiologic measurement of activity in auditory nerve and brainstem pathways	Placement of electrodes on child's head detects auditory stimuli presented through earphones one ear at a time.
9 months-2½ yr	Conditioned oriented responses or visual reinforced audiometry, 30-min test	Behavioral tests measuring child's responses to speech and frequency-specific stimuli presented through speakers	Both techniques condition child to associate speech or frequency-specific sound with reinforcement stimulus, such as lighted toy.

Adapted with permission from Bachmann KR, Arvedson JC: Early identification and intervention for children who are hearing impaired, *Pediatr Rev* 19:155–165, 1998.

where cerumen is produced. Note signs of irritation, foreign bodies, or infection.

Foreign bodies in the ear are not uncommon in children and range from erasers to beans. Symptoms may include pain, discharge, and affected hearing. Remove soft objects, such as paper or insects, with forceps. Remove small, hard objects, such as pebbles, with a suction tip, a hook, or irrigation. However, irrigation is contraindicated if the object is vegetative matter, such as beans or pasta, which swells when in contact with fluid.

! NURSING ALERT

If there is any doubt about the type of object in the ear and the appropriate method to remove it, refer the child to the appropriate practitioner.

The tympanic membrane is a translucent, light pearly pink or gray. Note marked erythema (which may indicate suppurative otitis media); a dull, nontransparent grayish color (sometimes suggestive of serous otitis media); or ashen gray areas (signs of scarring from a previous perforation). A black area usually suggests a perforation of the membrane that has not healed.

The characteristic tenseness and slope of the tympanic membrane cause the light of the otoscope to reflect at about the 5 or 7 o'clock position. The light reflex is a fairly well-defined, cone-shaped reflection, which normally points away from the face.

The bony landmarks of the drum are formed by the umbo, or tip of the malleus. It appears as a small, round, opaque, concave spot near the center of the drum. The manubrium (long process or handle) of the malleus appears to be a whitish line extending from the umbo upward to the margin of the membrane. At the upper end of the long process near the 1 o'clock position (in the right ear) is a sharp, knoblike protuberance, representing the short process of the malleus. Note the absence of the light reflex or loss or abnormal prominence of any of these landmarks.

Auditory Testing

Several types of hearing tests are available and recommended for screening in infants and children (American Academy of Pediatrics, 2003b) (Table 29-10). Universal newborn hearing screening is available in almost every state in the United States. The nurse must operate under a high index of suspicion for those children who may have conditions associated with hearing loss, whose parents are concerned about hearing loss, and who may have developed behaviors that indicate auditory impairment (Cunningham and Cox, 2003). Chapter 37 discusses types of hearing loss, causes, clinical manifestations, and appropriate treatment.

Nose

Inspection of External Structures

The nose is located in the middle of the face just below the eyes and above the lips. Compare its placement and alignment by drawing an imaginary vertical line from the center point between the eyes down to the notch of the upper lip. The nose should lie exactly vertical to this line, with each side exactly symmetric. Note its location, any deviation to one side, and asymmetry in overall size and in diameter of the nares (nostrils). The bridge of the nose is sometimes flat in Asian and African-American children. Observe the alae nasi for any sign of flaring, which indicates respiratory difficulty. Always report any flaring of the alae nasi. Fig. 29-25 illustrates the landmarks used in describing the external structures of the nose.

Inspection of Internal Structures

Inspect the anterior vestibule of the nose by pushing the tip upward, tilting the head backward, and illuminating the cavity with a flashlight or otoscope without the attached ear speculum. Note the color of the mucosal lining, which is normally redder than the oral membranes, as well as any swelling, discharge, dryness, or bleeding. There should be no discharge from the nose.

On looking deeper into the nose, inspect the turbinates, or concha, plates of bone that jut into the nasal cavity and are enveloped by mucous membrane. The turbinates greatly increase the surface area of the nasal cavity as air is inhaled. The spaces or channels between the turbinates are called the meatus and correspond to each of the three turbinates. Normally the front end of the inferior and middle turbinate and the middle meatus are seen. They should be the same color as the lining of the vestibule.

Inspect the septum, which should divide the vestibules equally. Note any deviation, especially if it causes an occlusion of one side of the nose. A perforation may be evident within the septum. If this is suspected, shine the light of the otoscope into one naris and look for admittance of light to the other. Because olfaction is an important function of the nose, testing for smell may be done at this point or as part of cranial nerve assessment (see Table 29-13).

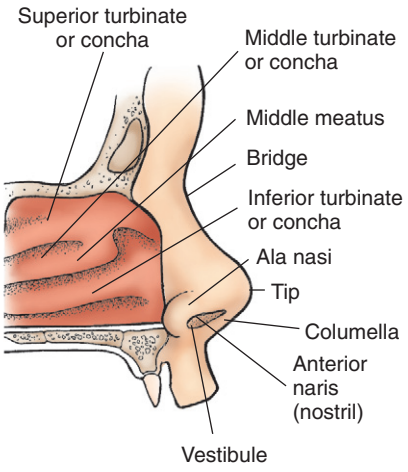

FIG 29-25 External landmarks and internal structures of nose.

Mouth and Throat

With a cooperative child, the nurse can accomplish almost the entire examination of the mouth and throat without the use of a tongue blade. Ask the child to open the mouth wide; to move the tongue in different directions for full visualization; and to say "ahh," which depresses the tongue for full view of the back of the mouth (tonsils, uvula, and oropharynx). For a closer look at the buccal mucosa, or lining of the cheeks, ask children to use their fingers to move the outer lip and cheek to one side (see Atraumatic Care box).

Infants and toddlers usually resist attempts to keep the mouth open. Because inspecting the mouth is upsetting, leave it for the end of the physical examination (along with examination of the ears) or do it during episodes of crying. However, the use of a tongue blade (preferably flavored) to depress the tongue may be needed. Place the tongue blade along the *side* of the tongue, not in the center back area where the gag reflex is elicited. Fig. 29-26, *B*, illustrates proper positioning of the child for the oral examination.

The major structure of the exterior of the mouth is the lips. The lips should be moist, soft, smooth, and pink, or a deeper hue than

ATRAUMATIC CARE

Encouraging Opening the Mouth for Examination

- Perform the examination in front of a mirror.
- Let child first examine someone else's mouth, such as the parent, the nurse, or a puppet (Fig. 29-26, *A*), and then examine child's mouth.
- Instruct child to tilt the head back slightly, breathe deeply through the mouth, and hold the breath; this action lowers the tongue to the floor of the mouth without the use of a tongue blade.
- Lightly brushing the palate with a cotton swab also may open the mouth for assessment.

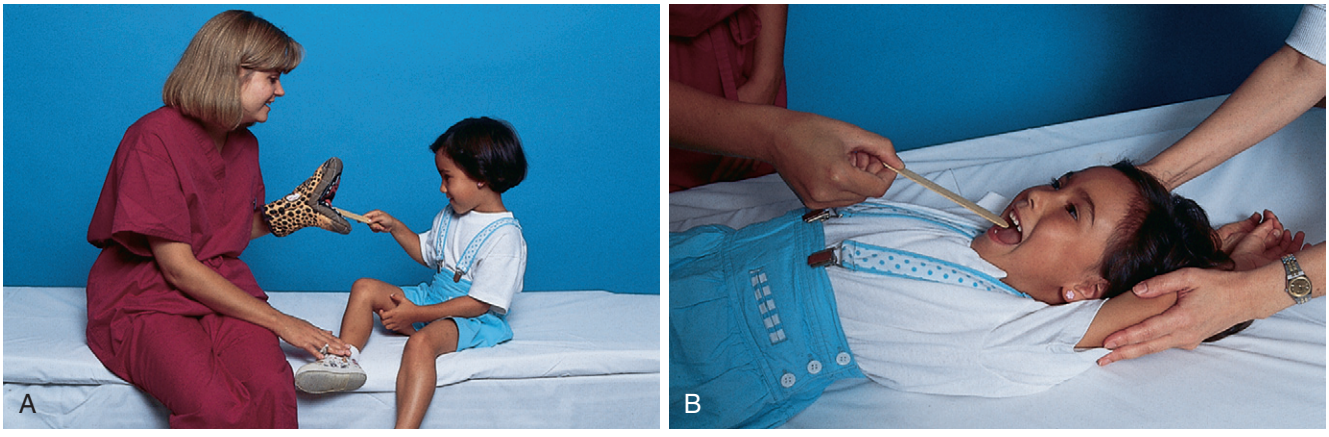

FIG 29-26 **A,** Encouraging child to cooperate. **B,** Positioning child for examination of mouth.

the surrounding skin. The lips should be symmetric when relaxed or tensed. Assess symmetry when the child talks or cries.

Inspection of Internal Structures

The major structures that are visible within the oral cavity and oropharynx are the mucosal lining of the lips and cheeks, gums (or gingiva), teeth, tongue, palate, uvula, tonsils, and posterior oropharynx (Fig. 29-27). Inspect all areas lined with mucous membranes (inside the lips and cheeks, gingiva, underside of the tongue, palate, and back of the pharynx) for color, any areas of white patches or ulceration, bleeding, sensitivity, and moisture. The membranes should be bright pink, smooth, glistening, uniform, and moist.

Inspect the teeth for number in each dental arch, for hygiene, and for occlusion or bite (see also Teething, Chapter 31). Discoloration of tooth enamel with obvious plaque (whitish coating on the surface of the teeth) is a sign of poor dental hygiene and indicates a need for counseling. Brown spots in the crevices of the crown of the tooth or between the teeth may be caries (cavities). Chalky white to yellow or brown areas on the enamel may indicate fluorosis (excessive fluoride ingestion). Teeth that appear greenish black may be stained temporarily from ingestion of supplemental iron.

Examine the gums (gingiva) surrounding the teeth. The color is normally coral pink, and the surface texture is stippled, similar to the appearance of an orange peel. In dark-skinned children, the gums are more deeply colored and a brownish area is often observed along the gum line.

Inspect the tongue for papillae—small projections that contain several taste buds and give the tongue its characteristic rough appearance. Note the size and mobility of the tongue. Normally the tip of the tongue should extend to the lips or beyond.

The roof of the mouth consists of the hard palate, which is located near the front of the oral cavity, and the soft palate, which is located toward the back of the pharynx and has a small midline protrusion called the uvula. Carefully inspect the palates to ensure they are intact. The arch of the palate should be dome shaped. A narrow, flat roof or a high, arched palate affects the placement of the tongue and can cause feeding and speech problems. Test movement of the uvula by eliciting a gag reflex. It should move upward to close off the nasopharynx from the oropharynx.

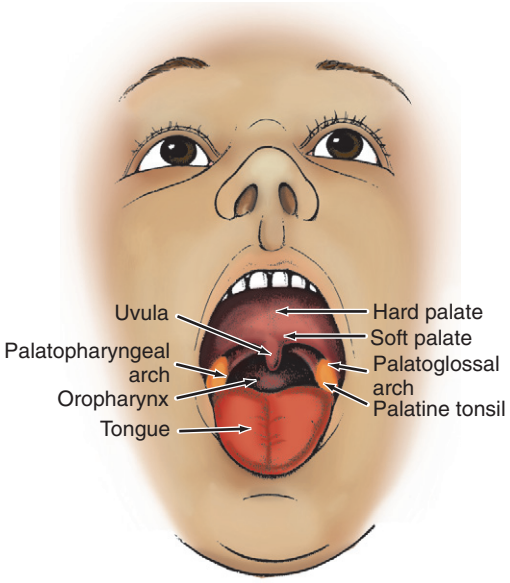

FIG 29-27 Interior structures of mouth.

Examine the oropharynx and note the size and color of the palatine tonsils. They are normally the same color as the surrounding mucosa; glandular, rather than smooth in appearance; and barely visible over the edge of the palatoglossal arches. The size of the tonsils varies considerably during childhood. However, report any swelling, redness, or white areas on the tonsils.

Chest

Inspect the chest for size, shape, symmetry, movement, breast development, and the bony landmarks formed by the ribs and sternum. The rib cage consists of 12 ribs on each side and the sternum, or breast bone, located in the midline of the trunk (Fig. 29-28). The sternum is composed of three main parts. The manubrium, the uppermost portion, can be felt at the base of the neck at the suprasternal notch. The largest segment of the sternum is the body, which forms the sternal angle (angle of Louis) as it articulates with the manubrium. At the end of the body is a small, movable process called the xiphoid. The angle of the costal margin as it attaches to the sternum is called the costal angle and is normally about 45 to 50 degrees. These bony structures are important landmarks in the location of ribs and intercostal spaces (ICSs), which are the spaces between the ribs. They are numbered according to the rib directly *above* the space. For example, the space immediately below the second rib is the second ICS.

The thoracic cavity is also divided into segments by drawing imaginary lines on the chest and back. Fig. 29-29 illustrates the anterior, lateral, and posterior divisions.

Measure the size of the chest by placing the measuring tape around the rib cage at the nipple line (see Fig. 29-9). For greatest accuracy, take two measurements—one during inspiration and the other during expiration—and record the average. Chest size is important mainly in relation to head circumference (see p. 795). Always report marked disproportions because most are caused by abnormal head growth; however, some may be a result of altered chest shape, such as barrel chest (chest is round) or pigeon chest (sternum protrudes outward).

During infancy, the chest's shape is almost circular, with the anteroposterior (front-to-back) diameter equaling the transverse, or lateral (side-to-side), diameter. As the child grows, the chest normally increases in the transverse direction, causing the anteroposterior diameter to be less than the lateral diameter. Note the angle made by the lower costal margin and the sternum, and palpate the junction of the ribs with the costal cartilage (costochondral junction) and sternum, which should be fairly smooth.

Movement of the chest wall should be symmetric bilaterally and coordinated with breathing. During inspiration the chest rises and expands, the diaphragm descends, and the costal angle increases. During expiration the chest falls and decreases in size, the diaphragm rises, and the costal angle narrows (Fig. 29-30). In children younger than 6 or 7 years, respiratory movement is principally abdominal or diaphragmatic. In older children, particularly girls, respirations are chiefly thoracic. In either case, the chest and abdomen should rise and fall together. Always report any asymmetry of movement.

While inspecting the skin surface of the chest, observe the position of the nipples and any evidence of breast development. Normally the nipples are located slightly lateral to the midclavicular line between the fourth and fifth ribs. Note symmetry of nipple placement and normal configuration of a darker-pigmented areola surrounding a flat nipple in the prepubertal child.

Pubertal breast development usually begins in girls between 10 and 14 years of age (see Chapter 35). Record early (precocious) or

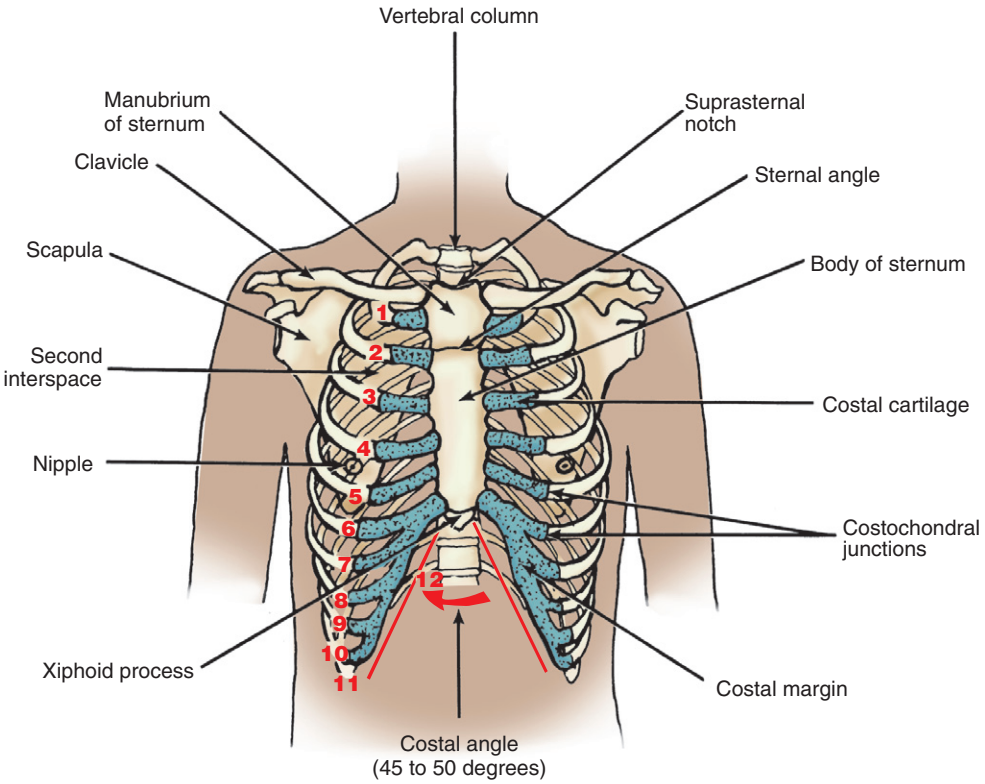

FIG 29-28 Rib cage.

delayed breast development, as well as evidence of any other **secondary sexual characteristics.** In males, breast enlargement (gynecomastia) may be caused by hormonal or systemic disorders, but more commonly it is a result of adipose tissue from obesity or a transitory body change during early puberty. In either situation, investigate the child's feelings regarding breast enlargement.

In adolescent girls who have achieved sexual maturity, palpate the breasts for evidence of any masses or hard nodules. Use this opportunity to discuss the importance of routine breast self-examination. To decrease any fear or concern that results when a mass is felt, emphasize that most palpable masses are benign.

Lungs

The lungs are situated inside the thoracic cavity, with one lung on each side of the sternum. Each lung is divided into an apex, which is slightly pointed and rises above the first rib; a base, which is wide and concave and rides on the dome-shaped diaphragm; and a body, which is divided into lobes. The right lung has three lobes—the upper, middle, and lower. The left lung has only two lobes—the upper and lower—because of the space occupied by the heart (Fig. 29-31).

Inspection of the lungs primarily involves observation of respiratory movements. Evaluate respirations for (1) rate (number per minute), (2) rhythm (regular, irregular, or periodic), (3) depth (deep or shallow), and (4) quality (effortless, automatic, difficult, or labored). Note the character of breath sounds, such as noisy, grunting, snoring, or heavy.

Evaluate respiratory movements by placing each hand flat against the back or chest with the thumbs in midline along the lower costal margin of the lungs. The child should be sitting during this procedure and, if cooperative, should take several deep breaths. During respiration your hands will move with the chest wall. Assess the amount and speed of respiratory excursion, and note any asymmetry of movement.

Experienced examiners may percuss the lungs. Percuss the anterior lung from apex to base, usually with the child in the supine or sitting position. Percuss each side of the chest in sequence to compare the sounds. When percussing the posterior lung, the procedure and sequence are the same, although the child should be sitting. Resonance is heard over all the lobes of the lungs that are not adjacent to other organs. Record and report any deviation from the expected sound.

GUIDELINES

Effective Auscultation

- Make certain child is relaxed and not crying, talking, or laughing. Record if child is crying.
- Check that room is comfortable and quiet.
- Warm stethoscope before placing it against skin.
- Apply firm pressure on chest piece but not enough to prevent vibrations and transmission of sound.
- Avoid placing stethoscope over hair or clothing, moving it against skin, breathing on tubing, or sliding fingers over chest piece, which may cause sounds that falsely resemble pathologic findings.
- Use a symmetric and orderly approach to compare sounds.

Auscultation

Auscultation involves using the stethoscope to evaluate breath sounds (see Guidelines box). Breath sounds are best heard if the child inspires deeply (see Atraumatic Care box). In the lungs, breath sounds are classified as *vesicular, bronchovesicular,* or *bronchial* (Box 29-13).

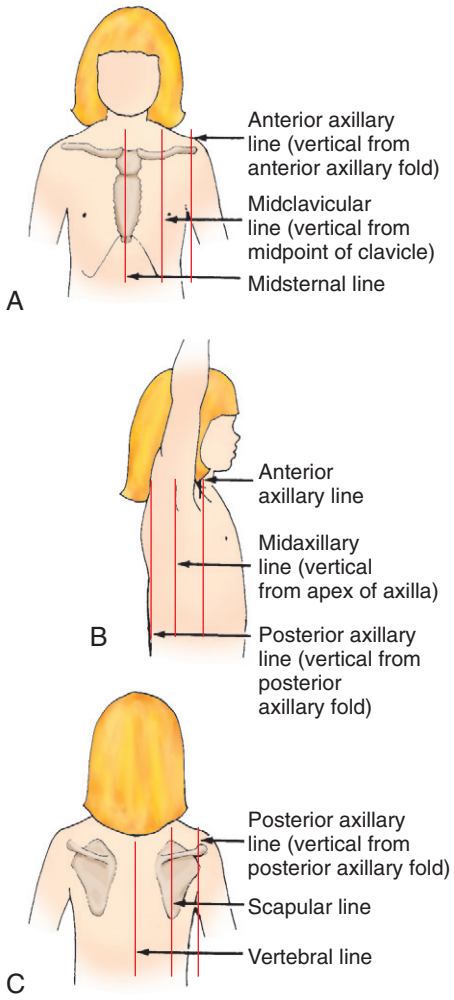

FIG 29-29 Imaginary landmarks of chest. **A,** Anterior. **B,** Right lateral. **C,** Posterior.

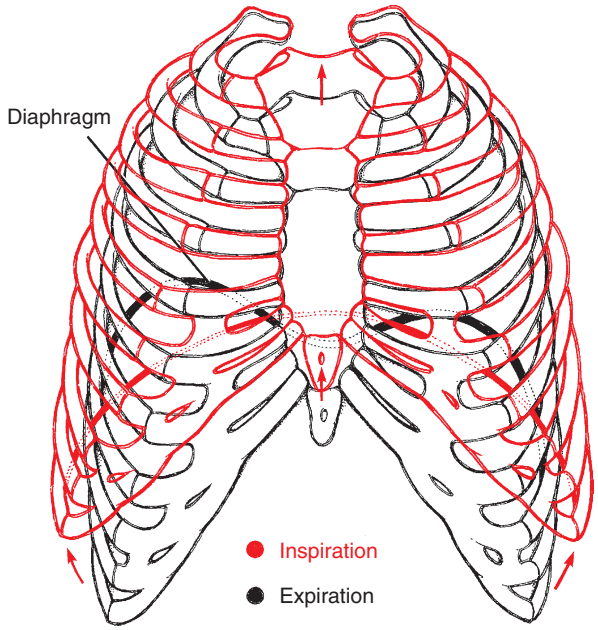

FIG 29-30 Movement of chest during respiration.

ATRAUMATIC CARE

Encouraging Deep Breaths

- Ask child to "blow out" the light on an otoscope or pocket flashlight; discreetly turn off the light on the last try so that the child feels successful.
- Place a cotton ball in child's palm; ask child to blow the ball into the air and have parent catch it.
- Place a small tissue on the top of a pencil and ask child to blow the tissue off.
- Have child blow a pinwheel, a party horn, or bubbles.

BOX 29-13 CLASSIFICATION OF NORMAL BREATH SOUNDS

Vesicular Breath Sounds

- Heard over entire surface of lungs, with exception of upper intrascapular area and area beneath manubrium.
- Inspiration is louder, longer, and higher pitched than expiration.
- Sound is soft, swishing noise.

Bronchovesicular Breath Sounds

- Heard over manubrium and in upper intrascapular regions where trachea and bronchi bifurcate.
- Inspiration is louder and higher pitched than in vesicular breathing.

Bronchial Breath Sounds

- Heard only over trachea near suprasternal notch.
- Inspiratory phase is short, and expiratory phase is long.

Absent or diminished breath sounds are always an abnormal finding warranting investigation. Fluid, air, or solid masses in the pleural space all interfere with the conduction of breath sounds. Diminished breath sounds in certain segments of the lung can alert the nurse to pulmonary areas that may benefit from chest physiotherapy. Increased breath sounds after pulmonary therapy indicate improved passage of air through the respiratory tract. Box 29-14 lists terms used to describe various respiration patterns.

Various pulmonary abnormalities produce adventitious sounds that are not normally heard over the chest. These sounds occur in addition to normal or abnormal breath sounds. They are classified into two main groups: crackles, which result from the passage of air through fluid or moisture; and wheezes, which are produced as air passes through narrowed passageways, regardless of the cause, such as exudate, inflammation, spasm, or tumor. Considerable practice with an experienced tutor is necessary to differentiate the various types of lung sounds. Often it is best to describe the type of sound heard in the lungs rather than trying to label it. Always report any abnormal sounds for further medical evaluation.

Heart

The heart is situated in the thoracic cavity between the lungs in the mediastinum and above the diaphragm (Fig. 29-32). About two thirds of the heart lies within the left side of the rib cage, with the other third on the right side as it crosses the sternum. The heart is positioned in the thorax like a trapezoid:

- **Vertically** along the right sternal border (RSB) from the second to the fifth rib
- **Horizontally** (long side) from the lower right sternum to the fifth rib at the left midclavicular line (LMCL)

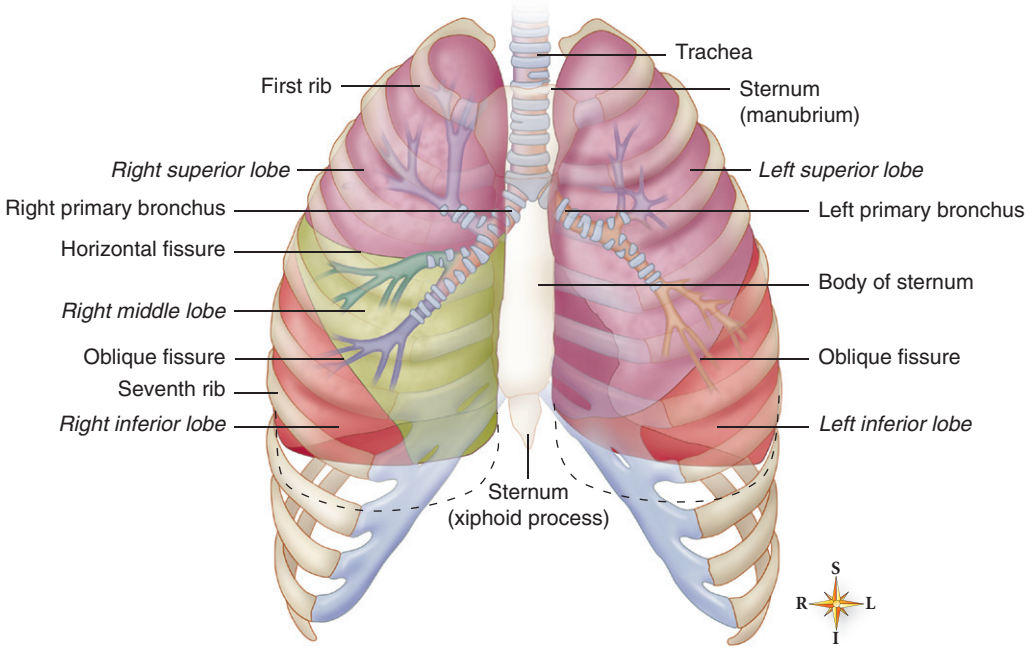

FIG 29-31 Location of lobes of lungs within thoracic cavity. (From Patton KT: *Anatomy and physiology,* ed 8, St Louis, 2013, Mosby.)

BOX 29-14 VARIOUS PATTERNS OF RESPIRATION

Tachypnea—Increased rate
Bradypnea—Decreased rate
Dyspnea—Distress during breathing
Apnea—Cessation of breathing
Hyperpnea—Increased depth
Hypoventilation—Decreased depth (shallow) and irregular rhythm
Hyperventilation—Increased rate and depth
Kussmaul respiration—Hyperventilation, gasping and labored respiration; usually seen in diabetic coma or other states of respiratory acidosis
Cheyne-Stokes respiration—Gradually increasing rate and depth with periods of apnea
Biot respiration—Periods of hyperpnea alternating with apnea (similar to Cheyne-Stokes except that depth remains constant)
Seesaw (paradoxic) respirations—Chest falls on inspiration and rises on expiration
Agonal—Last gasping breaths before death

- **Diagonally** from the left sternal border (LSB) at the second rib to the LMCL at the fifth rib
- **Horizontally** (short side) from the RSB and LSB at the second ICS—base of the heart

Inspection is easiest when the child is sitting in a semi-Fowler position. Look at the anterior chest wall from an angle, comparing both sides of the rib cage with each other. Normally they should be symmetric. In children with thin chest walls, a pulsation may be visible. Because comprehensive evaluation of cardiac function is not limited to the heart, also consider other findings such as the presence of all pulses (especially the femoral pulses) (Fig. 29-33), distended neck veins, clubbing of the fingers, peripheral cyanosis, edema, blood pressure, and respiratory status.

Use palpation to determine the location of the apical impulse (AI), the most lateral cardiac impulse that may correspond to the apex. The AI is found:

- Just lateral to the LMCL and fourth ICS in children younger than 7 years
- At the LMCL and fifth ICS in children older than 7 years

Although the AI gives a general idea of the size of the heart (with enlargement, the apex is lower and more lateral), its normal location is variable, making it an unreliable indicator of heart size.

The point of maximum intensity (PMI), as the name implies, is the area of most intense pulsation. Usually the PMI is located at the same site as the AI, but it can occur elsewhere. For this reason, the two terms should not be used synonymously.

Assess capillary refill time, an important test for circulation and hydration, by pressing the skin lightly on a central site (e.g., the forehead) or a peripheral site (e.g., the top of the hand) to produce a slight blanching. The time it takes for the blanched area to return to its original color is the capillary refill time.

! NURSING ALERT

Capillary refill should be brisk—less than 2 seconds. Prolonged refill may be associated with poor systemic perfusion or a cool ambient temperature.

Auscultation

Origin of Heart Sounds. The heart sounds are produced by the opening and closing of the valves and the vibration of blood against the walls of the heart and vessels. Normally two sounds—S_1 and S_2—are heard, which correspond, respectively, to the familiar "lub dub" often used to describe the sounds. S_1 is caused by closure of the tricuspid and mitral valves (sometimes called the

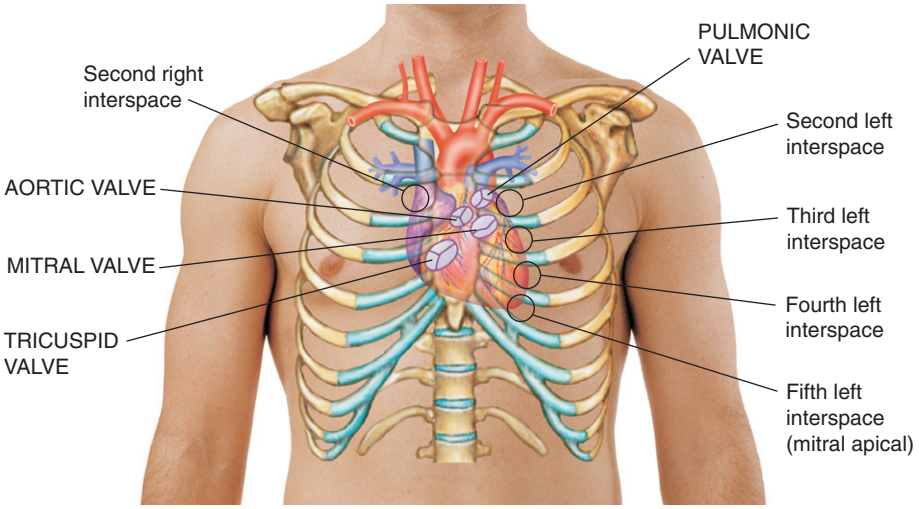

FIG 29-32 Position of heart within thorax. (From Seidel HM, Dains JE, Ball JW, et al: *Mosby's guide to physical examination*, ed 7, St Louis, 2011, Mosby.)

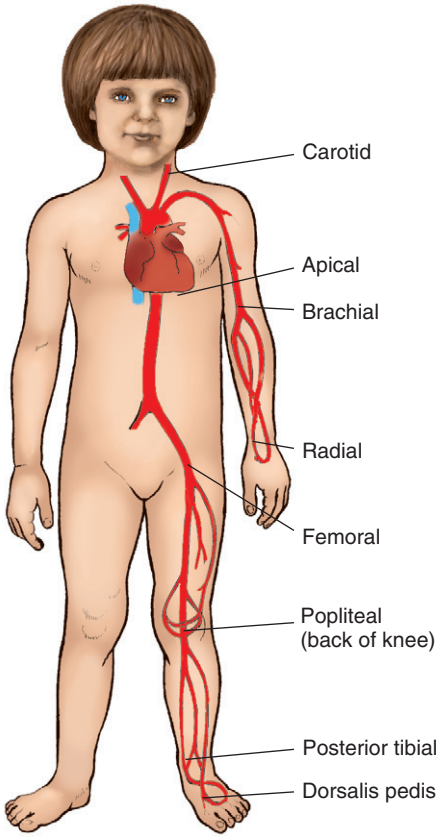

FIG 29-33 Location of pulses.

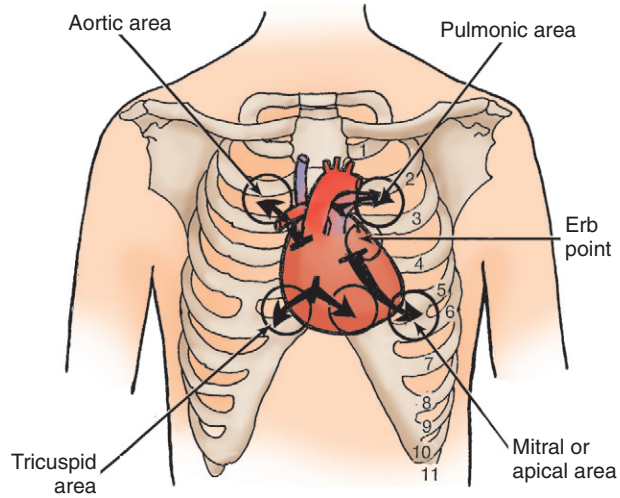

FIG 29-34 Direction of heart sounds for anatomic valve sites and areas *(circled)* for auscultation.

atrioventricular valves). S_2 is the result of closure of the pulmonic and aortic valves (sometimes called semilunar valves). Normally the split of the two sounds in S_2 is distinguishable and widens during inspiration. Physiologic splitting is a significant normal finding.

! NURSING ALERT

Fixed splitting, in which the split in S_2 does not change during inspiration, is an important diagnostic sign of atrial septal defect.

Two other heart sounds, S_3 and S_4, may be produced. S_3 is normally heard in some children. S_4 is rarely heard as a normal heart sound; it usually indicates the need for further cardiac evaluation.

Differentiating Normal Heart Sounds. Fig. 29-34 illustrates the approximate anatomic position of the valves within the heart chambers. Note that the anatomic location of valves does not correspond to the area where the sounds are heard best. The auscultatory sites are located in the direction of the blood flow through the valves.

Normally, S_1 is louder at the apex of the heart in the mitral and tricuspid area and S_2 is louder near the base of the heart in the pulmonic and aortic area (Table 29-11). Listen to each sound by inching down the chest. To distinguish between S_1 and S_2 heart sounds, simultaneously palpate the carotid pulse with the index and middle fingers and listen to the heart sounds; S_1 is synchronous with the carotid pulse.

Auscultate the following areas for sounds, such as murmurs, which may radiate to these sites: sternoclavicular area above the

TABLE 29-11 SEQUENCE OF AUSCULTATING HEART SOUNDS*

AUSCULTATORY SITE	CHEST LOCATION	CHARACTERISTICS OF HEART SOUNDS
Aortic area	Second right intercostal space close to sternum	S_2 heard louder than S_1; aortic closure heard loudest
Pulmonic area	Second left intercostal space close to sternum	Splitting of S_2 heard best, normally widens on inspiration; pulmonic closure heard best
Erb point	Second and third left intercostal spaces close to sternum	Frequent site of innocent murmurs and those of aortic or pulmonic origin
Tricuspid area	Fifth right and left intercostal spaces close to sternum	S_1 heard as louder sound preceding S_2 (S_1 synchronous with carotid pulse)
Mitral or apical area	Fifth intercostal space, left midclavicular line (third to fourth intercostal space and lateral to left midclavicular line in infants)	S_1 heard loudest; splitting of S_1 may be audible because mitral closure is louder than tricuspid closure S_1 heard best at beginning of expiration with child in recumbent or left side-lying position; occurs immediately after S_2; sounds like word S_1 S_2 S_3: "Ken-tuc-ky" S_4 heard best during expiration with child in recumbent position (left side-lying position decreases sound); occurs immediately before S_1; sounds like word S_4 S_1 S_2: "Ten-nes-see"

*Use both diaphragm and bell chest pieces when auscultating heart sounds. Bell chest piece is necessary for low-pitched sounds of murmurs, S_3, and S_4.

clavicles and manubrium, area along the sternal border, area along the left midaxillary line, and area below the scapulae.

Auscultate the heart with the child in at least two positions: sitting and reclining. If adventitious sounds are detected, further evaluate them with the child standing, sitting and leaning forward, and lying on the left side. For example, atrial sounds such as S_4 are heard best with the person in a recumbent position and usually fade if the person sits or stands.

Evaluate heart sounds for (1) quality (they should be clear and distinct—not muffled, diffuse, or distant); (2) intensity, especially in relation to the location or auscultatory site (they should not be weak or pounding); (3) rate (they should have the same rate as the radial pulse); and (4) rhythm (they should be regular and even). A particular dysrhythmia that occurs normally in many children is sinus dysrhythmia, in which the heart rate increases with inspiration and decreases with expiration. Differentiate this rhythm from a truly abnormal dysrhythmia by having children hold their breath. In sinus dysrhythmia, cessation of breathing causes the heart rate to remain steady.

Heart Murmurs. Another important category of the heart sounds is murmurs, which are produced by vibrations within the heart chambers or in the major arteries from the back-and-forth flow of blood. (For a more detailed discussion, see Assessment of Cardiac Function, Chapter 42.) Murmurs are classified as:

- **Innocent**—No anatomic or physiologic abnormality exists.
- **Functional**—No anatomic cardiac defect exists, but a physiologic abnormality such as anemia is present.
- **Organic**—A cardiac defect with or without a physiologic abnormality exists.

The description and classification of murmurs are skills that require considerable practice and training. In general, recognize murmurs as distinct swishing sounds that occur in addition to the normal heart sounds and record the (1) location, or the area of the heart in which the murmur is heard best; (2) time of the occurrence of the murmur within the S_1-S_2 cycle; (3) intensity (evaluate in relationship to the child's position); and (4) loudness. Table 29-12 lists the usual subjective method of grading the loudness or intensity of a murmur.

TABLE 29-12 GRADING THE INTENSITY OF HEART MURMURS

GRADE	DESCRIPTION
I	Very faint; often not heard if child sits up
II	Usually readily heard; slightly louder than grade I; audible in all positions
III	Loud, but not accompanied by a thrill
IV	Loud, accompanied by a thrill
V	Loud enough to be heard with a stethoscope barely touching the chest; accompanied by a thrill
VI	Loud enough to be heard with the stethoscope not touching the chest; often heard with the human ear close to the chest; accompanied by a thrill

Abdomen

Examination of the abdomen involves inspection, followed by auscultation and then palpation. Perform palpation last because it may distort the normal abdominal sounds. Knowledge of the anatomic placement of the abdominal organs is essential to differentiate normal, expected findings from abnormal ones (Fig. 29-35).

For descriptive purposes, the abdominal cavity is divided into four quadrants by drawing a vertical line midway from the sternum to the symphysis pubis and a horizontal line across the abdomen through the umbilicus. The sections are named:

- Left upper quadrant
- Left lower quadrant
- Right upper quadrant
- Right lower quadrant

Inspection

Inspect the contour of the abdomen with the child erect and supine. Normally the abdomen of infants and young children is cylindric

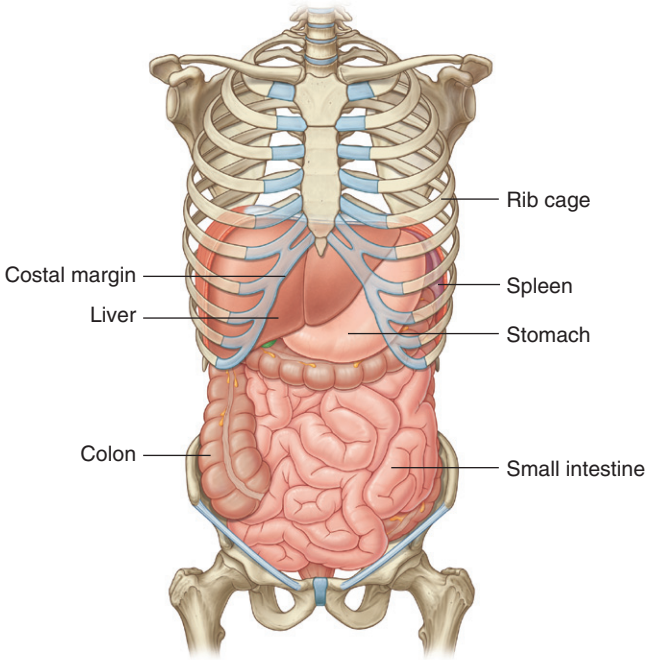

FIG 29-35 Location of structures in abdomen. (From Drake RL, Vogl W, Mitchell AWM: *Gray's anatomy for students,* New York, 2005, Churchill Livingstone.)

and, in the erect position, fairly prominent because of the physiologic lordosis of the spine. In the supine position, the abdomen appears flat. A midline protrusion from the xiphoid to the umbilicus or symphysis pubis is usually diastasis recti, or failure of the rectus abdominis muscles to join in utero. In a healthy child, a midline protrusion is usually a variation of normal muscular development.

! NURSING ALERT

A tense, boardlike abdomen is a serious sign of paralytic ileus and intestinal obstruction.

The skin covering the abdomen should be uniformly taut, without wrinkles or creases. Sometimes silvery, whitish striae ("stretch marks") are seen, especially if the skin has been stretched as in obesity. Superficial veins are usually visible in light-skinned, thin infants, but distended veins are an abnormal finding.

Observe movement of the abdomen. Normally chest and abdominal movements are synchronous. In infants and thin children, peristaltic waves may be visible through the abdominal wall; they are best observed by standing at eye level to and across from the abdomen. Always report this finding.

Examine the umbilicus for size, hygiene, and evidence of any abnormalities, such as hernias. The umbilicus should be flat or only slightly protruding. If a herniation is present, palpate the sac for abdominal contents and estimate the approximate size of the opening. Umbilical hernias are common in infants, especially in African-American children.

Hernias may exist elsewhere on the abdominal wall (Fig. 29-36). An inguinal hernia is a protrusion of peritoneum through the abdominal wall in the inguinal canal. It occurs mostly in males, is frequently bilateral, and may be visible as a mass in the scrotum. To locate a hernia, slide the little finger into the external inguinal ring at the base of the scrotum and ask the child to cough. If a hernia is present, it will hit the tip of the finger. If the child is too young to cough, have the child blow up a balloon or laugh to raise the intraabdominal pressure sufficiently to demonstrate the presence of an inguinal hernia.

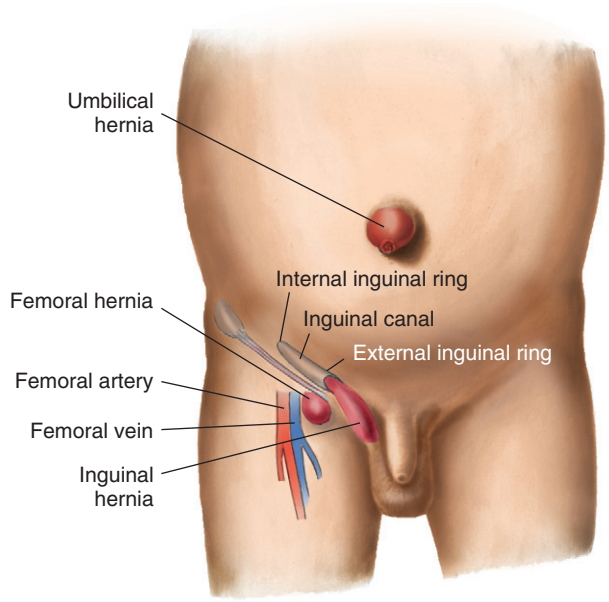

FIG 29-36 Location of hernias.

A femoral hernia, which occurs more frequently in girls, is felt or seen as a small mass on the anterior surface of the thigh just below the inguinal ligament in the femoral canal (a potential space medial to the femoral artery). Feel for a hernia by placing the index finger of your right hand on the child's right femoral pulse (left hand for left pulse) and the middle finger flat against the skin toward the midline. The ring finger lies over the femoral canal, where the herniation occurs. Palpation of hernias in the pelvic region is often part of the genital examination.

Auscultation

The most important finding to listen for is peristalsis, or bowel sounds, which sound like short metallic clicks and gurgles. Record their frequency per minute (e.g., 5 sounds/min). Stimulate bowel sounds by stroking the abdominal surface with a fingernail. Report absence of bowel sounds or hyperperistalsis, since either usually denotes an abdominal disorder.

Palpation

There are two types of palpation: superficial and deep. For superficial palpation, lightly place your hand against the skin and feel each quadrant, noting any areas of tenderness, muscle tone, and superficial lesions such as cysts. Because superficial palpation is often perceived as tickling, use several techniques to minimize this sensation and relax the child (see Atraumatic Care box). Admonishing the child to stop laughing only draws attention to the sensation and decreases cooperation.

Deep palpation is for palpating organs and large blood vessels and for detecting masses and tenderness that were not discovered during superficial palpation. Palpation usually begins in the lower quadrants and proceeds upward to avoid missing the edge of an enlarged liver or spleen. Except for palpating the liver, successful identification of other organs, such as the spleen, kidney, and part of the colon, requires considerable practice with tutored supervision. Report any questionable mass. The lower edge of the liver is

ATRAUMATIC CARE

Promoting Relaxation During Abdominal Palpation

- Position child comfortably, such as in a semireclining position in the parent's lap, with knees flexed.
- Warm your hands before touching the skin.
- Use distraction, such as telling stories or talking to child.
- Teach child to use deep breathing and to concentrate on an object.
- Give infant a bottle or pacifier.
- Begin with light, superficial palpation and gradually progress to deeper palpation.
- Palpate any tender or painful areas last.
- Have child hold the parent's hand and squeeze it if palpation is uncomfortable.
- Use the nonpalpating hand to comfort child, such as placing the free hand on the child's shoulder while palpating the abdomen.
- To minimize sensation of tickling during palpation:
  - Have children "help" with palpation by placing a hand over the palpating hand.
  - Have them place a hand on the abdomen with the fingers spread wide apart, and palpate between their fingers.

sometimes felt in infants and young children as a superficial mass 1 to 2 cm (0.4 to 0.8 inch) below the right costal margin (the distance is sometimes measured in fingerbreadths). Normally the liver descends during inspiration as the diaphragm moves downward. Do not mistake this downward displacement as a sign of liver enlargement.

! NURSING ALERT

If the liver is palpable 3 cm (1.2 in) below the right costal margin or the spleen is palpable more than 2 cm (0.8 in) below the left costal margin, these organs are enlarged—a finding that is always reported for further medical investigation.

Palpate the femoral pulses by placing the tips of two or three fingers (index, middle, or ring) along the inguinal ligament about midway between the iliac crest and symphysis pubis. Feel both pulses simultaneously to make certain that they are equal and strong (Fig. 29-37).

! NURSING ALERT

Absence of femoral pulses is a significant sign of coarctation of the aorta and is referred for medical evaluation.

Genitalia

Examination of genitalia conveniently follows assessment of the abdomen while the child is still supine. In adolescents, inspection of the genitalia may be left to the end of the examination. The best approach is to examine the genitalia matter-of-factly, placing no more emphasis on this part of the assessment than on any other segment. It helps to relieve children's and parents' anxiety by telling them the results of the findings; for example, the nurse might say, "Everything looks fine here."

If it is necessary to ask questions, such as about discharge or difficulty urinating, respect the child's privacy by covering the lower abdomen with the gown or underpants. To prevent embarrassing interruptions, keep the door or curtain closed and post a "do not disturb" sign. Have a drape ready to cover the genitalia if someone enters the room.

FIG 29-37 Palpating for femoral pulses.

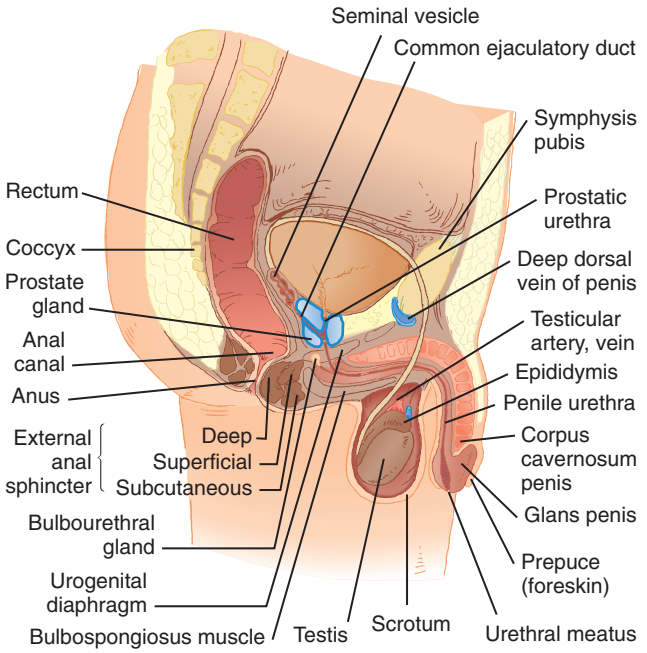

FIG 29-38 Major structures of genitalia in uncircumcised postpubertal male. (From Black JM: *Medical-surgical nursing: clinical management for positive outcomes,* ed 8, St Louis, 2008, Saunders.)

In examining the genitalia, wear gloves when touching body substances. It might be helpful for the adolescent to know that wearing gloves also prevents skin-to-skin contact.

The genital examination is an excellent time for eliciting questions or concern about body function or sexual activity. Also use this opportunity to increase or reinforce the child's knowledge of reproductive anatomy by naming each body part and explaining its function. This part of the health assessment is an opportune time to teach testicular self-examination to boys.

Male Genitalia

Note the external appearance of the glans and shaft of the penis, the prepuce, the urethral meatus, and the scrotum (Fig. 29-38). The penis is generally small in infants and young boys until puberty,

when it begins to increase in both length and width. In an obese child, the penis often looks abnormally small because of the folds of skin partially covering it at the base. Be familiar with normal pubertal growth of the external male genitalia to compare the findings with the expected sequence of maturation (see Chapter 35).

Examine the glans (head of the penis) and shaft (portion between the perineum and prepuce) for signs of swelling, skin lesions, inflammation, or other irregularities. Any of these signs may indicate underlying disorders, especially sexually transmitted infections.

Carefully inspect the urethral meatus for location and evidence of discharge. Normally it is centered at the tip of the glans. Also note hair distribution. Normally, before puberty, no pubic hair is present. Soft, downy hair at the base of the penis is an early sign of pubertal maturation. In older adolescents, hair distribution is diamond-shaped from the umbilicus to the anus.

Note the location and size of the scrotum. The scrota hang freely from the perineum behind the penis, and the left scrotum normally hangs lower than the right. In infants, the scrota appear large in relation to the rest of the genitalia. The skin of the scrotum is loose and highly rugated (wrinkled). During early adolescence, the skin normally becomes redder and coarser. In dark-skinned children, the scrota are usually more deeply pigmented.

Palpation of the scrotum includes identification of the testes, epididymis, and, if present, inguinal hernias. The two testes are felt as small, ovoid bodies about 1.5 to 2 cm (0.6 to 0.8 in) long—one in each scrotal sac. They do not enlarge until puberty, when they approximately double in size.

When palpating for the presence of the testes, avoid stimulating the cremasteric reflex, which is stimulated by cold, touch, emotional excitement, or exercise. This reflex pulls the testes higher into the pelvic cavity. Several measures are useful in preventing the cremasteric reflex during palpation of the scrotum. First, warm the hands. Second, if the child is old enough, examine him in a tailor or "Indian" position, which stretches the muscle, preventing its contraction (Fig. 29-39, *A*). Third, block the normal pathway of ascent of the testes by placing the thumb and index finger over the upper part of the scrotal sac along the inguinal canal (Fig. 29-39, *B*). If there is any question concerning the existence of two testes, place the index and middle fingers in a scissors fashion to separate the right and left scrota. If, after using these techniques, you have not palpated the testes, feel along the inguinal canal and perineum to locate masses that may be undescended testes. Although undescended testes may descend at any time during childhood and are checked at each visit, report any failure to palpate the testes.

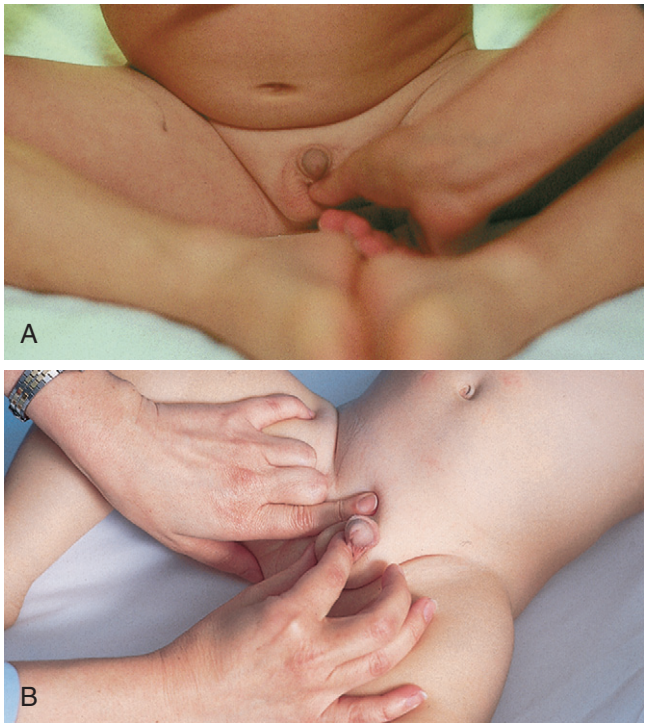

FIG 29-39 **A,** Preventing cremasteric reflex by having child sit in tailor position. **B,** Blocking inguinal canal during palpation of scrotum for descended testes.

Female Genitalia

The examination of female genitalia is limited to inspection and palpation of external structures. If a vaginal examination is required, the nurse should make an appropriate referral unless he or she is qualified to perform the procedure.

A convenient position for examination of the genitalia involves placing the young child supine on the examining table or in a semi-reclining position on the parent's lap with the feet supported on your knees as you sit facing the child. Divert the child's attention from the examination by instructing her to try to keep the soles of her feet pressed against each other. Separate the labia majora with the thumb and index finger and retract outward to expose the labia minora, urethral meatus, and vaginal orifice.

Examine the female genitalia for size and location of the structures of the vulva, or pudendum (Fig. 29-40). The mons pubis is a pad of adipose tissue over the symphysis pubis. At puberty the mons is covered with hair, which extends along the labia. The usual pattern of female hair distribution is an inverted triangle. The appearance of soft, downy hair along the labia majora is an early sign of sexual maturation. Note the size and location of the clitoris, a small, erectile organ located at the anterior end of the labia minora. It is covered by a small flap of skin, the prepuce.

The labia majora are two thick folds of skin running posteriorly from the mons to the posterior commissure of the vagina. Internal to the labia majora are two folds of skin called the labia minora. Although the labia minora are usually prominent in the newborn, they gradually atrophy, which makes them almost invisible until their enlargement during puberty. The inner surface of the labia should be pink and moist. Note the size of the labia and any evidence of fusion, which may suggest male scrota. Normally no masses are palpable within the labia.

The urethral meatus is located posterior to the clitoris and is surrounded by the Skene glands and ducts. Although not a prominent structure, the meatus appears as a small V-shaped slit. Note its location, especially if it opens from the clitoris or inside the vagina. Gently palpate the glands, which are common sites of cysts and sexually transmitted lesions.

The vaginal orifice is located posterior to the urethral meatus. Its appearance varies depending on individual anatomy and sexual activity. Ordinarily, examination of the vagina is limited to inspection. In virgins, a thin crescent-shaped or circular membrane, called the hymen, may cover part of the vaginal opening. In some instances it completely occludes the orifice. After rupture, small rounded pieces of tissue called caruncles remain. Although an imperforate hymen denotes lack of penile intercourse, a perforate one does not necessarily indicate sexual activity (see also Sexual Abuse, Chapter 35).

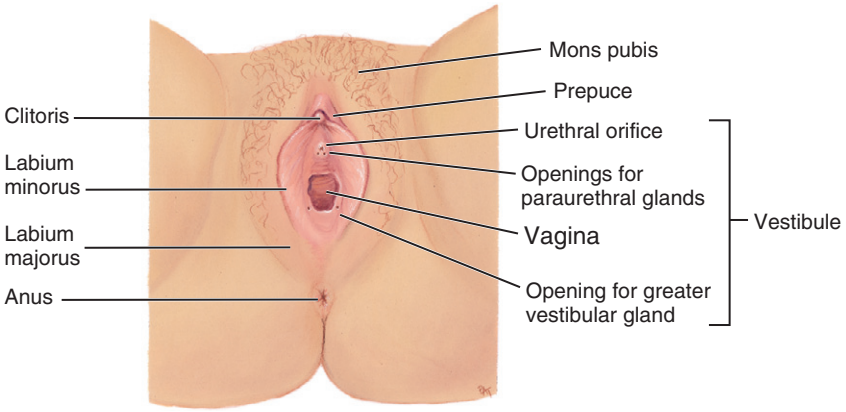

FIG 29-40 External structures of genitalia in postpubertal female. Labia are spread to reveal deeper structures. (From Applegate E: *The anatomy and physiology learning system,* ed 3, St Louis, 2006, Saunders.)

! NURSING ALERT

In girls who have been circumcised, the genitalia will appear different. Do not show surprise or disgust, but note the appearance and discuss the procedure with the young woman (see also Cultural Competence box, p. 59).

Surrounding the vaginal opening are Bartholin glands, which secrete a clear, mucoid fluid into the vagina for lubrication during intercourse. Palpate the ducts for cysts. Also note the discharge from the vagina, which is usually clear or white.

Anus

After examination of the genitalia, it is easy to identify the anal area, although the child should be placed on the abdomen. Note the general firmness of the buttocks and symmetry of the gluteal folds. Assess the tone of the anal sphincter by eliciting the anal reflex (anal wink). Gently scratching the anal area results in an obvious quick contraction of the external anal sphincter.

Back and Extremities

Spine

Note the general curvature of the spine. Normally the back of a newborn is rounded or C-shaped from the thoracic and pelvic curves. The development of the cervical and lumbar curves approximates development of various motor skills, such as cervical curvature with head control, and gives the older child the typical double-S curve.

Marked curvatures in posture are abnormal. Scoliosis, lateral curvature of the spine, is an important childhood problem, especially in girls. Although scoliosis may be identified by observing and palpating the spine and noting a sideways displacement, more objective tests include:

- With the child standing erect, clothed only in underpants (and bra if older girl), observe from behind, noting asymmetry of the shoulders and hips.
- With the child bending forward so that the back is parallel to the floor, observe from the side, noting asymmetry or prominence of the rib cage.

A slight limp, a crooked hemline, or complaints of a sore back are other signs and symptoms of scoliosis.

Inspect the back, especially along the spine, for any tufts of hair, dimples, or discoloration. Mobility of the vertebral column is easy to assess in most children because of their tendency to be in constant motion during the examination. However, you can test mobility by asking the child to sit up from a prone position or to do a modified sit-up exercise.

Movement of the cervical spine is an important diagnostic sign of neurologic problems, such as meningitis. Normally, movement of the head in all directions is effortless.

! NURSING ALERT

Hyperextension of the neck and spine, or opisthotonos, which is accompanied by pain when the head is flexed, is always referred for immediate medical evaluation.

Extremities

Inspect each extremity for symmetry of length and size; refer any deviation for orthopedic evaluation. Count the fingers and toes to be certain of the normal number. This is so often taken for granted that an extra digit (polydactyly) or fusion of digits (syndactyly) may go unnoticed.

Inspect the arms and legs for temperature and color, which should be equal in each extremity, although the feet may normally be colder than the hands.

Assess the shape of bones. There are several variations of bone shape in children. Although many of them cause parents concern, most are benign and require no treatment. Bowleg, or genu varum, is lateral bowing of the tibia. It is clinically present when the child stands with an outward bowing of the legs, giving the appearance of a bow. Usually there is an outward curvature of both femur and tibia (Fig. 29-41, *A*). Toddlers are usually bowlegged after beginning to walk until all their lower back and leg muscles are well developed. Unilateral or asymmetric bowlegs that are present beyond the age of 2 to 3 years, particularly in African-American children, may represent pathologic conditions requiring further investigation.

Knock-knee, or genu valgum, appears as the opposite of bowleg, in that the knees are close together but the feet are spread apart. It is determined clinically by using the same method as for genu varum but by measuring the distance between the malleoli, which normally should be less than 7.5 cm (3 in) (Fig. 29-41, *B*). Knock-knee is normally present in children from about 2 to 7 years of age.

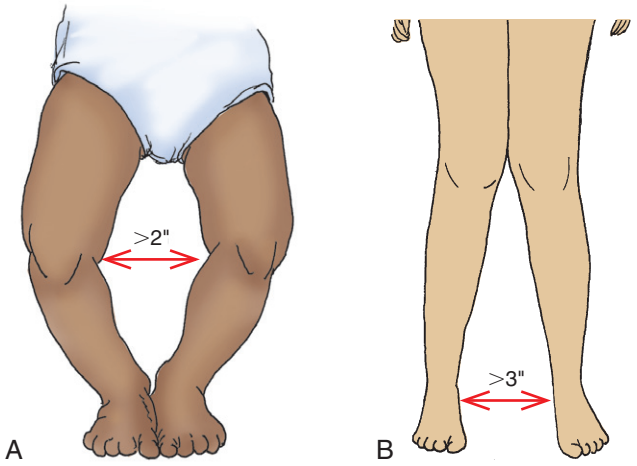

FIG 29-41 **A,** Bowleg. **B,** Knock-knee.

Knock-knee that is excessive, asymmetric, accompanied by short stature, or evident in a child nearing puberty requires further evaluation.

Next inspect the feet. Infants' and toddlers' feet appear flat because the foot is normally wide and the arch is covered by a fat pad. Development of the arch occurs naturally from the action of walking. Normally, at birth the feet are held in a valgus (outward) or varus (inward) position. To determine whether a foot deformity at birth is a result of intrauterine position or development, scratch the outer, then inner, side of the sole. If the foot position is self-correctable, it will assume a right angle to the leg. As the child begins to walk, the feet turn outward less than 30 degrees and inward less than 10 degrees.

Toddlers have a "toddling" or broad-based gait, which facilitates walking by lowering the center of gravity. As the child reaches preschool age, the legs are brought closer together. By school age, the walking posture is much more graceful and balanced.

The most common gait problem in young children is pigeon toe, or toeing in, which usually results from torsional deformities, such as internal tibial torsion (abnormal rotation or bowing of the tibia). Tests for tibial torsion include measuring the thigh-foot angle, which requires considerable practice for accuracy.

Elicit the plantar or grasp reflex by exerting firm but gentle pressure with the tip of the thumb against the lateral sole of the foot from the heel upward to the little toe and then across to the big toe. The normal response in children who are walking is flexion of the toes. Babinski sign, dorsiflexion of the big toe and fanning of the other toes, is normal during infancy but abnormal after about 1 year of age or when locomotion begins.

Joints

Evaluate the joints for range of motion. Normally this requires no specific testing if you have observed the child's movements during the examination. However, routinely investigate the hips in infants for congenital dislocation. Report any evidence of joint immobility or hyperflexibility. Palpate the joints for heat, tenderness, and swelling. These signs, as well as redness over the joint, warrant further investigation.

Muscles

Note symmetry and quality of muscle development, tone, and strength. Observe development by looking at the shape and contour of the body in both a relaxed and a tensed state. Estimate tone by grasping the muscle and feeling its firmness when it is relaxed and contracted. A common site for testing tone is the biceps muscle of the arm. Children are usually willing to "make a muscle" by clenching their fist.

Estimate strength by having the child use an extremity to push or pull against resistance, as in the following examples:

- **Arm strength**—Child holds the arms outstretched in front of the body and tries to raise the arms while downward pressure is applied.
- **Hand strength**—Child shakes hands with nurse and squeezes one or two fingers of the nurse's hand.
- **Leg strength**—Child sits on a table or chair with the legs dangling and tries to raise the legs while downward pressure is applied.

Note symmetry of strength in the extremities, hands, and fingers, and report evidence of paresis, or weakness.

BOX 29-15 TESTS FOR CEREBELLAR FUNCTION

Finger-to-nose test—With child's arm extended, ask child to touch the nose with the index finger with eyes open and then closed.
Heel-to-shin test—Have child stand and run the heel of one foot down the shin or anterior aspect of the tibia of the other leg, both with eyes opened and then closed.
Romberg test—Have child stand with eyes closed and heels together; falling or leaning to one side is abnormal and is called *Romberg sign.*

Neurologic Assessment

The assessment of the nervous system is the broadest and most diverse part of the examination process, since every human function, both physical and emotional, is controlled by neurologic impulses. Much of the neurologic examination has already been discussed, such as assessment of behavior, sensory testing, and motor function. The following focuses on a general appraisal of cerebellar function, deep tendon reflexes, and the cranial nerves.

Cerebellar Function

The cerebellum controls balance and coordination. Much of the assessment of cerebellar function is included in observing the child's posture, body movements, gait, and development of fine and gross motor skills. Tests such as balancing on one foot and the heel-to-toe walk assess balance. Test coordination by asking the child to reach for a toy, button clothes, tie shoes, or draw a straight line on a piece of paper (provided the child is old enough to do these activities). Coordination can also be tested by any sequence of rapid, successive movements, such as quickly touching each finger with the thumb of the same hand.

Several tests for cerebellar function can be performed as games (Box 29-15). When a Romberg test is done, stay beside the child if there is a possibility that he or she might fall. School-age children should be able to perform these tests, although in the finger-to-nose test preschoolers normally can only bring the finger within 5 to 7.5 cm (2 to 3 in) of the nose. Difficulty in performing these exercises indicates poor sense of position (especially with the eyes closed) and incoordination (especially with the eyes opened).

Reflexes

Testing reflexes is an important part of the neurologic examination. Persistence of primitive reflexes, loss of reflexes, or hyperactivity of deep tendon reflexes is usually a result of a cerebral insult.

Elicit reflexes by using the rubber head of the reflex hammer, flat of the finger, or side of the hand. If the child is easily frightened by equipment, use your hand or finger. Although testing reflexes is a simple procedure, the child may inhibit the reflex by unconsciously tensing the muscle. To avoid tensing, distract younger children with toys or talk to them. Older children can concentrate on the exercise of grasping their two hands in front of them and trying to pull them apart. This diverts their attention from the testing and causes involuntary relaxation of the muscles.

Deep tendon reflexes are stretch reflexes of a muscle. The most common deep tendon reflex is the knee jerk reflex, or patellar reflex (sometimes called the quadriceps reflex). Figs. 29-42 through 29-45 illustrate the reflexes normally elicited. Report any diminished or hyperreflexive response for further evaluation.

Cranial Nerves

Assessment of the cranial nerves is an important area of neurologic assessment (Fig. 29-46; Table 29-13). With young children, present the tests as games to foster trust and security at the beginning of the examination. Also include the cranial nerve test when examining each system, such as tongue movement and strength, gag reflex, swallowing, cardinal positions of gaze (Fig. 29-47), and position of the uvula during examination of the mouth.

FIG 29-42 Testing for triceps reflex. Child is placed supine with forearm resting over chest, and triceps tendon is struck. Alternate procedure: child's arm is abducted, with upper arm supported and forearm allowed to hang freely. Triceps tendon is struck. Normal response is partial extension of forearm.

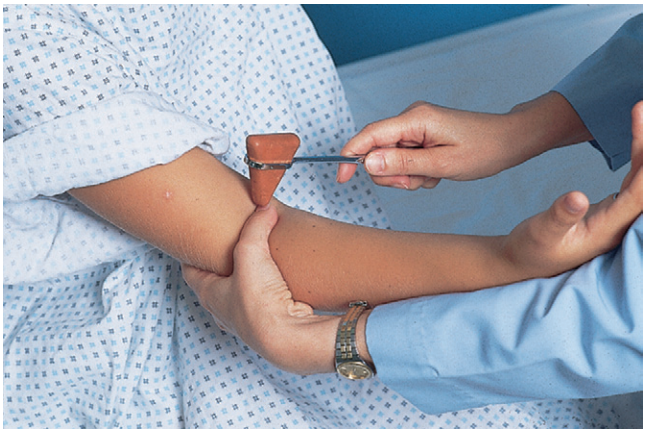

FIG 29-43 Testing for biceps reflex. Child's arm is held by placing partially flexed elbow in examiner's hand with examiner's thumb over antecubital space. Examiner's thumbnail is struck with hammer. Normal response is partial flexion of forearm.

FIG 29-44 Testing for patellar, or knee jerk, reflex, using distraction. Child sits on edge of examining table (or on parent's lap) with lower legs flexed at knee and dangling freely. Patellar tendon is tapped just below kneecap. Normal response is partial extension of lower leg.

FIG 29-45 Testing for Achilles reflex. Child should be in same position as for knee jerk reflex. Foot is supported lightly in examiner's hand, and Achilles tendon is struck. Normal response is plantar flexion of foot (foot pointing downward).

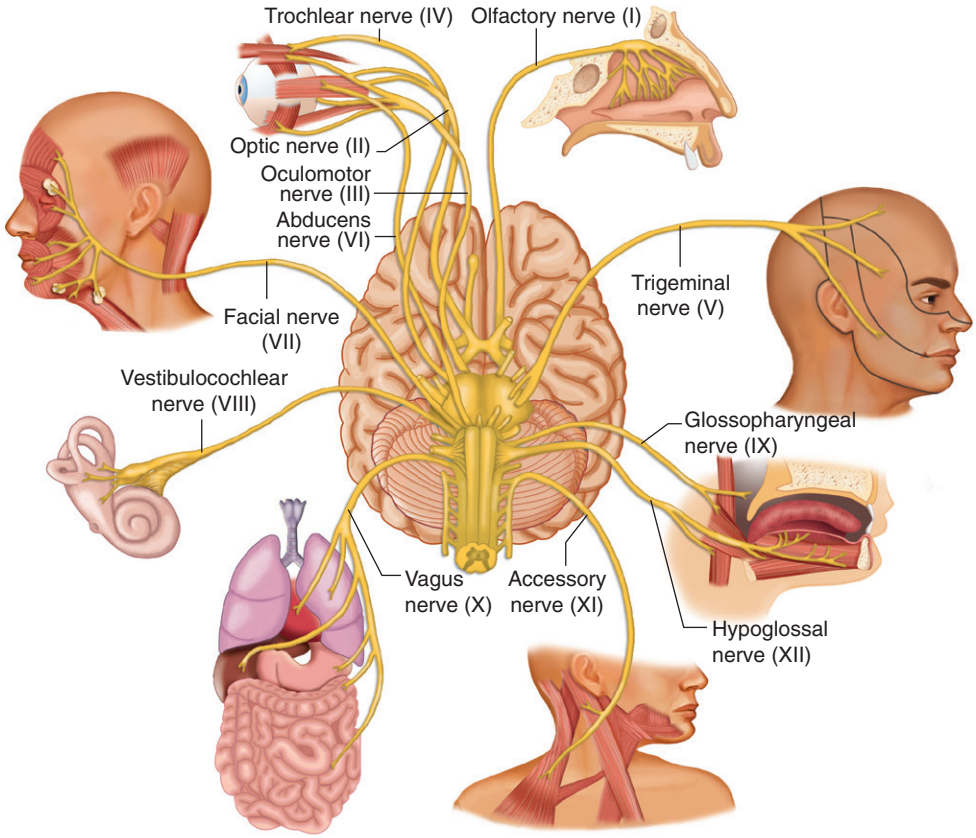

FIG 29-46 Cranial nerves. (From Patton KT, Thibodeau GA: *Anatomy & physiology,* ed 8, St Louis, 2013, Mosby.)

TABLE 29-13 ASSESSMENT OF CRANIAL NERVES

DESCRIPTION AND FUNCTION	TESTS
I—Olfactory Nerve	
Olfactory mucosa of nasal cavity Smell	With eyes closed, have child identify odors such as coffee, alcohol from a swab, or other smells; test each nostril separately.
II—Optic Nerve	
Rods and cones of retina, optic nerve Vision	Check for perception of light, visual acuity, peripheral vision, color vision, and normal optic disc.
III—Oculomotor Nerve	
Extraocular muscles of eye: Superior rectus—moves eyeball up and in Inferior rectus—moves eyeball down and in Medial rectus—moves eyeball nasally Inferior oblique—moves eyeball up and out	Have child follow an object (toy) or light in six cardinal positions of gaze (see Fig. 29-47).
Pupil constriction and accommodation	Perform *PERRLA* (**P**upils **E**qual, **R**ound, **R**eact to **L**ight, and **A**ccommodation).
Eyelid closing	Check for proper placement of lid.
IV—Trochlear Nerve	
Superior oblique (SO) muscle—moves eye down and out	Have child look down and in (see Fig. 29-47).
V—Trigeminal Nerve	
Muscles of mastication	Have child bite down hard and open jaw; test symmetry and strength.
Sensory—face, scalp, nasal, and buccal mucosa	With child's eyes closed, see if child can detect light touch in mandibular and maxillary regions. Test corneal and blink reflex by touching cornea lightly (approach from side so that child does not blink before cornea is touched).

Continued

TABLE 29-13 ASSESSMENT OF CRANIAL NERVES—cont'd

DESCRIPTION AND FUNCTION	TESTS
VI—Abducens Nerve	
Lateral rectus (LR) muscle—moves eye temporally	Have child look toward temporal side (see Fig. 29-47).
VII—Facial Nerve	
Muscles for facial expression	Have child smile, make funny face, or show teeth to see symmetry of expression.
Anterior two thirds of tongue (sensory)	Have child identify sweet or salty solution; place each taste on anterior section and sides of protruding tongue; if child retracts tongue, solution will dissolve toward posterior part of tongue.
VIII—Auditory, Acoustic, or Vestibulocochlear Nerve	
Internal ear Hearing and balance	Test hearing; note any loss of equilibrium or presence of vertigo.
IX—Glossopharyngeal Nerve	
Pharynx, tongue	Stimulate posterior pharynx with a tongue blade; child should gag.
Posterior third of tongue Sensory	Test sense of sour or bitter taste on posterior segment of tongue.
X—Vagus Nerve	
Muscles of larynx, pharynx, some organs of gastrointestinal system, sensory fibers of root of tongue, heart, and lung	Note hoarseness of voice, gag reflex, and ability to swallow. Check that uvula is in midline; when stimulated with tongue blade, it should deviate upward and to stimulated side.
XI—Accessory Nerve	
Sternocleidomastoid and trapezius muscles of shoulder	Have child shrug shoulders while applying mild pressure; with examiner's hands placed on shoulders, have child turn head against opposing pressure on either side; note symmetry and strength.
XII—Hypoglossal Nerve	
Muscles of tongue	Have child move tongue in all directions; have child protrude tongue as far as possible; note any midline deviation. Test strength by placing tongue blade on one side of tongue and having child move it away.

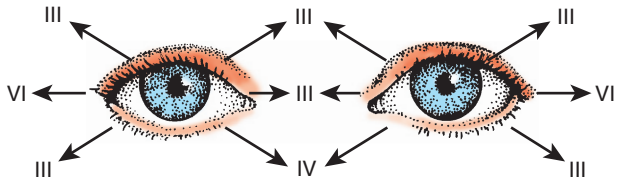

FIG 29-47 Checking extraocular movements in the six cardinal positions indicates the functioning of cranial nerves III, IV, and VI. (From Ignatavicius DD, Workman ML: *Medical-surgical nursing: patient-centered collaborative care,* ed 6, St Louis, 2009, Saunders.)

KEY POINTS

- To effectively establish a setting for communication, nurses must make an appropriate introduction and ensure privacy and confidentiality.
- When communicating with parents, nurses need to encourage parental involvement, listen carefully, use silence, and be empathic.
- Communication with children must reflect their developmental stage.
- Nonverbal communication with children may take the form of writing, drawing, and play.
- The objectives of performing a health history are to identify pertinent information, determine the chief complaint, analyze the present illness, secure the patient's health history, review biologic systems, and record a family medical history and child psychosocial and sexual history.
- Family assessment is the collection of data about family composition and relationships among its members; it also focuses on home and community environment, parents' occupation and education, and cultural and religious traditions.
- The family function interview examines interaction and roles, power, decision making, problem solving, communication, and expression of feelings and individuality.
- Nutritional assessment is performed by determination of dietary intake, clinical examination, and biochemical analysis.

- Growth measurements during the physical examination focus on length or height, weight, skinfold thickness, and arm and head circumference. Assessment of growth is measured against standard growth charts to determine a child's status in comparison with other children of the same age.
- Measurements of temperature, pulse, respiration, and BP constitute the physiologic approach to assessment.
- The child's general appearance is a cumulative, subjective impression of physical appearance, state of nutrition, behavior, personality, interactions with parents and nurse, posture, development, and speech.
- Assessment of the skin, which primarily involves inspection and palpation, focuses on color, texture, temperature, moisture, and turgor. The nurse needs to be aware of both physiologic and ethnic factors that may affect these areas.
- In assessment of the lymph nodes, the nurse examines, by palpation, the part of the body in which the glands are located.
- The head is inspected for shape, symmetry, mobility, and muscle control.
- Examination of the eyes includes placement and alignment, inspection of external and internal structures, and vision testing.
- The ear examination encompasses placement and alignment, external and internal structures, and auditory testing.
- The lungs are examined by inspection, palpation, percussion, and auscultation.
- Auscultation is the most important procedure for examining the heart.
- Abdominal assessment follows an orderly sequence of inspection, auscultation, and palpation, since palpation may distort normal abdominal sounds.
- Examination of the genitalia may provoke anxiety in the child, and the nurse must avoid any transference of anxiety.
- Neurologic assessment addresses behavior; motor, sensory, and cerebellar function; reflexes; and cranial nerves.

CHAPTER

30

Pain Assessment and Management in Children

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify measures to assess pain in children.
- List various types of pain-assessment tools for use with children.
- Outline essential pain-management strategies to reduce pain in children.
- Review common types of pain experienced by children.
- Discuss evidence to support specific pain-management strategies.

PAIN ASSESSMENT

Many children and adolescents continue to suffer from inadequately treated pain of all types (Perquin, Hazebroek-Kampschreur, Hunfeld, et al., 2000). Several research studies suggest that the undertreatment of pain in children is related to inconsistent practice in pain assessment, administration of analgesics at subtherapeutic levels, prolonged intervals between medications (Jacob and Puntillo, 2000), and lack of systematic monitoring and evaluation of relief (Jacob, Miaskowski, Savedra, et al., 2003a, 2003b; Jacob and Mueller, 2008). Optimal pain management begins with thorough assessment, which guides the selection of treatments. Acute pain assessment is easier to perform than complex pain that may be chronic, recurrent, or persistent.

Assessment of Acute Pain

Acute pain in children may have several causes such as: (1) medical procedures (immunization, venipuncture for blood draw or intravenous therapy, lumbar puncture for diagnosis or treatment, bone marrow aspiration, skin debridement for severe burns; (2) surgical (appendectomy, tonsillectomy) and orthopedic (spinal fusion) procedures; (3) medical treatments (chemotherapy-induced mucositis or peripheral neuropathy); (4) injury (such as falls, burns, motor vehicle accidents, other traumatic injuries); (5) infection; and (6) exacerbation of disease-related pain (e.g., arthritis, sickle cell disease, cancer).

Pain Intensity

Traditionally assessment measures are defined as behavioral measures, physiologic measures, and measures of self-reports. These measures predominantly address the domain of pain intensity. The behavioral measures of pain (for infants and children younger than 4 years; Table 30-1) and self-reports of pain (for children 4 years and older; Table 30-2) have been developed, validated, and widely used. Self-report measures are not sufficiently valid for children below 3 years of age because many are not able to accurately self-report their pain. Distress behaviors such as vocalization, facial expression, and body movement have been associated with pain (Figs. 30-1 and 30-2; Box 30-1). These behaviors are helpful in evaluating pain in infants and children with limited communication skills. However, discriminating between pain behaviors and reactions from other sources of distress such as hunger, anxiety, or other types of discomfort is not always easy. These factors decrease the specificity and sensitivity of behavioral measures (see Table 30-1).

Behavioral assessment is useful for measuring pain in infants and preverbal children who do not have the language skills to communicate that they are in pain or in children with mental clouding and confusion that limit their ability to communicate meaningfully. Behavior provides important information that cannot be obtained from self-report. Behavioral assessment may provide a more complete picture of the total pain experience when administered in conjunction with a subjective self-report measure. However, behavioral pain scales may be more time-consuming than self-reports. These measures depend on a trained observer to watch and record children's behaviors such as vocalization, facial expression, and body movements that suggest discomfort. Behaviors are assigned numbers from 0 to 4 to represent different intensities of distress. Scores are added to determine the child's pain rating.

TABLE 30-1 SUMMARY OF SELECTED BEHAVIORAL PAIN ASSESSMENT SCALES FOR YOUNG CHILDREN

AGES OF USE	RELIABILITY AND VALIDITY	VARIABLES	SCORING RANGE
Objective Pain Score (OPS) (Hannallah, Broadman, Belman, et al., 1987)			
4 months-18 years	Concurrent validity with linear analog pain scale, Spearman's r: 0.721 with scores ≥6 and 0.419 with scores <6 Interrater agreement, coefficient alpha: 0.986 for one rater and 0.983 for the other Concurrent validity with CHEOPS, Pearson correlation coefficient: 0.88 and 0.94	Blood pressure (0-2) Crying (0-2) Moving (0-2) Agitation (0-2) Verbal evaluation or body language (0-2)	0 = no pain; 10 = worst pain
Children's Hospital of Eastern Ontario Pain Scale (CHEOPS) (McGrath, Johnson, Goodman, et al., 1985)			
1-5 years	Interrater reliability: 90%-99.5% Internal correlation: significant correlations between pairs of items Concurrent validity between CHEOPS and visual analog scale (VAS): 0.91; between individual and total scores of CHEOPS and VAS: 0.50-0.86 Construct validity with preanalgesia and postanalgesia scores: 6.3-9.9	Cry (1-3) Facial (0-2) Child verbal (0-2) Torso (1-2) Touch (1-2) Legs (1-2)	4 = no pain; 13 = worst pain
Nurses Assessment of Pain Inventory (NAPI) (Stevens, 1990)			
Newborn-16 years	Not tested by original author; later tested by Joyce, Schade, Keck, et al. (1994) Interrater agreement: weighted kappa 0.37-0.80 Discriminant validity: statistically significant differences between preanalgesia and postanalgesia scores ($p < 0.0001$) Reliability: Cronbach alpha: 0.35-0.69	Body movement (0-2) Facial (0-3) Touching (0-2)	0 = no pain; 7 = worst pain
Behavioral Pain Score (BPS) (Robieux, Kumar, Radhakrishnan, et al., 1991)			
3-36 months	Original article stated, "reliability of the VAS and BPS scores was tested by a k test"; no further testing of reliability or validity mentioned	Facial expression (0-2) Cry (0-3) Movements (0-3)	0 = no pain; 8 = worst pain
Modified Behavioral Pain Scale (MBPS) (Taddio, Nulman, Koren, et al., 1995)			
4-6 months	Concurrent validity between MBPS and VAS scores: correlation coefficient 0.68 ($p < 0.001$) and 0.74 ($p < 0.001$) Construct validity using prevaccination and postvaccination scores with EMLA vs. placebo: significantly lower scores with EMLA ($p < 0.01$) Internal consistency of items: significant correlations between items Interrater agreement ICC: 0.95, $p < 0.001$ Test-retest reliability: 0.95, $p < 0.001$	Facial expression (0-3) Cry (0-4) Movements (0, 2, 3)	0 = no pain; 10 = worst pain
Riley Infant Pain Scale (RIPS) (Schade, Joyce, Gerkensmeyer, et al., 1996)			
<36 months and for children with cerebral palsy	Interrater agreement using intraclass correlation coefficient: 0.53-0.83, $p < 0.0001$ Discriminant validity using Mann-Whitney U test with preanalgesia and postanalgesia scores: statistically significant ($p < 0.001$) Sensitivity: 0.23-0.31 Specificity: 0.86-0.90 Interrater reliability using two-way cross-tabulations and kappa statistics (r[87] = 0.94; $p < 0.001$) and kappa values above 0.50 for each category	0: Neutral face/smiling, calm, sleeping quietly, no cry, consolable, moves easily 1: Frowning/grimace, restless body movements, restless sleep, whimpering, winces with touch 2: Clenched teeth, moderate agitation, sleeps intermittently, difficult to console, cries with touch 3: Full cry expression, thrashing/flailing, sleeping prolonged periods interrupted by jerking or no sleep, screaming/high-pitched cry, inconsolable, screams when touched/moved	0 = no pain; 3 = worst pain

Continued

TABLE 30-1 SUMMARY OF SELECTED BEHAVIORAL PAIN ASSESSMENT SCALES FOR YOUNG CHILDREN—cont'd

AGES OF USE	RELIABILITY AND VALIDITY	VARIABLES	SCORING RANGE
FLACC Postoperative Pain Tool (Merkel, Voepel-Lewis, Shayevitz, et al., 1997)			
2 months-7 years	Validity using analysis of variance for repeated measures to compare FLACC scores before and after analgesia; preanalgesia FLACC scores significantly higher than postanalgesia scores at 10, 30, and 60 min (p <0.001 for each time) Correlation coefficients used to compare FLACC pain scores and OPS pain scores; significant positive correlation between FLACC and OPS scores (r = 0.80; p <0.001); positive correlation also found between FLACC scores and nurses' global ratings of pain (r[47] = 0.41; p <0.005)	Face (0-2) Legs (0-2) Activity (0-2) Cry (0-2) Consolability (0-2)	0 = no pain; 10 = worst pain
FLACC Scale*			
	0	**1**	**2**
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent- to- constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or talking to; distractible	Difficult to console or comfort

*From Merkel SI, Voepel-Lewis T, Shayevitz JR, et al: The FLACC: a behavioral scale for scoring postoperative pain in young children, *Pediatr Nurs* 23(3):293–297, 1997. TABLE 30-2 PAIN-RATING SCALES FOR CHILDREN

PAIN SCALE, DESCRIPTION	INSTRUCTIONS	RECOMMENDED AGE AND COMMENTS
Wong-Baker FACES Pain-Rating Scale*		
Consists of six cartoon faces ranging from smiling face for "no pain" to tearful face for "worst pain"	*Original instructions:* Explain to child that each face is for a person who feels happy because there is no pain (hurt) or sad because there is some or a lot of pain. FACE 0 is very happy because there is no hurt. FACE 1 hurts just a little bit. FACE 2 hurts a little more. FACE 3 hurts even more. FACE 4 hurts a whole lot; but FACE 5 hurts as much as you can imagine, although you don't have to be crying to feel this badly. Ask child to choose face that best describes own pain. Record number under chosen face on pain assessment record. *Brief word instructions:* Point to each face using the words to describe the pain intensity. Ask child to choose face that best describes own pain and record appropriate number.	Children as young as 3 years Using original instructions without affect words such as happy or sad or brief words resulted in same range of pain rating, probably reflecting child's rating of pain intensity. For coding purposes, numbers 0, 2, 4, 6, 8, 10 can be substituted for 0-5 system to accommodate 0-10 system. The FACES provides three scales in one: facial expressions, numbers, and words. Research supports cultural sensitivity of FACES for Caucasian, African-American, Hispanic, Thai, Chinese, and Japanese children.

TABLE 30-2 PAIN-RATING SCALES FOR CHILDREN—cont'd

PAIN SCALE, DESCRIPTION	INSTRUCTIONS	RECOMMENDED AGE AND COMMENTS
Oucher (Beyer, Denyes, and Villarruel, 1992)		
Consists of six photographs of a Caucasian child's face representing "no hurt" to "biggest hurt you could ever have"; also includes vertical scale with numbers from 0 to 100; scales for African-American and Hispanic children have been developed (Villarruel and Denyes, 1991)	*Numeric scale:* Point to each section of scale to explain variations in pain intensity: "0 means no hurt." "This means little hurts" (pointing to lower part of scale, 1-29). "This means middle hurts" (pointing to middle part of scale, 30-69). "This means big hurts" (pointing to upper part of scale, 70-99). "100 means the biggest hurt you could ever have." Score is actual number stated by child. *Photographic scale:* Point to each photograph and explain variations in pain intensity using following language: first picture from bottom is "no hurt," second is "a little hurt," third is "a little more hurt," fourth is "even more hurt than that," fifth is "pretty much or a lot of hurt," and sixth is "biggest hurt you could ever have." Score pictures from 0 to 5, with bottom picture scored as 0. *General:* Practice using Oucher by recalling and rating previous pain experiences (e.g., falling off bike). Child points to number or photograph that describes pain intensity associated with experience. Obtain current pain score from child by asking, "How much hurt do you have right now?"	Children 3-13 years Use numeric scale if child can count of any two numbers or by tens (Jordan-Marsh, Yoder, Hall, et al., 1994). Determine whether child has cognitive ability to use photographic scale; child should be able to rate six geometric shapes from largest to smallest. Determine which ethnic version of Oucher to use. Allow child to select version of Oucher or use version that most closely matches physical characteristics of child. NOTE: Ethnically similar scale may not be preferred by child when given choice of ethnically neutral cartoon scale (Luffy and Grove, 2003).
Poker Chip Tool (Hester, Foster, Jordan-Marsh, et al., 1998)		
Uses four red poker chips placed horizontally in front of child	Say to child: "I want to talk with you about the hurt you may be having right now." Align chips horizontally in front of child on bedside table, clipboard, or other firm surface. Tell child, "These are pieces of hurt." Beginning at chip nearest child's left side and ending at one nearest right side, point to chips and say, "This (first chip) is a little bit of hurt and this (fourth chip) is the most hurt you could ever have." For a young child or any child who may not fully comprehend the instructions, clarify by saying, "That means this (1) is just a little hurt, this (2) is a little more hurt, this (3) is more yet, and this (4) is the most hurt you could ever have." Do not give children an option for 0 hurt. Research with Poker Chip Tool has verified that children without pain will so indicate by responses such as, "I don't have any." Ask child, "How many pieces of hurt do you have right now?" After initial use of Poker Chip Tool, some children internalize the concept "pieces of hurt." If child gives response such as, "I have one right now," before you ask or lay out poker chips, record number of chips on Pain Flow Sheet. Clarify child's answer by statements such as, "Oh, you have a little hurt? Tell me about the hurt."	Children as young as 4 years Determine whether child has cognitive ability to use numbers by identifying larger of any two numbers.
Word-Graphic Rating Scale† (Tesler, Savedra, Holzemer, et al., 1991)  No pain · Little pain · Medium pain · Large pain · Worst possible pain		
Uses descriptive words (may vary in other scales) to denote varying intensities of pain	Explain to child, "This is a line with words to describe how much pain you may have. This side of the line means no pain, and over here the line means worst possible pain." (Point with your finger where "no pain" is, and run it along the line to "worst possible pain" as you say it.) "If you have no pain, you would mark like this." (Show example.) "If you have some pain, you would mark somewhere along the line, depending on how much pain you have." (Show example.) "The more pain you have, the closer to worst pain you would mark. The worst pain possible is marked like this." (Show example.) "Show me how much pain you have right now by marking with a straight, up-and-down line anywhere along the line to show how much pain you have right now." With millimeter rule, measure from the "no pain" end to mark and record this measurement as pain score.	Children 4-17 years

Continued

TABLE 30-2 PAIN-RATING SCALES FOR CHILDREN—cont'd

PAIN SCALE, DESCRIPTION	INSTRUCTIONS	RECOMMENDED AGE AND COMMENTS
Numeric Scale		
Uses straight line with endpoints identified as "no pain" and "worst pain" and sometimes "medium pain" in the middle; divisions along line marked in units from 0-10 (high number may vary)	Explain to child that at one end of line is 0, which means that person feels no pain (hurt). At other end is usually 5 or 10, which means the person feels worst pain imaginable. The numbers 1-5 or 1-10 are for very little pain to a whole lot of pain. Ask child to choose number that best describes own pain.	Children as young as 5 yr as long as they can count and have some concept of numbers and their values in relation to other numbers Scale may be used horizontally or vertically. Number coding should be same as other scales used in facility.
Visual Analog Scale (VAS) (Cline, Herman, Shaw, et al., 1992)		
Defined as vertical or horizontal line that is drawn to certain length such as 10 cm (4 in) and anchored by items that represent extremes of the subjective phenomenon such as pain that is measured	Ask child to place mark on line that best describes amount of own pain. With centimeter ruler measure from "no pain" end to the mark and record this measurement as the pain score.	Children as young as 4.5 years, preferably 7 years Vertical or horizontal scale may be used. Research shows that children ages 3-18 years least prefer VAS compared with other scales (Luffy and Grove, 2003; Wong and Baker, 1988).
Color Tool (Eland and Banner, 1999)		
Uses markers for child to construct own scale that is used with body outline	Present eight markers to child in random order. Ask child, "Of these colors, which color is like _____?" (the event identified by child as having hurt the most). Place the marker (represents severe pain) away from other markers. Ask child, "Which color is like a hurt but not quite as much as _____?" (the event identified by child as having hurt the most). Place this marker with the marker chosen to represent severe pain. Ask child, "Which color is like something that hurts just a little?" Place the marker with the other colors. Ask child, "Which color is like no hurt at all?" Show the four marker choices to the child in order from worst to no-hurt color. Ask child to show on body outlines where he or she hurts using markers chosen. After child has colored hurts, ask if they are current hurts or hurts from the past. Ask if child knows why area hurts if it is not clear to you why it does.	Children as young as 4 years, provided they know the colors, are not color blind, and are able to construct the scale if in pain.

*Wong-Baker FACES Pain Rating Scale reference manual describing development and research of the scale is available from City of Hope Pain/Palliative Care Resource Center, 1500 East Duarte Road, Duarte, CA 91010; (626) 359-8111, ext. 3829; fax (626) 301-8941; www.elsevierhealth.com/WOW/. Use of FACES with children is demonstrated in *Whaley and Wong's Pediatric Nursing Video Series,* "Pain Assessment and Management," narrated by Donna Wong, PhD, RN. Available from Elsevier, 3251 Riverport Lane, Maryland Heights, MO, 63043; (800) 426-4545; fax (800) 535-9935; www.elsevierhealth.com.

†Instructions for Word-Graphic Rating Scale from Acute Pain Management Guideline Panel: *Acute pain management in infants, children, and adolescents: operative and medical procedures;* quick reference guide for clinicians, ACHPR Pub No 92-0020, Rockville, MD, 1992, Agency for Health Care Research and Quality, US Department of Health and Human Services. Word-Graphic Rating Scale is part of the Adolescent Pediatric Pain Tool and is available from Pediatric Pain Study, University of California, School of Nursing, Department of Family Health Care Nursing, San Francisco, CA 94143-0606; (415) 476-4040.

Behavioral measures are most reliable when measuring short, sharp procedural pain such as during injections or lumbar punctures and in infants. They are less reliable when measuring longer-lasting pain and in older children, when pain scores on behavioral measures do not always correlate with the children's own reports of pain intensity. Behavioral pain measures have been developed and validated on short, sharp pain or on pain in the recovery room immediately after arousal from anesthesia.

The most commonly used behavioral pain measure is the FLACC. The FLACC Pain Assessment Tool (Manworren and Hynan, 2003; Merkel, Voepel-Lewis, Shayevitz, et al., 1997) is an interval scale that includes five categories of behavior: facial expression (F), leg movement (L), activity (A), cry (C), and consolability (C). It measures pain by quantifying pain behaviors with scores ranging from 0 (no pain behaviors) to 10 (most possible pain behaviors). Other behavioral measures (see Table 30-1) include the (1) Children's Hospital of Eastern Ontario Pain Scale (CHEOPS), which was developed in collaboration with experienced recovery room nurses who were queried about which behaviors they most frequently observed to determine whether a child is in pain (McGrath, Johnson, Goodman, et al., 1985; Suraseranivongse, Montapaneewat T, Manon J, 2005); (2) Toddler-Preschooler Postoperative Pain Scale (TPPPS), which is an observational scale developed for measuring postoperative pain in children ages 1 to 5 years (Suraseranivongse, Montapaneewat T, Manon J, 2005; Tarbell, Cohen, and Marsh, 1992); (3) the Parent's Postoperative Pain Rating Scale (PPPRS), which is a scale that parents may use to rate their children's pain by noting changes in the frequency of a number of behaviors (Chambers, 2003; Chambers, Finley, McGrath, et al., 2003; Chambers and Craig, 1998; Finley, Chambers, and McGrath, et al., 2003); and (4) Parents' Postoperative Pain Measure (PPPM), which was developed based on cues parents reported observing in their children following surgery (e.g., changes in appetite, activity level).

In critical care settings the COMFORT scale (Ambuel, Hamlett, Marx, 1992) is recommended. The COMFORT scale is a behavioral, unobtrusive method of measuring distress in unconscious and ventilated patients. It has eight indicators: alertness, calmness/agitation,

BOX 30-1 DEVELOPMENTAL CHARACTERISTICS OF CHILDREN'S RESPONSES TO PAIN

Young Infant
- Generalized body response of rigidity or thrashing, possibly with local reflex withdrawal of stimulated area
- Loud crying
- Facial expression of pain (brows lowered and drawn together, eyes tightly closed, and mouth open and squarish)
- No association demonstrated between approaching stimulus and subsequent pain

Older Infant
- Localized body response with deliberate withdrawal of stimulated area
- Loud crying
- Facial expression of pain or anger
- Physical resistance, especially pushing stimulus away after it is applied

Young Child
- Loud crying, screaming
- Verbal expressions such as "Ow," "Ouch," "It hurts"
- Thrashing of arms and legs
- Attempts to push stimulus away before it is applied
- Lack of cooperation; need for physical restraint
- Requests termination of procedure
- Clings to parent, nurse, or other significant person
- Requests emotional support such as hugs or other forms of physical comfort
- May become restless and irritable with continuing pain
- Behaviors occurring in anticipation of actual painful procedure

School-Age Child
- May see all behaviors of young child, especially during actual painful procedure, but less in anticipatory period
- Stalling behavior such as, "Wait a minute" or "I'm not ready"
- Muscular rigidity such as clenched fists, white knuckles, gritted teeth, contracted limbs, body stiffness, closed eyes, wrinkled forehead

Adolescent
- Less vocal protest
- Less motor activity
- More verbal expressions such as, "It hurts" or "You're hurting me"
- Increased muscle tension and body control

Data from Craig KD, McMahon RJ, Morison JD, et al: Developmental changes in infant pain expression during immunization injections, *Soc Sci Med* 19(12):1331–1337, 1984; and Katz ER, Kellerman J, Siegel SE: Behavioral distress in children with cancer undergoing medical procedures: developmental considerations, *J Consult Clin Psychol* 48(3):356–365, 1980.

respiratory response, physical movement, blood pressure, heart rate, muscle tone, and facial tension. Each indicator is scored between 1 and 5 based on the behaviors exhibited by the patient. Patients are observed unobtrusively for 2 minutes, and the total score is derived by adding the scores of each indicator. The total scores can range between 8 and 40. A score of 17 to 26 generally indicates adequate sedation and pain control. Because of the complexity of measuring blood pressure and heart rate, this scale is used primarily for patients in a critical care setting.

For children 3 to 4 years the most frequently used measure of pain intensity is the Faces Pain Scale. There are many different "faces" scales. Faces scales provide a series of facial expressions depicting gradations of pain. They are appealing to children and easy to use because children can simply point to the face that represents how they feel. Two faces scales, the Bieri Faces Pain Scale—Revised (Hicks, von Baeyer CL, Spafford PA, et al., 2001) and the Wong-Baker FACES Pain Scale (Wong and Baker, 1988), are the most widely used. The Bieri scale is made up of six faces depicting increasing gradation of pain severity from 0 = "no pain" on the left face to 5 = "most pain possible" on the right face. In developing this scale the authors did not include a smiling face at the "no pain" end or tears at the "most pain" end and validated it so it is equivalent to a 0-to-10 metric system. The Wong-Baker FACES Pain Scale consists of six cartoon faces ranging from a smiling face for "no pain" to a tearful face for "worst pain." The child is asked to choose a face that describes his or her pain.

For children 8 years and older the numeric rating scale (NRS), specifically the 0-to-10 scale, is most widely used in clinical practice because it is easy to use and document. However, there is little research to support the reliability and validity of the NRS, except in the context of the Oucher Pain Scale (Beyer, Turner, Jones, 2005). The visual analog scale (VAS), a 10-centimeter line anchored by numbers or words "*no pain*" on the left, and "*worst pain*" on the right is another measure of pain intensity with established reliability and validity (Tesler, Savedra, and Holzemer, et al., 1991). It requires a higher degree of abstraction than the NRS, but it cannot be used in telephone follow-up.

Global Judgment of Improvement and of Satisfaction with Treatment

Although pain intensity is the dimension that is most commonly assessed, patients or patient surrogates should also be asked to rate a global judgment of satisfaction with pain treatment. The ratings mean something different from one patient or surrogate to another. Some may focus on the relief of pain; whereas others may consider side effects of the treatment. The global question should be posed with indications of what should be considered in the answer such as, "Considering pain relief, side effects, physical recovery, and emotional recovery, how satisfied were you with the treatments your child is receiving for pain?"

Adverse Events and Symptoms

After pain medications are initiated, not only should pain intensity be reassessed, but treatment-emergent adverse events should also be evaluated. Adverse events refer to newly emerging signs, symptoms, laboratory findings, or diseases that occur after medications for pain are initiated. Constipation is the most frequent symptom and is often not assessed, particularly for patients on prolonged opioid treatments. There is no particular strategy to measure either the occurrence or severity of the events. Children older than 10 years may be able to provide this information. In younger children parents or caregivers should be asked about adverse events and symptoms.

Physical Recovery

Another domain is physical recovery, which includes aspects of physical functioning that are influenced by the procedure or injury causing acute pain. For example, swallowing 50 mL of water is important after tonsillectomy. Possible assessments of the physical recovery domain include time to ambulation, time to resume swallowing, time to normal spirometry, oral intake, and time out of bed. However, measures such as tolerance of physical therapy may be inconsistent. One child may be intolerant of physical therapy because he or she did not want to go when asked, whereas another might be said to be intolerant to it only if he or she cried and refused to continue with it. These measures of physical recovery should be assessed systematically to evaluate interventions to control pain following procedures and injuries that have specific effects on physical functioning.

Emotional Response

The domain of emotional response includes all aspects of negative affect or distress secondary to pain such as anxiety, depression, fear, distress, dysphoria, or unhappiness. Behaviors indicating avoidance, withdrawal, or resistance need to be assessed. In children 8 years and older the PedIMMPACT group recommends the use of the Adolescent Pediatric Pain Tool (APPT) (Savedra, Holzemer, and Tesler, 1993), which allows children to describe the quality of the pain using a word list. The 56 words are grouped according to sensory, affective, and evaluative qualities of pain; it has been validated and can be used for children 8 years of age and over

Assessment of Chronic and Recurrent Pain

Pain that persists for 3 months or more or beyond the expected period of healing is defined as chronic pain (Merskey and Bogduk, 1994). Complex regional pain syndrome and chronic daily headache are the most common chronic pain conditions in children. Pain that is episodic and recurs is defined as *recurrent pain*. The time frame within which episodes of pain recur is at least 3 months. Recurrent pain in children includes migraine headache, episodic sickle cell pain, recurrent abdominal pain, and recurrent limb pain. van Dijk, McGrath, Pickett, et al (2006) reported that 57% of school-age children were having at least one recurrent pain (headaches, stomach pains, growing pains), and at least 6% had one or more chronic pain (disease related, back pain). Chronic and recurrent pain adversely affects the psychosocial and physical well-being of children. The domains for the assessment of chronic or recurrent pain are the same for acute pain (pain intensity global judgment of satisfaction with treatment, symptoms and adverse events, physical functioning, emotional functioning, economic factors) and two additional domains (role functioning and sleep). Because the time course of chronic and recurrent pain is different from that of acute pain, measures used to assess the impact of chronic and recurrent pain must consider timing and duration as key factors.

Pain diaries are commonly used to assess pain symptoms and response to treatment in children and adolescents with recurrent and chronic pain (Ely, Dampier, Gilday, et al., 2002; Dampier, Ely, Brodecki, et al., 2002a, 2002b; Palermo and Valenzuela, 2003; Palermo, Valenzuela, and Stork, 2004; Stinson, Stevens, Feldman, et al., 2008; Stone, Broderick, Schwartz, et al., 2003). Most pain diaries use NRSs or VASs with varying anchors such as faces scales or words. Children as young as 6 years have been included in diary studies. Conventional paper-and-pencil measures have been associated with several limitations such as poor compliance, missing data, hoarding responses, and back-and-forward filling (Palermo and Valenzuela, 2003; Stone, Broderick, Schwartz, et al., 2003). An

increasing number of studies are converting paper diaries into electronic diaries for use in school-age children and adolescents with recurrent or chronic pain (Palermo, Valenzuela, and Stork, 2004; Stinson, Stevens, Feldman, et al., 2008; Stone, Broderick, Schwartz, et al., 2003). Electronic diaries were found to show higher accuracy of children's diary responses and higher compliance rates when compared to the paper format. However, electronic diaries are more expensive and may have a number of logistic issues that must be resolved.

The PedIMMPACT group recommends the same approach for measuring global judgment of satisfaction with treatment, symptoms, and adverse events. The physical functioning domain in chronic and recurrent pain is focused on activities of everyday life such as sitting or walking or more vigorous activities such as running and other sports. The recommendation is to use a measure such as the Functional Disability Inventory (Walker and Greene, 1991, No. 43) for assessing physical functioning in school-age children and adolescents. The Functional Disability Inventory assesses the child's ability to perform everyday physical activities and has established psychometric properties with different populations (Claar and Walker, 2006; Reid, Lang, and McGrath, 1997; Vervoort, Gougert, Eccleston, et al., 2006). For younger children (less than 7 years), the PedsQL developed by Varni, Seid, and Rode (1999) is recommended for assessing the physical functioning domain as it relates to pain. The PedsQL is a multidimensional scale with both parent- and child-report versions. It assesses (1) physical functioning, (2) emotional functioning, (3) social functioning, and (4) school functioning.

The emotional functioning domain most often refers to depression and anxiety because they are elevated in children with chronic and recurrent pain (Palermo, 2000). However, most of these children do not have clinical levels of anxiety or depression. The Children's Depression Inventory (Kovacs, 1981) and the Revised Child Anxiety and Depression Scale (Chorpita, Yim, and Moffitt, et al., 2000) have been used to assess anxiety and depression in children and adolescents with chronic or recurrent pain.

Chronic and recurrent pain can significantly interfere with the roles that children and adolescents perform such as being a student, friend, and family member. School attendance is used as a measure of role functioning in school-age children with chronic or recurrent pain. Absence from school is an important measure of fulfillment of the role of student. Other measures such as the PedsQL (Varni, Seid, and Rode, 1999) and PedMIDAS (Hershey, Powers, Vockell, et al., 2001; 2004) have been validated for measurement of role functioning in these children.

Sleep disruption is also common in chronic and recurrent pain. More than half of children with pain-related conditions (headache, juvenile idiopathic arthritis, or sickle cell disease) report difficulties sleeping (Walters and Williamson, 1999; Palermo and Kiska, 2005). Sleep diaries in which the child (or parent) keeps a record of the time to go to bed, fall asleep, and wake up are useful for assessment of pain interference with sleep. The sleep diary was validated with sleep actigraphy in healthy children ages 13 and 14 years (Gaina, Sekine, and Chen, 2004). In addition, the Sleep Habits Questionnaire (Owens, Spirito, McGuinn, 2000) may be useful for assessing sleep behaviors in school-age children with chronic or recurrent pain.

Multidimensional Measures

Several cognitive skills such as measurement, classification, and seriation (the ability to accurately place in ascending or descending order) become explicit between approximately 7 and 10 years of age.

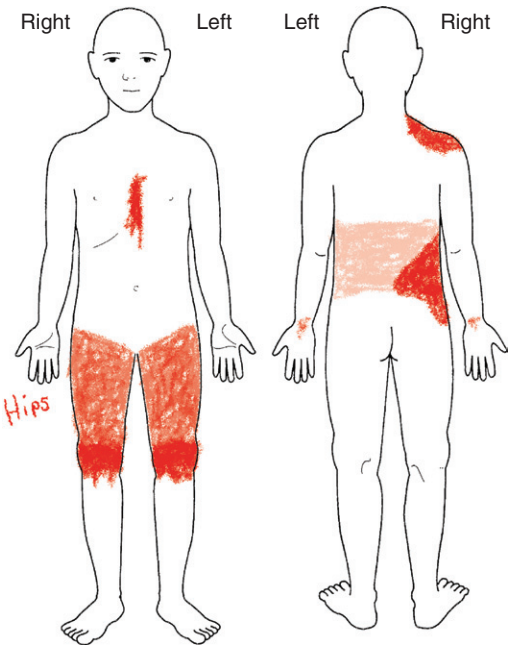

FIG 30-3 Adolescent Pediatric Pain Tool: body outlines for pain assessment. Instructions: "Color in the areas on these drawings to show where you have pain. Make the marks as big or as small as the place where the pain is." Tool has been completed by a child with sickle cell disease. (From Savedra MC, Tesler MD, Holzemer WL, Ward JA, School of Nursing, University of California–San Francisco; copyright 1989, 1992.)

Older children are able to use the 0-to-10 NRS that is currently used by adolescents and adults. However, the use of the 0-to-10 NRS is only an assessment of pain intensity, which may not change in some pain states (Jacob, Miaskowski, Savedra, et al., 2003a). Other dimensions such as pain quality, pain location, and spatial distribution of pain may change without a change in pain intensity.

Two multidimensional assessment tools that assess not only pain intensity but also pain location and pain quality have been well validated in children 8 years and older. Modeled after the McGill Pain Questionnaire (Melzack, 1975), the APPT is a multidimensional pain instrument for children and adolescents that is used to assess three dimensions of pain: location, intensity, and quality (Fig. 30-3). The APPT is a one-page, two-sided instrument with a front and back body outline on one side (Savedra, Tesler, Holzemer, et al., 1989; Savedra, Holzemer, Tesler, et al., 1993). On the back side is a 100-mm word-graphic rating scale (Tesler, Savedra, Holzemer, et al., 1991) and a pain descriptor list (Wilkie, Holzemer, Tesler, et al., 1990). Each of the three components of the APPT is scored separately. The body outline is scored by placing a clear plastic template overlay with 43 body areas on the body outline diagram. An estimate of the pervasiveness of the pain is made by counting the number of body areas marked. A ruler or micrometer preprinted on the APPT is used to score the word-graphic rating scale. The number of millimeters from the left side of the scale to the point marked by the child is measured; the numeric value provides an overall evaluation of the amount of pain the child is experiencing. The total number of words on the descriptor list is counted; scores range from 0 to 56. The clinician then counts the number of words selected in each of three categories—evaluative (0-8), sensory (0-37), and affective (0-11)—and calculates a percentage score for each one (Savedra, Holzemer, Tesler, et al., 1993).

An advantage to using the APPT is that in some pain states pain-intensity ratings do not change, but pain location and spatial distribution of pain may decrease over time (Jacob, Miaskowski, Savedra, et al., 2003a). The total surface area may decrease, but some children may perceive the remaining sites as equal in pain intensity. In addition to pain location, assessments of pain quality may be able to distinguish the presence of the different dimensions of pain (temporal, affective, evaluative, and sensory). Words may not be quantifiable on NRSs yet represent the pain experience such as *horrible* and *terrible* from the evaluative dimension, *screaming* and *terrifying* from the affective dimension, or *sharp* and *stabbing* from the sensory dimension. The different qualities of pain may also represent whether pain is of an ischemic and inflammatory nature in the cutaneous, subcutaneous, and musculoskeletal tissues, as opposed to pain that is more neuropathic, which may be described using words such as *shooting, burning,* or *shocklike* (McCaffery and Pasero, 1999).

The Pediatric Pain Questionnaire (PPQ) is a multidimensional pain instrument to assess patient and parental perceptions of the pain experience in a manner appropriate for the cognitive-developmental level of children and adolescents. The PPQ represents an attempt to assess the complexities of pediatric chronic, recurrent pain and targeted chronic musculoskeletal pain in children with juvenile rheumatoid arthritis. It consists of eight questions: (1) the pain history, (2) pain language, (3) the colors children associate with pain, (4) the emotions they experience, (5) their worst pain experiences, (6) the ways they cope with pain, (7) the positive aspects of pain, and (8) the location of their current pain. The PPQ includes three components: (1) VASs; (2) color-coded rating scales; and (3) verbal descriptors to provide information about the sensory, affective, and evaluative dimensions of chronic pain (Varni, Thompson, and Hanson, 1987). It also has information about the child's and family's pain history, symptoms, pain-relief interventions, and socioenvironmental situations that may influence pain. The child, parent, and health care provider complete the form separately.

The number of pain measures available for use in infants and young children has increased dramatically and adds a layer of complexity to the assessment of pain in children. The current trend supports a common metric for measurement of pain in children (von Baeyer and Hicks, 2000). Most instruments consist of 0 for no pain to a range of 4 to 160 for the top anchors in pain measures. A pain score of 5 may mean a lot of pain (if a 0 to 5 scale is used) or very little (if a 0 to 100 scale is used), and it may not be clearly specified which score corresponds to which scale. Other health care providers who do not specialize in pediatric pain may be confused by the available instruments and scoring methods and may not be able to determine the effectiveness of interventions by the pain score documented. An advantage to using a common metric is that a certain score may be considered as the point at which an intervention is required or a point at which relief may be considered adequate (von Baeyer and Hicks, 2000). The 0-to-10 system was reported to be preferred by health care providers and would make pain scores easier to read, interpret, and integrate into research and practice.

ASSESSMENT OF PAIN IN SPECIFIC POPULATIONS

Children with Communication and Cognitive Impairment

The assessment of pain in children with communication and cognitive impairment can be challenging. Children who have significant difficulties in communicating with others about their pain include those with significant neurologic impairments (e.g., cerebral palsy), intellectual disability, metabolic disorders, autism, severe brain injury, and communication barriers (e.g., critically ill children who are on ventilators or heavily sedated or have neuromuscular disorders, loss of hearing, or loss of vision). These children are at greater risk than other children for undertreatment of pain because they have medical problems that may cause pain and they undergo painful procedures. Their behaviors include moaning, inconsistent patterns of play and sleep, changes in facial expression, and other physical problems that may mask expression of pain and be difficult to interpret (Hadden and von Baeyer, 2002). These children often experience spasticity, contractures, and orthopedic surgical treatment that may be painful.

The mother or primary caregiver is an important source of information during assessment (Breau, MacLaren, McGrath, et al., 2003). As many as 60% of parents of children with severe cognitive impairment reported that their child experienced pain or severe discomfort that was not being managed effectively (Lenton, Stallard, Lewis, et al., 2001; Stallard, Williams, Velleman, et al., 2002). The most frequently reported pain behaviors are crying; being less active; seeking comfort; moaning; not cooperating; being irritable; being stiff, spastic, tense, or rigid; sleeping less; being difficult to satisfy or pacify; flinching or moving body part away; and being agitated or fidgety (Hadden and von Baeyer, 2002). Parents also reported that some daily living activities were painful such as assisted stretching and walking, independent standing, toileting, putting on splints, occupational therapy, range of motion, and physical therapy.

Stallard, Williams, Lenton, et al. (2001) asked the parents of cognitively impaired and noncommunicative children to assess the presence, severity, and duration of their pain during a 2-week observation period. Parents reported that 84% experienced pain on 5 or more separate days, with 32% experiencing pain on 12 or more days. Of the 74 episodes that lasted longer than 30 minutes, 33.8% occurred at night. Most pain episodes were judged to last longer than 10 minutes, with 48% of the children having episodes lasting longer than 10 minutes on 5 or more days. Although the experience of pain was common among this group of children, none was receiving treatment for relief or management of pain.

The Non-communicating Children's Pain Checklist is a pain measurement tool specifically designed for children with cognitive impairments (Breau, McGrath, Camfield, et al., 2002). The scale discriminates between periods of pain and calm and can predict behavior during subsequent episodes of pain (Fig. 30-4). The scale consists of six subscales (vocal, social, facial, activity, body and limbs, physiologic signs), which are scored based on the number of times the items are observed over a 10-minute period (0 = not at all, 1 = just a little, 2 = fairly often, 3 = very often).

Another tool, the Pain Indicator for Communicatively Impaired Children (PICIC), distinguishes between pain and nonpain in communicatively impaired children with life-threatening illness (Stallard, Williams, Velleman, et al., 2002). The PICIC has six core pain cues: (1) crying with or without tears; (2) screaming, yelling, groaning, or moaning; (3) screwed up or distressed looking face; (4) body appearing stiff or tense; (5) difficulty in comforting or consoling; and (6) flinching or moving away if touched. The items are rated using a 4-point Likert scale (1 = not at all, 2 = a little, 3 = often, 4 = all the time).

Cultural Differences

Several barriers to effective pain treatment in non-English speaking patients have been documented and include inadequate assessment

Non-communicating Children's Pain Checklist — Postoperative Version (NCCPC-PV)

NAME:_____ UNIT/FILE #: _____ DATE:_____ (dd/mm/yy)

OBSERVER:_____ START TIME:_____ AM/PM STOP TIME:_____AM/PM

How often has this child shown these behaviors in the last 10 minutes? Please circle a number for each behavior. If an item does not apply to this child (for example, this child cannot reach with his/her hands), then indicate "not applicable" for that item.

0 = NOT AT ALL	1 = JUST A LITTLE	2 = FAIRLY OFTEN	3 = VERY OFTEN	NA = NOT APPLICABLE

I. Vocal

1. Moaning, whining, whimpering (fairly soft)	0	1	2	3	NA
2. Crying (moderately loud)	0	1	2	3	NA
3. Screaming/yelling (very loud)	0	1	2	3	NA
4. A specific sound or word for pain (e.g., a word, cry, or type of laugh)	0	1	2	3	NA

II. Social

5. Not cooperating, cranky, irritable, unhappy	0	1	2	3	NA
6. Less interaction with others, withdrawn	0	1	2	3	NA
7. Seeking comfort or physical closeness	0	1	2	3	NA
8. Being difficult to distract, not able to satisfy or pacify	0	1	2	3	NA

III. Facial

9. A furrowed brow	0	1	2	3	NA
10. A change in eyes, including squinching of eyes, eyes opened wide, eyes frowning	0	1	2	3	NA
11. Turning down of mouth, not smiling	0	1	2	3	NA
12. Lips puckering up, tight, pouting, or quivering	0	1	2	3	NA
13. Clenching or grinding teeth, chewing, or thrusting tongue out	0	1	2	3	NA

IV. Activity

14. Not moving, less active, quiet	0	1	2	3	NA
15. Jumping around, agitated, fidgety	0	1	2	3	NA

V. Body and Limbs

16. Floppy	0	1	2	3	NA
17. Stiff, spastic, tense, rigid	0	1	2	3	NA

Continued

USING THE NCCPC-PV

The NCCPC-PV was designed to be used for children age 3 to 18 years who are unable to speak because of cognitive (mental/intellectual) impairments or disabilities. It can be used *whether or not* a child has physical impairments or disabilities. Descriptions of the types of children used to validate the NCCPC-PV can be found in: Breau, L.M., Finley, G.A., McGrath, P.J., & Camfield, C.S. (2002). Validation of the Non-communicating Children's Pain Checklist — Postoperative Version. *Anesthesiology, 96* (3), 528-535. The NCCPC-PV was designed to be used without training by parents and caregivers (carers), or by other adults who are not familiar with a specific child (do not know them well).

The NCCPC-PV may be freely copied for clinical use or use in research funded by not-for-profit agencies. For-profit agencies should contact Lynn Breau: Pediatric Pain Research, IWK Health Centre, 5850 University Avenue, Halifax, Nova Scotia, Canada, B3J 3G9 (lbreau@ns.sympatico.ca).

The NCCPC-PV was intended for use for pain after surgery or due to other procedures conducted in hospital. If short- or long-term pain is suspected for a child at home or in a long-term residential setting, the **Non-communicating Children's Pain Checklist — Revised** may be used. It can be obtained by contacting Lynn Breau. Information regarding the NCCPC-R can be found in: Breau, L.M., McGrath, P.J., Camfield, C.S. & Finley, G.A. (2002). Psychometric Properties of the Non-communicating Children's Pain Checklist—Revised. *Pain, 99,* 349-357.

ADMINISTRATION

To complete the NCCPC-R, base your observations on the child's behavior over **10 minutes**. ***It is not necessary to watch the child continuously for this period***. However, it is recommended that the observer be in the child's presence for the majority of this time (e.g., be in the same room with the child). Although shorter observation periods may be used, the cut-off scores described below may not apply.

At the end of the observation time, indicate how frequently (how often) each item was seen or heard. This should not be based on the child's typical behavior or in relation to what he or she usually does. A guide for deciding the frequency of items is below:

0 = Not present at all during the observation period. (Note: If the item is not present because the child is not capable of performing that act, it should be scored as "NA").
1 = Seen or heard rarely (hardly at all), but is present.
2 = Seen or heard a number of times, but not continuous (not all the time).
3 = Seen or heard often, almost continuous (almost all the time); anyone would easily notice this if they saw the child for a few moments during the observation time.
NA = Not applicable. This child is not capable of performing this action.

SCORING

1. Add up the scores for each subscale and enter below that subscale number in the Score Summary at the bottom of the sheet. Items marked "NA" are scored as "0" (zero).
2. Add up all subscale scores for Total Score.
3. Check whether the child's score is greater than the cut-off score.

CUT-OFF SCORE

Based on the scores of 24 children age 3 to 18 (Breau, Finley, McGrath, & Camfield, 2002), a **Total Score of 11 or more** indicates a child has **moderate to severe pain**. Based on unpublished data from this same sample, a ***Total score of 6-10*** indicates a child has **mild pain**. When parents and caregivers completed the NCCPC-PV in hospital for the study group, this was accurate 88% of the time. When other observers completed the NCCPC-PV, this was accurate 75% of the time. A Total Score of 10 or less indicates less than moderate/severe pain. This was correct in the study group for parents and caregivers 81% of the time and for other observers 63% of the time.

USE OF CUT-OFF SCORES

As with all observational tools, caution should be taken in using cut-off scores, because they may not be 100% accurate. They should not be used as the only basis for deciding whether a child should be treated for pain. In some cases children may have lower scores when pain is present. For more detailed instructions for use of the NCCPC-PV in such situations, please refer to the full manual, available from Lynn Breau: Pediatric Pain Research, IWK Health Centre, 5850 University Avenue, Halifax, Nova Scotia, Canada, B3J 3G9 (lbreau@ns.sympatico.ca).

FIG 30-4, cont'd

of pain, concern about side effects of and tolerance to analgesics, patient and family reluctance to report pain, fear that pain means worse disease, reluctance to take pain medications, and lack of adherence to prescribed analgesics (Abbe, Simon, Angiolilo, et al., 2006; Bruera, Willey, Ewert-Flannagan, et al., 2005; Flores and Vega, 1998; Flores, Abreu, Olivar, et al., 1998). Non-English speaking patients pose additional language and cultural barriers that make pain assessment and treatments more challenging.

A major challenge in the assessment and management of pain in children is the cultural appropriateness of pain assessment tools that has been validated only in Caucasian and English-speaking children. Observational scales and interview questionnaires for pain may not

be as reliable for pain assessment as self-report scales in Hispanic children. In Chinese children who learned to read Chinese characters vertically downward and from right to left, the use of vertically oriented VASs resulted in less error than horizontally oriented scales. Therefore cultural background may influence the reliability of pain assessment tools developed in a single cultural context (Bernstein and Pachter, 2003).

The Oucher Pain Scale (see Table 30-2), originally developed and validated as a self-report of pain intensity for Caucasian children 3 to 12 years old, now features culturally specific photographs with pictures of children who more closely match the physical characteristics of children (Beyer and Knott, 1998). The Oucher consists of a 0-to-10 numeric scale for older children and a six-picture photographic scale for younger children. The five versions of the Oucher are: (1) White or Caucasian, (2) Black or African-American, (3) Hispanic, (4) First Nations (boy and girl), and Asian (boy and girl). They can be downloaded free of charge at www.oucher.org, and include instructions and information related to validity and reliability.

The APPT also has a Spanish version (Van Cleve, Munoz, Bossert, et al., 2001) that has been used in children and adolescents with cancer (Jacob, McCarthy, Sambuco, et al., 2008; Van Cleve, Bossert, Beecroft, et al., 2004). Jacob, McCarthy, and Sambuco et al. (2008) examined the pain experience of Spanish-speaking children with cancer who were asked about their pain during the week before a scheduled oncology clinic appointment. They found that 41% of the patients were experiencing pain. Some were experiencing moderate-to-severe pain and did not receive medications because they were not reporting their pain. The APPT has a body outline that may be useful for non-English speaking children to communicate the location and extensiveness of the pain. To minimize the risk of undertreatment of pain, non-English speaking children and adolescents may be given the body outline diagram of the APPT, and clinicians may encourage them to use the body outline diagram for communicating pain (Jacob, McCarthy, Sambuco, et al., 2008).

Children with Chronic Illness and Complex Pain

Questionnaires and pain assessment scales do not always provide the most meaningful means of assessing pain in children, particularly for those with complex pain. Some children cannot relate to a face or number that describes their pain and may not be able to isolate pain from other concurrent symptoms they are experiencing. Experiencing multiple symptoms makes the task of having to isolate the pain symptom from other symptoms difficult in children with cancer. Rating the pain does not always accurately convey to others how they really feel (Woodgate and Yanofsky, 2004).

In children with chronic illness, particularly those with complex pain, the most important aspect of the assessment is the relationship developed between the child and the family; and it is in developing this relationship that the pain team gets the sense of what the pain experience is like for the child and family. The pain experience may interfere with the child's ability to eat, sleep, and perform daily activities and routines (Miaskowski and Lee, 1999; Morin, Gibson, and Wade, 1998). It may also be complicated by pain processes that occur in the central nervous system (e.g., hyperalgesia, central sensitization, windup), by other symptoms (e.g., fatigue, nausea, vomiting, diarrhea, constipation) that accompany medical treatments, and by complications (e.g., infections, unexpected development of fistulas, typhlitis) from disease or treatments.

Other important questions to ask the family include the (1) onset of pain (i.e., was the onset sudden, unexpected, off and on, ongoing); (2) pain duration or pattern (i.e., when did the pain start; how long does it last); (3) the effectiveness of the current treatment (i.e., which medications and doses help; what other strategies have you tried that work); (4) factors that aggravate or relieve the pain (i.e., which situations, positions, events, or activities make the pain worse, what makes the pain better); (5) other symptoms (e.g., nausea) and complications (e.g., fever, difficulty with breathing) that occur concurrently; and (6) interference with the child's sleep, mood, function, and interactions with family (McCaffery and Pasero, 1999). Asking if the pain is better or worse at certain times during the day or night can also assess variations and rhythms of pain. Other aspects warranting careful assessment that may pose barriers to effective management include family issues and relationships, fears and concerns about addictions (see Community Focus box), the clinician's and family's lack of knowledge about pain, inappropriate use of pain medications, ineffective management of adverse effects from medications, and the use of different modalities (McCaffery and Pasero, 1999).

COMMUNITY FOCUS

Fear of Opioid Addiction

One of the reasons for the unfounded but prevalent fear of addiction from opioids used to relieve pain is a misunderstanding of the differences between physical dependence, tolerance, and addiction. Health care professionals and the community often confuse addiction with the physiologic effects of opioids, when in reality these three events are unrelated.

The American Society of Addiction Medicine defines these three terms as follows:

Physical dependence on an opioid is a physiologic state in which abrupt cessation of the opioid, or administration of an opioid antagonist, results in a withdrawal syndrome. Physical dependence on opioids is an expected occurrence in all individuals in the presence of continuous use of opioids for therapeutic or nontherapeutic purposes. It does not, in and of itself, imply addiction.

Tolerance is a form of neuroadaptation to the effects of chronically administered opioids (or other medications) that is indicated by the need for increasing or more frequent doses of the medication to achieve the initial effects of the drug. A person may develop tolerance both to the analgesic effects of opioids and to some of the unwanted side effects such as respiratory depression, sedation, or nausea. Tolerance varies in occurrence, but it does not, in and of itself, imply addiction.

Addiction in the context of pain treatment with opioids is characterized by a persistent pattern of dysfunctional opioid use that may involve any or all of the following:

- Adverse consequences associated with the use of opioids
- Loss of control over the use of opioids
- Preoccupation with obtaining opioids, despite the presence of adequate analgesia

Nurses must educate older children, parents, and health professionals about the extremely low risk of real addiction (less than 1%) from the use of opioids to treat pain. Infants, young children, and comatose or terminally ill children simply cannot become addicted because they are incapable of a consistent pattern of drug-seeking behavior such as stealing, drug dealing, prostitution, and use of family income to obtain opioids for nonanalgesic reasons.

Data from American Society of Addiction Medicine: *Public policy statement on definitions related to the use of opioids for pain treatment, 2001,* www.asam.org.

PAIN MANAGEMENT

Unrelieved pain may lead to potential long-term physiologic, psychosocial, and behavioral consequences (Goldschneider and Anand, 2003; Weisman, Bernstein, and Schechter, 1998). Management of pain should be a priority for all clinicians.

Nonpharmacologic Management

Pain is often associated with fear, anxiety, and stress. A number of nonpharmacologic techniques (see Guidelines box) such as distraction, relaxation, guided imagery, and cutaneous stimulation provide coping strategies that may help reduce pain perception, make pain more tolerable, decrease anxiety, and enhance the effectiveness of analgesics or reduce the dosage required (Rusy and Weisman, 2000). In addition, these techniques decrease the perceived threat of pain, provide a sense of control, enhance comfort, and promote rest and sleep (McCaffery and Pasero, 1999). Although there is a paucity of research on the effectiveness of many of these interventions, the strategies are safe, noninvasive, and inexpensive; and most are independent nursing functions. Environmental and psychologic factors may exert a powerful influence on children's pain perceptions and may be modified by using psychosocial strategies, education, parental support, and cognitive behavioral interventions. For children undergoing repeated painful procedures, cognitive-behavioral interventions are effective for decreasing anxiety and distress (McGrath and Hillier, 2003).

If the child cannot identify a familiar coping technique, the nurse can describe several strategies and let him or her select the most appealing one. Experimentation with several strategies that are suitable to the child's age, pain intensity, and abilities is often necessary to determine the most effective approach. Parents should be involved in the selection process; they may be familiar with the child's usual coping skills and can help identify potentially successful strategies. Involving parents also encourages their participation in learning the skill with the child and acting as coach. If the parent cannot help the child, other appropriate people may include a grandparent, older sibling, nurse, or child-life specialist (McGrath and Hillier, 2003).

Children should learn to use a specific strategy before pain occurs or becomes severe. To reduce the child's effort, instructions for a strategy such as distraction or relaxation can be audiotaped and played during a period of comfort. However, even after they have learned an intervention, children often need help using it during a painful procedure. The intervention can also be used after the procedure. This gives the child a chance to recover, feel mastery, and cope more effectively (McGrath and Hillier, 2003).

Several studies have documented the effectiveness of nonpharmacologic analgesia such as containment, positioning, nonnutritive sucking (Fig. 30-5), and kangaroo holding in neonates during painful procedures. **Containment** is achieved through positioning and blanket rolls (Cole and Jorgensen, 1997). It provides a "nest" that enhances the infant's feelings of security and decreases stress. Comforting measures and swaddling have been demonstrated to reduce crying and heart rate after procedures such as heel punctures and injections. Infants between 27 and 34 weeks of gestational age who were swaddled after a routine heelstick procedure were able to calm crying immediately, decrease heart rate, and return to a sleep state; in comparison, infants who were not swaddled took a minimum of 10 minutes to return to baseline physiologic and behavioral levels (Fearon, Kisilevsky, Hains, et al., 1997). Proper positioning with the infant held in a midline orientation, hand-to-mouth activity, and proper flexion can promote self-soothing behaviors. "Facilitated tucking," which is holding the infant's extremities flexed and contained close to the trunk, during heel lance procedures has been demonstrated to decrease heart rate, decrease crying time, and promote stability in the sleep-wake cycles after the lance.

FIG 30-5 Sucking following oral sucrose can enhance analgesia before a heelstick in a preterm infant.

Nonnutritive sucking (pacifier) attenuates behavioral, physiologic, and hormonal responses to pain from procedures such as heel punctures, venipuncture, and immunization injections. The administration of concentrated sucrose with and without nonnutritive sucking has been demonstrated to have calming and pain-relieving effects for invasive procedures in neonates (see Evidence-Based Practice box). The amount of time crying was decreased with 0.24 to 0.48 g (0.008 to 0.17 oz; 2 mL) of a 12% to 24% sucrose solution administered orally 2 minutes before a heel lance or venipuncture (Stevens, Yamada, and Ohlsson, 2005). The use of multimodal therapy, such as sucrose in combination with swaddling or nonnutritive sucking, is recommended to manage pain in neonates undergoing minor painful procedures such as heel punctures and circumcision.

Kangaroo care is a skin-to-skin holding of infants dressed only in diapers against their mother's or father's chest (Gray, Watt, and Blass, 2000; Johnston, Stevens, Pinelli, et al., 2003). Infants who spent 1-to-3 hours in kangaroo care showed increased frequency in quiet sleep, longer duration of quiet sleep, and decreased crying in the neonatal intensive care unit (NICU); and they cried less at the age of 6 months when compared with neonates who did not receive skin-to-skin contact. Significant differences were found in pain responses during heel lancing between infants who were kangaroo held and those who were not. In the study by Gray, Watt, and Blass (2000), heart rate increased by 8-to-10 beats/min in the kangaroo care group versus 36-to-38 beats/min in the control group of neonates who were swaddled in bassinets; grimacing was 64% less, and crying was 82% less. In another study infant responses to pain during heel lance procedures were compared using kangaroo holding (Fig. 30-6) with the neonate held upright at a 60-degree angle between the mother's breasts for maximal skin-to-skin contact (Johnston, Stevens, Pinelli, et al., 2003). A blanket was placed over the neonate's back, and the mother's clothes were wrapped around the neonate for 30 minutes before the lancing procedure, during, and at least 30 minutes after the heelstick. Another group remained in the isolette in a prone position, swaddled with a blanket and the heel accessible, for 30 minutes before the heel lancing procedure. Pain scores were significantly lower in kangaroo-held infants.

Many terms are used to describe approaches to health care that are outside the realm of conventional medicine as practiced in the United States. Complementary and alternative medicine (CAM), as

GUIDELINES

Nonpharmacologic Strategies for Pain Management

General Strategies

- Prepare child before potentially painful procedures but avoid "planting" the idea of pain.
  - For example, instead of saying, "This is going to (or may) hurt," say, "Sometimes this feels like pushing, sticking, or pinching, and sometimes it doesn't bother people. Tell me what it feels like to you."
  - Use "nonpain" descriptors when possible (e.g., "It feels like heat" rather than "It's a burning pain"). This allows for variation in sensory perception, avoids suggesting pain, and gives child control in describing reactions.
  - Avoid evaluative statements or descriptions (e.g., "This is a terrible procedure" or "It really will hurt a lot").
- Stay with child during a painful procedure.
  - Allow parents to stay with child if child and parent desire; encourage parent to talk softly to child and remain near child's head.
- Educate child about the pain, especially when explanation may lessen anxiety (e.g., that pain may occur after surgery and does not indicate that something is wrong); reassure child that he or she is not responsible for the pain.
- For long-term pain control give child a doll, which represents "the patient," and allow him or her to do everything to the doll that is done to the child; pain control can be emphasized through the doll by stating, "Dolly feels better after the medicine."

Specific Strategies

Distraction

- Involve child in play; use radio, tape recorder, CD player, or computer game; have child sing or use rhythmic breathing.
- Have child take a deep breath and blow it out until told to stop.
- Have child blow bubbles to "blow the hurt away."
- Have child concentrate on yelling or saying "ouch," with instructions to "yell as loud or soft as you feel it hurt; that way I know what's happening."
- Have child look through kaleidoscope (type with glitter suspended in fluid-filled tube) and encourage him or her to concentrate by asking, "Do you see the different designs?"
- Use humor such as watching cartoons, telling jokes or funny stories, or acting silly with child.
- Have child read, play games, or visit with friends.

Relaxation

- With an infant or young child:
  - Hold in a comfortable, well-supported position such as vertically against the chest and shoulder.
  - Rock in a wide, rhythmic arc in a rocking chair or sway back and forth rather than bouncing child.
  - Repeat one or two words softly such as "Mommy's here."
- With a slightly older child:
  - Ask child to take a deep breath and "go limp as a rag doll" while exhaling slowly; then ask him or her to yawn (demonstrate if needed).
  - Help child assume a comfortable position (e.g., pillow under neck and knees).
  - Begin progressive relaxation: starting with the toes, systematically instruct child to let each body part "go limp" or "feel heavy"; if child has difficulty relaxing, instruct him or her to tense or tighten each body part and then relax it.
  - Allow child to keep eyes open, since children may respond better if eyes are open rather than closed during relaxation.

Guided Imagery

- Have child identify some highly pleasurable real or imaginary experience.
- Have child describe details of the event, including as many senses as possible (e.g., "feel the cool breezes," "see the beautiful colors," "hear the pleasant music").
- Have child write down or tape record script.
- Encourage child to concentrate only on the pleasurable event during the painful time; enhance the image by recalling specific details through reading the script or playing the tape.
- Combine with relaxation and rhythmic breathing.

Positive Self-Talk

- Teach child positive statements to say when in pain (e.g., "I'll be feeling better soon," "When I go home, I'll feel better, and we'll eat ice cream").

Thought Stopping

- Identify positive facts about the painful event (e.g., "It doesn't last long").
- Identify reassuring information (e.g., "If I think about something else, it doesn't hurt as much").
- Condense positive and reassuring facts into a set of brief statements and have child memorize them (e.g., "Short procedure, good veins, little hurt, nice nurse, go home").
- Have child repeat the memorized statements whenever thinking about or experiencing the painful event.

Behavioral Contracting

- Informal—May be used with children as young as 4 or 5 years of age:
  - Use stars, tokens, or cartoon character stickers as rewards.
  - Give child who is uncooperative or procrastinating during a procedure a limited time (measured by a visible timer) to complete the procedure.
  - Proceed as needed if child is unable to comply.
  - Reinforce cooperation with a reward if the procedure is accomplished within specified time.
- Formal—Use written contract, which includes:
  - Realistic (seems possible) goal or desired behavior.
  - Measurable behavior (e.g., agrees not to hit anyone during procedures).
  - Contract written, dated, and signed by all people involved in any of the agreements.
  - Identified rewards or consequences that are reinforcing.
  - Goals that can be evaluated.
  - Commitment and compromise requirements for both parties (e.g., while timer is used, nurse will not nag or prod child to complete procedure).

EVIDENCE-BASED PRACTICE

Reduction of Minor Procedural Pain in Infants

Ask the Question

In newborns and infants, does sucrose provide adequate analgesia during minor painful procedures? Are the effects age dependent?

Search for the Evidence

Search Strategies

Search selection criteria included English publications within the past 10 years, research-based articles (level 1 or lower) on neonates or infants undergoing venipuncture or immunizations.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Joanna Briggs Institute, National Guideline Clearinghouse (AHQR), TRIP Database Plus, PedsCCM, BestBETs

Critically Analyze the Evidence

Studies evaluated whether sucrose provides adequate analgesia for minor painful procedures.

Venipuncture vs. Heel Lance for Blood Sampling

- Venipuncture performed by skilled phlebotomists results in less pain than heelstick for blood sampling (Shah and Ohlsson, 2004).
- Decreased pain scores, cry duration, and mother's rating of infant's pain demonstrated venipuncture as the preferred method of blood collection (Shah and Ohlsson, 2004).
- Infants receiving heelstick may also require more than one stick to get enough for the sample; venipuncture reduces the risk of additional sticks (Shah and Ohlsson, 2004).

Glucose vs. EMLA cream for venipuncture in neonates

- 30% oral glucose and placebo on the skin group had significantly lower Premature Infant Pain Profile (PIPP) scores and duration of crying than the EMLA (lidocaine and prilocaine) and oral placebo group (Gradin, Lenclen, Gajdos, et al., 2002).
- Fewer patients in the glucose group were scored on the PIPP as having pain or a score above 6 (19.3% compared with 41.7%) (Gradin, Lenclen, Gajdos, et al., 2002).

Glucose compared with EMLA for venipuncture pain

- Combination of EMLA and 1 mL oral glucose (300 mg/mL) significantly reduced pain response associated with diphtheria-pertussis-tetanus immunizations in 3-month-old infants (Lindh, Wiklund, Blomquist, et al., 2003).

Sucrose for minor painful procedures (heel lance and venipuncture)

- A total of 150 full-term newborns were randomly assigned to one of six treatment groups: (1) no treatment, (2) 2 mL of sterile water placebo, (3) 2 mL of 30% glucose, (4) 2 mL of 30% sucrose, (5) 2 mL of 30% sucrose with pacifier, and (6) pacifier alone. The pacifier alone was more effective than sweet solutions; sweet solutions and the pacifier were significantly more effective than the placebo; and sucrose and glucose were equally effective in lowering pain scores (Carbajal, Chauvet, Couderc, et al., 1999).
- Behavioral state, difficulty, and duration of venipuncture were not significantly different between 2 mL of a placebo of sterile water or 25% sucrose slowly over 2 minutes into the mouth by syringe 4 minutes before venipunctures. Heart rate, crying times, and neonatal facial coding system scores were significantly lower in the treatment group (25% sucrose) (Acharya, Annamali, Taub, et al., 2004).
- A 2-mL amount of 24% sucrose solution alone was the most effective analgesic compared with placebo (spring water), EMLA, or EMLA combined with 2 mL of sucrose. The combination of EMLA and sucrose did not enhance the analgesic effects (Abad, Diaz-Gomez, Domenech, et al., 2001).
- Sucrose in a wide variety of dosages delivered by syringe or pacifier was found to decrease crying time, heart rate, facial action, and composite pain scores during venipuncture and heel lance (Stevens, Yamada, and Ohlsson, 2005).
- Use of sucrose in a range of 0.012 to 0.12 g (0.05 to 0.5 mL) of a 24% solution 2 minutes before a single heel lance or venipuncture is safe and effective for pain relief (Stevens, Yamada, and Ohlsson, 2005).
- Concomitant use of other methods of pain relief, including use of pacifier, rocking, kangaroo care, or holding along with sucrose intervention, is recommended (Stevens, Yamada, and Ohlsson, 2005).

Apply the Evidence: Nursing Implications

There is *good evidence* with *strong recommendation* (Guyatt, Oxman, Vist, et al., 2008) for using sucrose to provide adequate analgesia during minor painful procedures. Sucrose is effective in reducing pain response in infants 6 months of age and younger undergoing minor acute painful procedures. The most effective dose has been 24% solution given at least 2 minutes before a procedure. Doses of 50% to 75% have been effective for relieving pain during immunizations in infants up to 6 months of age, suggesting that higher concentrations may be required for older infants. Effective dose volumes range from 0.05 to 2 mL, with lower volumes used for low-birth-weight infants and larger volumes used for older infants. Sucrose in combination with nonpharmacologic support during a procedure may increase the analgesic response for older infants (2 months) even with lower concentrations of sucrose. Interventions include using a pacifier, holding, swaddling, skin-to-skin contact, and rocking. Administration can be by a labeled oral syringe, dipped pacifier, or bottle, depending on the infant's ability and age. Comparisons between sucrose and glucose have been inconclusive.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe the use of sucrose to provide analgesia during minor painful procedures.

Skills

Base the individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by using sucrose for analgesia during minor painful procedures.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate strengths and weakness of evidence for sucrose use during minor painful procedures.

FIG 30-6 Mother using kangaroo hold with her newborn infant. Note placement of the infant directly on the mother's skin.

defined by the National Center for Complementary and Alternative Medicine, is a group of diverse medical and health care systems, practices, and products that are not currently considered part of conventional medicine (Myers, Stuber, Bonamer-Rheingans, et al., 2005). Although some scientific evidence exists regarding some CAM therapies, most key questions are yet to be answered through well-designed scientific studies (i.e., questions such as whether these therapies are safe and whether they work for the diseases or medical conditions for which they are used.

CAM therapies may be grouped into five classes: (1) biologically based (foods, special diets, herbal or plant preparations, vitamins, other supplements); (2) manipulative treatments (chiropractic, osteopathy, massage); (3) energy-based (Reiki, bioelectric or magnetic treatments, pulsed fields, alternating and direct currents); (4) mind-body techniques (mental healing, expressive treatments, spiritual healing, hypnosis, relaxation); and (5) alternative medical systems (homeopathy, naturopathy, ayurvedic, traditional Chinese medicine that includes acupuncture and moxibustion).

Current estimates of pediatric CAM use range from 10% to 15%, derived from children sampled at health care facilities, with chronic conditions, and/or from countries other than the United States. For the U.S. population, pediatric CAM use was estimated to be 31% to 84% (Myers, Stuber, Bonamer-Rheingans, et al., 2005; Rusy and Weisman, 2000). Those who used CAM were found in each age-group, and the mean age was 10.3 years. The majority used unconventional therapy for chronic, as opposed to life-threatening, medical conditions. The therapies that are used increasingly include herbal medicine, massage, megavitamins, self-help groups, folk remedies, energy healing, and homeopathy (Myers, Stuber, Bonamer-Rheingans, et al., 2005; Rusy and Weisman, 2000).

Pharmacologic Management

For mild pain (<3 on 0-to-10 scale) or moderate pain (4 to 6 on 0-to-10 scale) acetaminophen (Tylenol, Paracetamol) and nonsteroidal antiinflammatory drugs (NSAIDs) are suitable (Table 30-3). For moderate (5 to 6) to severe pain (7 to 10 on 0-to-10 scale) opioids are needed (Table 30-4). A combination (acetaminophen with codeine) works better in some cases because nonopioids act at the peripheral nervous system and opioids act at the central nervous system. Oxycodone is available without a nonopioid in an immediate- and controlled-release preparation (OxyContin). Morphine is considered the gold standard for the management of severe pain. When morphine is not a suitable opioid, drugs such as hydromorphone (Dilaudid) and fentanyl (Sublimaze) are effective substitutes. Although fentanyl is used as an anesthetic in the operating room, it is classified as an analgesic. It can be administered safely by nurses by the intravenous (IV) (Fig. 30-7), intramuscular (IM), transmucosal, and transdermal routes (Algren, Gursoy, Johnson, et al., 1998; Golianu, Krane, Galloway, et al., 2000).

! NURSING ALERT

The optimum dosage of an analgesic is one that controls pain without causing severe side effects. This usually requires titration, the gradual adjustment of drug dosage (usually by increasing the dose) until optimum pain relief without excessive sedation is achieved. Dosage recommendations are only safe initial dosages (see Tables 30-4 and 30-5), not optimum dosages.

TABLE 30-3 NONSTEROIDAL ANTIINFLAMMATORY DRUGS (NSAIDs) APPROVED FOR CHILDREN*†

DRUG	DOSAGE	COMMENTS
Acetaminophen (Tylenol)	10-15 mg/kg/dose every 4-6 hr not to exceed 5 doses in 24 hr or 75 mg/kg/day, orally	Available in numerous preparations Nonprescription Higher dosage range may provide increased analgesia
Choline magnesium trisalicylate (Trilisate)	Children <37 kg (81.5 lbs): 50 mg/kg/day divided into 2 doses Children >37 kg (81.5 lbs): 2250 mg/day divided into 2 doses	Available in suspension, 500 mg/5 mL Prescription
Ibuprofen (children's Motrin, children's Advil)	Children >6 mo: 5-10 mg/kg/dose every 6-8 hr not to exceed 40 mg/kg/day	Available in numerous preparations Available in suspension, 100 mg/5 mL, and drops, 100 mg/2.5 mL Nonprescription
Naproxen (Naprosyn)	Children >2 yr: 10 mg/kg/day divided into 2 doses	Available in suspension, 125 mg/5 mL, and several different dosages for tablets Prescription
Tolmetin (Tolectin)	Children >2 yr: 20 g/kg/day divided into 3-4 doses	Available in 200-mg, 400-mg, and 600-mg tablets Prescription

Data from Olin BR et al: *Drug facts and comparisons,* St Louis, 2002, Facts and Comparisons.
*Newer formulations of nonsteroidal antiinflammatory drugs (NSAIDs) selectively inhibit one of the enzymes of cyclooxygenase (COX-2, which is responsible for pain transmission) but do not inhibit the other (COX-1). Inhibition of COX-1 decreases prostaglandin production, which is necessary for normal organ function. For example, prostaglandins help maintain gastric mucosal blood flow and barrier protection, regulate blood flow to the liver and kidneys, and facilitate platelet aggregation and clot formation. Theoretically the COX-2 NSAIDs provide similar analgesic and antiinflammatory benefits with fewer gastric and platelet side effects than the nonselective agents. COX-2 NSAIDs are approved for use in patients older than 18 years of age.
†All NSAIDs in this table (except acetaminophen) have significant antiinflammatory, antipyretic, and analgesic actions. Acetaminophen has a weak antiinflammatory action, and its classification as an NSAID is controversial. Patients respond differently to various NSAIDs; therefore changing from one drug to another may be necessary for maximum benefit. Acetylsalicylic acid (aspirin) is also an NSAID but is not recommended for children because of its possible association with Reye's syndrome. The NSAIDs in this table have no known association with Reye's syndrome. However, caution should be exercised in prescribing any salicylate-containing drug (e.g., Trilisate) for children with known or suspected viral infection. Side effects of ibuprofen, naproxen, and tolmetin include nausea, vomiting, diarrhea, constipation, gastric ulceration, bleeding nephritis, and fluid retention. Acetaminophen and choline magnesium trisalicylate are well tolerated in the gastrointestinal tract and do not interfere with platelet function. NSAIDs (except acetaminophen) should not be given to patients with allergic reactions to salicylates. All the NSAIDs should be used cautiously in patients with renal impairment.

Several drugs known as *coanalgesics* or **adjuvant** *analgesics* may be used alone or with opioids to control pain symptoms and opioid side effects. Drugs frequently used to relieve anxiety, cause sedation, and provide amnesia are diazepam (Valium) and midazolam (Versed). However, these drugs are not analgesics and should be used to enhance the effects of analgesics and not as a substitute for them. Other adjuvants include tricyclic antidepressants (e.g., amitriptyline, imipramine) and antiepileptics (e.g., gabapentin, carbamazepine, clonazepam) for neuropathic pain (Table 30-5), stool softeners and laxatives for constipation, antiemetics for nausea and vomiting, diphenhydramine for itching, steroids for inflammation and bone pain, and dextroamphetamine and caffeine for possible increased analgesia and decreased sedation (McCaffery and Pasero, 1999).

Children (except infants younger than about 3 to 6 months) metabolize drugs more rapidly than adults; younger children may require higher doses of opioids to achieve the same analgesic effect. Therefore the therapeutic effect and duration of analgesia vary. Children's dosages are usually calculated according to body weight, except in children with a weight greater than 50 kg (110 lbs), in whom the weight formula may exceed the average adult dose. In this case the adult dose is used. Conversion factors for selected opioids must be used when a change is made from IV (preferred) or IM to oral. Immediate conversion from IM or IV to the suggested equianalgesic oral dose may result in a substantial error. For example, the dose may be significantly more or less than that which the child requires. Small changes ensure small errors. Several routes of analgesic administration can be used (Box 30-2); the most effective and least traumatic route should be selected.

Transmucosal and Transdermal Analgesia

Oral transmucosal fentanyl (Oralet) provides nontraumatic preoperative and preprocedural analgesia and sedation (Golianu, Krane, Galloway, et al., 2000). Fentanyl is also available as a transdermal patch (Duragesic). Although contraindicated for acute pain management, it may be used for older children and adolescents who have cancer or sickle cell pain or patients who are opioid tolerant.

One of the most significant improvements in the ability to provide atraumatic care to children is the anesthetic cream LMX (a 4% liposomal lidocaine cream) or **EMLA (eutectic mixture of local anesthetics)** (Abdelkefi, Abdennebi, Mellouli, et al., 2004; Choi, Irwin, Hui, et al., 2003; Egekvist and Bjerring, 2000; Gad, Olsen, Lysgaard, et al., 2005; Rogers and Ostrow, 2004; Santiago, Abad, Fernandez, et al., 2000; Uziel, Berkovitch, Gazarian, et al., 2003). The eutectic mixture (lidocaine 2.5% and prilocaine 2.5%), the melting point of which is lower than that of the two anesthetics alone, permits effective concentrations of the drug to penetrate intact skin (Fig. 30-8).

In some situations there isn't ample time for topical preparations such as LMX or EMLA to take effect, and refrigerant sprays such as

TABLE 30-4 DOSAGE OF SELECTED OPIOIDS FOR CHILDREN

DRUG	APPROPRIATE EQUIANALGESIC	APPROXIMATE EQUIANALGESIC PARENTERAL DOSE	RECOMMENDED STARTING DOSE (CHILDREN <50 KG (110 LBS) BODY WEIGHT)*	
			ORAL	PARENTERAL*
Morphine	30 mg every 3-4 hr	10 mg every 3-4 hr	0.2-0.4 mg/kg every 3-4 hr 0.3-0.6 mg/kg time released every 12 hr	0.1-0.2 mg/kg IM every 3-4 hr 0.02-0.1 mg/kg IV bolus every 2 hr 0.015 mg/kg every 8 min PCA 0.01-0.02 mg/kg/hr IV infusion (neonates) 0.01-0.06 mg/kg/hr IV infusion (child)
Fentanyl (Sublimaze) (oral mucosal form [Actiq])†	Not available	0.1 mg IV	5-15 mcg/kg; maximum dose 400 mcg	0.5-1.5 mcg/kg IV bolus every 30 min 1-2 mcg/hr IV infusion
Codeine‡	200 mg every 3-4 hr	130 mg every 3-4 hr	1 mg/kg every 3-4 hr	Not recommended
Hydromorphone§ (Dilaudid)	7.5 mg every 3-4 hr	1.5 mg every 3-4 hr	0.04-0.1 mg/kg every 3-4 hr	0.02-0.1 mg/kg every 3-4 hr 0.005-0.2 mg/kg IV bolus every 2 hr
Hydrocodone and acetaminophen (Lorcet, Lortab, Vicodin, others)	30 mg every 3-4 hr	Not available	0.2 mg/kg every 3-4 hr	Not available
Levorphanol (Levo-Dromoran)	4 mg every 6-8 hr	2 mg every 6-8 hr	0.04 mg/kg every 6-8 hr	0.02 mg/kg every 6-8 hr
Meperidine (Demerol)‖	300 mg every 2-3 hr	100 mg every 3 hr	Not recommended	0.75 mg/kg every 2-3 hr
Methadone (Dolophine, others)¶	20 mg every 6-8 hr	10 mg every 6-8 hr	0.2 mg/kg every 6-8 hr	0.1 mg/kg every 6-8 hr
Oxycodone (Roxicodone, OxyContin; also in Percocet, Percodan, Tylox, others)	20 mg every 3-4 hr	Not available	2 mg/kg every 3-4 hr#	Not available

Data from Acute Pain Management Guideline Panel: *Acute pain management: operative or medical procedures and trauma: clinical practice guideline,* AHCPR Pub No 92-0032, Rockville, MD, 1992, Agency for Health Care Policy and Research, Public Health Service, US Department of Health and Human Services; Berde C, Ablin A, Glazer J, et al: American Academy of Pediatrics Report of the Subcommittee on Disease-Related Pain in Childhood Cancer, *Pediatrics* 86(5 pt 2):820, 1990.

IM, Intramuscularly; *IV,* intravenous; *PCA,* patient-controlled analgesia.

NOTE: Published tables vary in suggested doses that are equianalgesic to morphine. Clinical response is criterion that must be applied for each patient; titration to clinical response is necessary. Because there is incomplete cross-tolerance among these drugs, it is usually necessary to use a lower than equianalgesic dose when changing drugs and retitrate to response.

CAUTION: Recommended doses do not apply to patients with renal or hepatic insufficiency or other conditions affecting drug metabolism and kinetics.

***CAUTION:** Doses listed for patients with body weight less than 50 kg (110 lbs) cannot be used as initial starting doses in infants younger than 6 months of age. For nonventilated infants younger than 6 months the initial opioid dose should be about ¼ to ⅓ of the dose recommended for older infants and children. For example, morphine could be used at a dose of 0.03 mg/kg instead of the traditional 0.1 mg/kg.

†Actiq is indicated only for management of breakthrough cancer pain in patients with malignancies who are already receiving and are tolerant to opioid therapy, but it can be used for preoperative or preprocedural sedation/analgesia.

‡**CAUTION:** Codeine doses above 65 mg often are not appropriate because of diminishing incremental analgesia with increasing doses but continually increasing constipation and other side effects. Dosages are from McCaffery M, Pasero C: *Pain: a clinical manual,* ed 2, St Louis, 1999, Mosby.

§For morphine, hydromorphone, and oxymorphone, rectal administration is an alternate route for patients unable to take oral medications, but equianalgesic doses may differ from oral and parenteral doses because of pharmacokinetic differences.

‖Meperidine is not recommended for continuous pain control (i.e., after surgery) because of risk of normeperidine toxicity.

¶Initial dose is 10%-25% of equianalgesic morphine dose. Parenteral Dolophine is no longer available in the United States.

#**CAUTION:** Doses of aspirin and acetaminophen in combination with opioid or nonsteroidal antiinflammatory drug preparations must also be adjusted to patient's body weight. Daily dose of acetaminophen should not exceed 75 mg/kg, or 4000 mg.

FIG 30-7 Nurse programming a patient-controlled analgesia pump to administer analgesia.

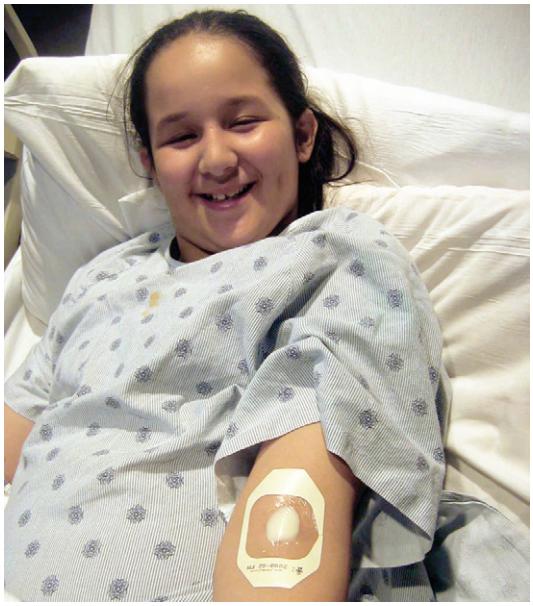

FIG 30-8 LMX is an effective analgesic before intravenous insertion or blood draw.

TABLE 30-5 MANAGEMENT OF OPIOID SIDE EFFECTS

SIDE EFFECT	ADJUVANT DRUGS	NONPHARMACOLOGIC TECHNIQUES
Constipation	**Senna and docusate sodium** *Tablet:* 2-6 yr: Start with ½ tablet once a day; maximum: 1 tablet twice a day 6-12 yr: Start with 1 tablet once a day; maximum: 2 tablets twice a day >12 yr: Start with 2 tablets once a day; maximum: 4 tablets twice a day *Liquid:* 1 mo-1 yr: 1.25-5 mL q hs 1-5 yr: 2.5-5 mL q hs 5-15 yr: 5-10 mL q hs >15 yr: 10-25 mL q hs **Casanthranol and docusate sodium** *Liquid:* 5-15 mL q hs *Capsules:* 1 cap PO q hs **Bisacodyl:** PO or PR 3-12 yr: 5 mg/dose/day >12 yr: 10-15 mg/dose/day **Lactulose** 7.5 mL/day after breakfast Adult: 15-30 mL/day PO **Mineral oil:** 1-2 tsp/day PO **Magnesium citrate** <6 yr: 2-4 mL/kg PO once 6-12 yr: 100-150 mL PO once >12 yr: 150-300 mL PO once **Milk of Magnesia** <2 yr: 0.5 mL/kg/dose PO once 2-5 yr: 5-15 mL/day PO 6-12 yr: 15-30 mL PO once >12 yr: 30-60 mL PO once	Increase water intake Prune juice, bran cereal, vegetables

TABLE 30-5 MANAGEMENT OF OPIOID SIDE EFFECTS—cont'd

SIDE EFFECT	ADJUVANT DRUGS	NONPHARMACOLOGIC TECHNIQUES
Sedation	**Caffeine:** single dose of 1-1.5 mg PO **Dextroamphetamine:** 2.5-5 mg PO in AM and early afternoon **Methylphenidate:** 2.5-5 mg PO in AM and early afternoon Consider opioid switch if sedation is persistent	Caffeinated drinks (e.g., Mountain Dew, cola drinks)
Nausea, vomiting	**Promethazine:** 0.5 mg/kg q 4-6 hr; maximum: 25 mg/dose **Ondansetron:** 0.1-0.15 mg/kg IV or PO q 4 hr; maximum: 8 mg/dose **Granisetron:** 10-40 mcg/kg q 2-4 hr; maximum: 1 mg/dose **Droperidol:** 0.05-0.06 mg/kg IV q 4-6 hr; can be very sedating	Imagery, relaxation Deep, slow breathing
Pruritus	**Diphenhydramine:** 1 mg/kg IV or PO q 4-6 hr prn; max: 25 mg/dose **Hydroxyzine:** 0.6 mg/kg/dose PO q 6 hr; maximum: 50 mg/dose **Naloxone:** 0.5 mcg/kg q 2 min until pruritus improves (diluted in solution of 0.1 mg of naloxone per 10 mL of saline) **Butorphanol:** 0.3-0.5 mg/kg IV (use cautiously in opioid-tolerant children; may cause withdrawal symptoms); maximum: 2 mg/dose because mixed agonist-antagonist	Oatmeal baths, good hygiene Exclude other causes of itching Change opioids
Respiratory depression: mild to moderate	Hold dose of opioid Reduce subsequent doses by 25%	Arouse gently, give oxygen, encourage to deep breathe
Respiratory depression: severe	**Naloxone** *During disease pain management:* 0.5 mcg/kg in 2-min increments until breathing improves (American Pain Society, 1999; McCaffery and Pasero, 1999) Reduce opioid dose if possible Consider opioid switch *During sedation for procedures:* 5-10 mcg/kg until breathing improves (Yaster, Krance, Kaplan, et al., 1997) Reduce opioid dose if possible Consider opioid switch	Oxygen, bag and mask if indicated
Dysphoria, confusion, hallucinations	Evaluate medications, eliminate adjuvant medications with central nervous system effects as symptoms allow Consider opioid switch if possible **Haloperidol** (Haldol): 0.05-0.15 mg/kg/day divided in 2-3 doses; maximum: 2-4 mg/day	Rule out other physiologic causes
Urinary retention	Evaluate medications, eliminate adjuvant medications with anticholinergic effects (e.g., antihistamines, tricyclic antidepressants) Occurs more frequently with spinal analgesia than with systemic opioid use **Oxybutynin** 1 yr: 1 mg tid 1-2 yr: 2 mg tid 2-3 yr: 3 mg tid 4-5 yr: 4 mg tid >5 yr: 5 mg tid	Rule out other physiologic causes In/out or indwelling urinary catheter

hs, At bedtime; *IV,* intravenously; *PO,* by mouth; *PR,* by rectum; *prn,* as needed; *q,* every; *tid,* 3 times a day.

ethyl chloride and fluoromethane can be used (Reis and Holubkov, 1997). When sprayed on the skin, these sprays vaporize, rapidly cool the area, and provide superficial anesthesia. Hospital formularies may have other products with lidocaine, prilocaine, or amethocaine topical preparations that require less time for application. A randomized controlled trial compared the efficacy and safety of amethocaine gel (which is applied for 30 minutes) and EMLA cream (which is applied for 60 minutes) before a port-a-cath puncture. Children rated the pain following the puncture using the FACES Pain Scale (coded 0 to 5). Both groups had low pain scores, less than or equal to 2, and it did not make a significant difference whether the amethocaine or the EMLA cream was used. The researchers concluded that the amethocaine was clinically equivalent to EMLA, but the amethocaine gel required less time for anesthesia (Bishai, Taddio, Bar-Oz, et al., 1999).

Monitoring Side Effects

Although both nonopioids and opioids have side effects, the major concern is with side effects from opioids (Box 30-3). Respiratory depression is the most serious complication and is most likely to occur in sedated patients. The respiratory rate may decrease gradually, or respirations may cease abruptly. Lower limits of normal are

BOX 30-2 ROUTES AND METHODS OF ANALGESIC DRUG ADMINISTRATION

Oral
- Oral route preferred because of convenience, cost, and relatively steady blood levels
- Higher dosages of oral form of opioids required for equivalent parenteral analgesia
- Peak drug effect occurs after 1 to 2 hours for most analgesics
- Delay in onset a disadvantage when rapid control of severe or fluctuating pain is desired

Sublingual, Buccal, or Transmucosal
- Tablet or liquid placed between cheek and gum (buccal) or under tongue (sublingual)
- Highly desirable because more rapid onset than oral route
- Produced less first-pass effect through liver than oral route, which normally reduces analgesia from oral opioids (unless sublingual or buccal form is swallowed, which occurs often in children)
- Few drugs commercially available in this form
- Many drugs can be compounded into sublingual troche or lozenge*
- Actiq—Oral transmucosal fentanyl citrate in hard confection base on plastic holder; indicated only for management of breakthrough cancer pain in patients with malignancies who are already receiving and are tolerant to opioid therapy, but can be used for preoperative or preprocedural sedation and analgesia

Intravenous (IV) (Bolus)
- Preferred for rapid control of severe pain
- Provides most rapid onset of effect, usually in about 5 minutes
- Advantage for acute pain, procedural pain, and breakthrough pain
- Needs to be repeated hourly for continuous pain control
- Drugs with short half-life (morphine, fentanyl, hydromorphone) preferable to avoid toxic accumulation of drug

IV (Continuous)
- Preferred over bolus and intramuscular injection for maintaining control of pain
- Provides steady blood levels
- Easy to titrate dosage

Subcutaneous (SC) (Continuous)
- Used when oral and IV routes not available
- Provides equivalent blood levels to continuous IV infusion
- Suggested initial bolus dose to equal 2-hour IV dose; total 24-hour dosage usually requires concentrated opioid solution to minimize infused volume; use smallest-gauge needle that accommodates infusion rate

Patient-Controlled Analgesia (PCA)
- Generally refers to self-administration of drugs, regardless of route
- Typically uses programmable infusion pump (IV, epidural, SC) that permits self-administration of boluses of medication at preset dose and time interval (lockout interval is time between doses)
- PCA bolus administration often combined with initial bolus and continuous (basal or background) infusion of opioid
- Optimum lockout interval not known but must be at least as long as time needed for onset of drug
  - Should effectively control pain during movement or procedures
  - Longer lockout provides larger dose

Family-Controlled Analgesia
- One family member (usually a parent) or other caregiver designated as child's primary pain manager with responsibility for pressing PCA button
- Guidelines for selecting primary pain manager for family-controlled analgesia:
  - Spends a significant amount of time with patient
  - Is willing to assume responsibility of being primary pain manager
  - Is willing to accept and respect patient's reports of pain (if able to provide) as best indicator of how much pain the patient is experiencing; knows how to use and interpret a pain-rating scale
  - Understands purpose and goals of patient's pain-management plan
  - Understands concept of maintaining steady analgesic blood level
  - Recognizes signs of pain and side effects and adverse reactions to opioid

Nurse-Activated Analgesia
- Child's primary nurse designated as primary pain manager and is only person who presses PCA button during that nurse's shift
- Guidelines for selecting primary pain manager for family-controlled analgesia also applicable to nurse-activated analgesia
- May be used in addition to basal rate to treat breakthrough pain with bolus doses; patient assessed every 30 minutes for need for bolus dose
- May be used without a basal rate as means of maintaining analgesia with around-the-clock bolus doses

Intramuscular
NOTE: Not recommended for pain control; not current standard of care
- Painful administration (hated by children)
- Some drugs can cause tissue and nerve damage
- Wide fluctuation in absorption of drug from muscle
- Faster absorption from deltoid than from gluteal sites
- Shorter duration and more expensive than oral drugs
- Time consuming for staff and unnecessary delay for child

Intranasal
- Available commercially as butorphanol (Stadol NS); approved for those older than 18 years of age
- Should not be used in patient receiving morphinelike drugs because butorphanol is partial antagonist that reduces analgesia and may cause withdrawal

Intradermal
- Used primarily for skin anesthesia (e.g., before lumbar puncture, bone marrow aspiration, arterial puncture, skin biopsy)
- Local anesthetics (e.g., lidocaine) cause stinging, burning sensation
- Duration of stinging dependent on type of "caine" used
- To avoid stinging sensation associated with lidocaine:
  - Buffer solution by adding 1 part sodium bicarbonate (1 mEq/mL) to 9 to 10 parts 1% or 2% lidocaine with or without epinephrine (see Evidence-Based Practice box on p. 855)
- Normal saline with preservative, benzyl alcohol, anesthetizes venipuncture site
- Use same dose as for buffered lidocaine (see Evidence-Based Practice box on p. 855)

Topical or Transdermal
- EMLA (eutectic mixture of local anesthetics [lidocaine and prilocaine]) cream and anesthetic disk or 4% lidocaine cream (LMX4)
  - Eliminates or reduces pain from most procedures involving skin puncture
  - Must be placed on intact skin over puncture site and covered by occlusive dressing or applied as anesthetic disc for 1 hour or more before procedure (see Evidence-Based Practice box on p. 855)

BOX 30-2 ROUTES AND METHODS OF ANALGESIC DRUG ADMINISTRATION—cont'd

- Synera, S-Caine (lidocaine/tetracaine)
  - Apply for 20-30 minutes
  - Do not apply to broken skin
- Lidocaine-adrenaline-tetracaine (LAT), tetracaine-phenylephrine (tetraphen)
  - Provides skin anesthesia about 15 minutes after application on nonintact skin
  - Gel (preferable) or liquid placed on wounds for suturing
  - Adrenaline not for use on end arterioles (fingers, toes, tip of nose, penis, earlobes) because of vasoconstriction
- Transdermal fentanyl (Duragesic)
  - Available as patch for continuous pain control
  - Safety and efficacy not established in children younger than 12 years of age
  - Not appropriate for initial relief of acute pain because of long interval to peak effect (12 to 24 hours); for rapid onset of pain relief give an immediate-release opioid
  - Orders for "rescue doses" of an immediate-release opioid recommended for breakthrough pain, a flare of severe pain that breaks through the medication being administered at regular intervals for persistent pain
  - Has duration of up to 72 hours for prolonged pain relief
  - If respiratory depression occurs, possible need for several doses of naloxone
- Vapocoolant
  - Use of prescription spray coolant such as Fluori-Methane or ethyl chloride (Pain-Ease); applied to the skin for 10 to 15 seconds immediately before needle puncture; anesthesia lasts about 15 seconds
  - Some children dislike cold; may be less uncomfortable to spray coolant on a cotton ball and then apply this to the skin
  - Application of ice to skin for 30 seconds has been found to be ineffective

Rectal

- Alternative to oral or parenteral routes
- Variable absorption rate
- Generally disliked by children
- Many drugs able to be compounded into rectal suppositories*

Regional Nerve Block

- Use of long-acting local anesthetic (bupivacaine or ropivacaine) injected into nerves to block pain at site
- Provides prolonged analgesia after surgery such as after inguinal herniorrhaphy
- May be used to provide local anesthesia for surgery such as dorsal penile nerve block for circumcision or reduction of fractures

Inhalation

- Use of anesthetics such as nitrous oxide to produce partial or complete analgesia for painful procedures
- Side effects (e.g., headache) possible from occupational exposure to high levels of nitrous oxide

Epidural or Intrathecal

- Involves catheter placed into epidural, caudal, or intrathecal space for continuous infusion or single or intermittent administration of opioid with or without a long-acting local anesthetic (e.g., bupivacaine, ropivacaine)
- Analgesia primarily from direct effect of drug on opioid receptors in spinal cord
- Respiratory depression rare but may have slow and delayed onset; can be prevented by checking level of sedation and respiratory rate and depth hourly for initial 24 hours and decreasing dose when excessive sedation is detected
- Nausea, itching, and urinary retention common dose-related side effects from the epidural opioid
- Mild hypotension, urinary retention, and temporary motor or sensory deficits common unwanted effects of epidural local anesthetic
- Catheter for urinary retention inserted during surgery to decrease trauma to child; if inserted when child is awake, anesthetize urethra with lidocaine

Data primarily from American Pain Society: *Principles of analgesic use in the treatment of acute pain and chronic cancer pain,* ed 4, Glenview, Ill, 1999, The Society; and McCaffery M, Pasero C: *Pain: a clinical manual,* ed 2, St Louis, 1999, Mosby.
*For further information about compounding drugs in troche or suppository form, contact Professional Compounding Centers of America (PCCA), 9901 S. Wilcrest Drive, Houston, TX 77009; (800) 331–2498; www.pccarx.com.

not established for children, but any significant change from a previous rate calls for increased vigilance. A slower respiratory rate does not necessarily reflect decreased arterial oxygenation; an increased depth of ventilation may compensate for the altered rate. If respiratory depression or arrest occurs, the nurse must be prepared to intervene quickly (see Guidelines box).

Although respiratory depression is the most feared side effect, constipation is a common and sometimes serious side effect of opioids. Opioids decrease peristalsis and increase anal sphincter tone. If prolonged use of opioids is expected, prevention with stool softeners and laxatives is more effective than treatment once constipation occurs. Dietary treatment such as increased fiber is usually not sufficient to promote regular bowel evacuation. However, dietary measures such as increased fluid and fruit intake and physical activity are encouraged. Another common side effect is pruritus from epidural or IV infusion. Pruritus can be treated with low doses of IV naloxone, nalbuphine, or diphenhydramine. Children may also experience nausea and vomiting; however, these subside after 2 days of opioid administration. Oral or rectal antiemetics may be necessary to minimize nausea and vomiting.

Both **tolerance** and physical dependence can occur with prolonged use of opioids (see Community Focus box on p. 839). Physical dependence is a normal, natural, physiologic state of "neuroadaptation." When opioids are discontinued abruptly without weaning, withdrawal symptoms occur. Symptoms of withdrawal occur at 24 hours after abrupt discontinuation and reach a peak within 72 hours. They include signs of neurologic excitability (irritability, tremors, seizures, increased motor tone, insomnia), gastrointestinal dysfunction (nausea, vomiting, diarrhea, abdominal cramps), and autonomic dysfunction (sweating, fever, chills, tachypnea, nasal congestion, rhinitis). They can be anticipated and prevented by weaning patients from opioids that were administered for more than 5 to 10 days. Adherence to a weaning protocol to prevent or minimize withdrawal symptoms from opioids is required. A weaning flow sheet (Fig. 30-9) may be used to assess the efficacy of opioid weaning in neonates (Franck and Vilardi, 1995; Franck,

BOX 30-3 SIDE EFFECTS OF OPIOIDS

General
- Constipation (possibly severe)
- Respiratory depression
- Sedation
- Nausea and vomiting
- Agitation, euphoria
- Mental clouding
- Hallucinations
- Orthostatic hypotension
- Pruritus
- Urticaria
- Sweating
- Miosis (may be sign of toxicity)
- Anaphylaxis (rare)

Signs of Tolerance
- Decreasing pain relief
- Decreasing duration of pain relief

Signs of Withdrawal Syndrome in Patients with Physical Dependence

Initial Signs of Withdrawal
- Lacrimation
- Rhinorrhea
- Yawning
- Sweating

Later Signs of Withdrawal
- Restlessness
- Irritability
- Tremors
- Anorexia
- Dilated pupils
- Gooseflesh
- Nausea, vomiting

GUIDELINES

Managing Opioid-Induced Respiratory Depression

If Respirations Are Depressed
- Assess sedation level.
- Reduce infusion by 25% when possible.
- Stimulate patient (shake shoulder gently, call by name, ask to breathe).

If Patient Cannot Be Aroused or Is Apneic
- Administer naloxone (Narcan):
  - For children weighing less than 40 kg (88 lbs), dilute 0.1 mg naloxone in 10 mL sterile saline to make 10 mcg/mL solution and give 0.5 mcg/kg.
  - For children weighing more than 40 kg (88 lbs), dilute 0.4-mg ampule in 10 mL sterile saline and give 0.5 mL.
- Administer bolus by slow intravenous push every 2 minutes until effect is obtained.
- Closely monitor patient. Duration of antagonist action of naloxone may be shorter than that of opioid, requiring repeated doses of naloxone.
- Tolerance occurs when the dose of an opioid needs to be increased to achieve the same analgesic effect that was previously achieved at a lower dose (see Community Focus box on p. 839). Tolerance may develop after 10 to 21 days of morphine administration. Treatment of tolerance involves increasing the dose or decreasing the duration between doses. Treatment of physical dependence involves gradually reducing the dose over several days to prevent withdrawal symptoms. Following are guidelines for treating physical dependence from morphine (Max, Payne, Edwards, et al., 1999):
- Gradually reduce dose (similar to tapering of steroids).
- Give half of previous daily dose every 6 hours for first 2 days.
- Then reduce dose by 25% every 2 days. Continue this schedule until total daily dosage of 0.6 mg/kg/day of morphine (or equivalent) is reached. After 2 days on this dose discontinue opioid.
  - You may also switch to oral methadone, using one fourth of equianalgesic dose as initial weaning dose and proceeding as described previously.

NOTE: Respiratory depression caused by benzodiazepines (e.g., diazepam [Valium] or midazolam [Versed]) can be reversed with flumazenil [Romazicon]). Pediatric dosing experience suggests 0.01 mg/kg (0.1 mL/kg); if no (or inadequate) response after 1 or 2 minutes, administer same dose and repeat as needed at 60-second intervals for maximum dosage of 1 mg (10 mL) (Yaster, Krance, Kaplan, et al., 1997).

Vilardi, Durand, et al., 1998). In older infants and young children (7 months to 10 years) the Withdrawal Assessment Tool–1 may be used to assess and monitor withdrawal symptoms in pediatric critically ill children who are exposed to opioids and benzodiazepines for prolonged periods (Franck, Harris, Soetenga, et al., 2008).

Parents and older children may fear addiction when opioids are prescribed. The nurse should address these concerns with assurance that any such risk is extremely low. It may be helpful to ask the question, "If you did not have this pain, would you want to take this medicine?" The answer is invariably no, which reinforces the solely therapeutic nature of the drug. It is also important to avoid making statements to the family such as, "We don't want you to get used to this medicine," or "By now you shouldn't need this medicine," which may reinforce the fear of becoming addicted. Although both physical dependence and tolerance are physiologic states, addiction or psychologic dependence is a psychologic state and implies a "cause-effect" mode of thinking, such as, "I need the drug because it makes me feel better." Infants and children do not have the cognitive ability to make the cause-effect association and therefore cannot become addicted. The use of opioid analgesics early in life has not been demonstrated to increase the risk for addiction later in life. Nurses need to explain to parents the differences among physical dependence, tolerance, and addiction and allow them to express concerns about the use and duration of use of opioids. When infants and children are treated appropriately with opioids, they may be at risk for physical tolerance and physical dependence but not psychologic dependence or addiction (McCaffery and Pasero, 1999).

Unfortunately individuals who have severe, unrelieved pain may become intensely focused on finding relief. Sometimes behaviors such as "clock watching" make patients appear to others to be preoccupied with obtaining opioids. However, this preoccupation focuses on finding relief of pain, not on using opioids for reasons other than pain control. This phenomenon has been termed *pseudoaddiction* and must not be confused with real addiction.

Evaluation of Effectiveness of Pain Regimen

The effectiveness of analgesics can be enhanced by a supportive attitude toward the child. By reinforcing the cause and effect of the medication and analgesia, the nurse can condition the child to expect pain relief, provided the regimen is likely to be effective. A pain-relief scale or periodic ratings of pain intensity should be used for evaluation of effectiveness of pain regimens.

The response to therapy should be evaluated 15 to 30 minutes after each dose, and titration should continue to the highest achievable amount of relief (Max, Payne, Edwards, et al., 1999). In a retrospective study that examined the pain experience of children with sickle cell disease, evidence of pain relief from medications was documented for less than half (44.8%) of the patients in the emergency department (ED) (Jacob and Mueller, 2008). Even though the Joint Commission on Accreditation of Healthcare Organizations required documentation of pain assessments with vital signs, evidence of pain relief was not documented in 41.4% of the episodes. If titration methods were used in the ED or during the course of hospitalization, they were not reflected in the amount of medications received by the children (Jacob and Mueller, 2008; Jacob, Miaskowski, Savedra, et al., 2003a).

Directions: Score every 2-4 hours per guideline
Score greater than 8-12 may indicate withdrawal

Guidelines for use of the flow sheet

Use of form

Use the flowsheet for all infants who have received continuous or around-the-clock opioid medication for 3 days or more, or more than 3 doses per day for more than 5 days. This patient population will most often include postoperative patients, agitated intubated infants, and all post-ECMO patients.

Instructions

1. Write drug, dose, and frequency of analgesics and sedatives ordered
2. Enter date, name of drug (abbreviated MS=morphine sulfate or FENT=fentanyl), and administration time of drugs given in the appropriate boxes; indicate if dose frequency given is an increase or decrease from the ordered dose
3. Scoring must be performed every 4 hours during weaning of opioids, every 2 hours if score is 8 or greater. The score for each item indicates the presence of the sign during the previous 2-4 hours (depending on the scoring interval). Every 4-hour scoring should continue until the patient is off all opioids for 48-72 hours. Place a "0" in the column after the sign if it is not seen during the scoring period.

Central nervous system

Crying behavior: Score 2 points if patient exhibits crying or cry behavior for a duration of ≤50% of the scoring interval. Score 3 points if cumulative crying behavior totals >50% of the scoring interval.
NOTE: Crying behavior is accompanied by the facial expressions associated with crying, but without audible sounds because of endotracheal intubation.
Sleeping: Score 3 points if patient sleeps for ≤25% of the scoring interval. Score 2 points if patient sleeps for 26%-75% of the scoring interval. Score 1 point if patient sleeps for >75% of the scoring interval.
Moro (startle) reflex: Score 2 points if patient has some arm and/or leg extension when touched or when disturbed by loud noises. Score 3 points if patient has marked arm and/or leg extension that is accompanied by crying behavior, hyperalert state, or continued arm and/or leg tremors after being startled.
Tremors—disturbed: Score 1 point if patient has mild tremors when disturbed. Score 2 points if patient has moderate to severe tremors when disturbed. NOTE: Tremors are alternating movements that are rhythmic, of equal rate and amplitude, and can usually be stopped by flexion of the limb.
Increased muscle tone: Score 2 points if patient exhibits fisting or tight flexion of extremities that are difficult to extend.

Metabolic

Temperature: Score 1 point if patient's temperature is 37.2°-38.4°C. Score 2 points if patient's temperature is >38.4°C.
Respiratory rate: Score 1 point if patient's spontaneous respiratory rate is >60/minute. Score 2 points if patient's spontaneous respiratory rate is >60/minute and accompanied by retractions.
Suction: Score 2 points if patient is suctioned more than twice during a 4-hour period.
Sweating: Score 1 point if patient exhibits any type of sweating, including beads of sweat, or if skin is moist to touch.
Yawning: Score 1 point if patient yawns >3-4 times in succession or yawns 1-2 times often during a 4-hour period.
Sneezing: Score 1 point if patient sneezes >3-4 times in succession or sneezes 1-2 times during a 4-hour period.
Nasal stuffiness: Score 1 point for nasal stuffiness.

Gastrointestinal

Emesis of formula/stomach contents: Score 2 points if patient has 1 or more episodes of emesis during a 4-hour period.
Projectile vomiting: Score 3 points if patient has 1 or more episodes of projectile vomiting.
Loose stools: Score 2 points if patient has loose stools characterized by a water ring around some solid stool. The stools will often be frequent. NOTE: Do not score for "breast milk" stools: frequent, small, seedy, yellow stools.
Watery stools: Score 3 points if patient has stools that consist of only liquid. The stools will often be frequent.

Total score: Add up all the scores in the column and place the total score in this box. Clinical signs that appear continuously, such as respiratory rate >60 or regular poor feeding, should be included in the total score.
Adjusted score: The adjusted score is used when a sign is detected that is expected to occur independently of withdrawal, due to a preexisting condition (high respiratory rate in infant with bronchopulmonary dysplasia). The decision to adjust the score should be made after discussion with the health care team during rounds, and the rationale should be recorded in a problem-oriented note. Circle the signs to be excluded and deduct the points from the total score to obtain the adjusted score.
Initials of person scoring: The person scoring should write his/her initials in this space.

FIG 30-9 Weaning flow sheet to monitor opioid weaning in neonates. (Modified from Franck L, Vilardi J: Assessment and management of opioid withdrawal in ill neonates, *Neonatal Netw* 14[2]:39–48, 1995.)

Several harmful effects occur with unrelieved pain, particularly when pain is prolonged. A number of physiologic stress responses in the body are triggered during pain, and they lead to negative consequences that involve multiple systems. Unrelieved pain may prolong the stress response and adversely affect an infant's or child's recovery, whether it is from trauma, surgery, or disease. In a landmark study by Anand and Hickey (1992), 30 neonates received deep intraoperative anesthesia with high doses of the opioid sufentanil, followed after surgery with an infusion of opioids for 24 hours; and 15 neonates received lighter anesthesia with halothane and morphine followed after surgery by intermittent morphine and diazepam. The 15 neonates who received the lighter anesthesia and

intermittent postoperative opioids had more severe hyperglycemia and lactic acidemia, and four postoperative deaths occurred in the group. The 30 neonates who received deep anesthesia had a lower incidence of complications (sepsis, metabolic acidosis, disseminated intravascular coagulation) and no deaths.

Poorly controlled acute pain can predispose patients to chronic pain syndromes. A guiding principle in pain management is that prevention of pain is always better than treatment (Benjamin, Swinson, and Nagel, 2000). Pain that is established and severe is often more difficult to control. When pain is unrelieved, sensory input from injured tissues reaches spinal cord neurons and may enhance subsequent responses. Long-lasting changes in cells within spinal cord pain pathways may occur after a brief painful stimulus and lead to the development of chronic pain conditions. Basbaum (1999a, 1999b) reported a series of studies that emphasize a distinct neurochemistry of acute and persistent pain and concluded that persistent pain is not merely a prolonged acute pain symptom of some other disease. Underlying physiologic mechanisms lead to the persistence of pain (Marx, 2004; Woolf and Salter, 2000).

In a study of nursing practice related to pain assessment and management in different pediatric specialty units (Jacob and Puntillo, 2000), complaints of pain were noted, but specific pain scores or notations about responses to analgesics after administration were seldom documented. Pain scores were not available before and after analgesics; therefore it was not possible to conclude whether analgesics were effective. Thus nurses need to evaluate and monitor pain in a timely fashion after administration of analgesics; titrate dosage to effect; or make recommendations for an alternate analgesic, addition of another analgesic, or a combination of analgesics, adjuvants, and nonpharmacologic strategies if pain persists.

Consequences of Untreated Pain

Despite current research on the neonate's experience of pain, infant pain often remains inadequately managed. The mismanagement of infant pain is partially the result of misconceptions regarding the effects of pain on the neonate and the lack of knowledge of immediate and long-term consequences of untreated pain. Infants respond to noxious stimuli through (1) physiologic indicators (i.e., increased heart rate and blood pressure, variability in heart rate and intracranial pressure [ICP]), (2) decreases in Sao_2 and skin blood flow, and (3) behavioral indicators (i.e., muscle rigidity, facial expression, crying, withdrawal, and sleeplessness) (Anand, Grunau, and Oberlander, 1997; Bildner and Krechel, 1996). The physiologic and behavioral changes and a variety of neurophysiologic responses to noxious stimulation are responsible for acute and long-term consequences of pain.

Anand and Hickey (1987) described responses of infants to painful stimuli. Chemical and hormonal responses were observed following noxious stimuli without the use of an anesthetic or analgesic. Such responses included increases in β-endorphin secretion (an endogenous opioid), plasma renin activity, plasma epinephrine and norepinephrine, catecholamines, growth hormone, glucagon, aldosterone, and other corticosteroids. The result of these chemical and hormonal increases includes the breakdown of fat and carbohydrate stores; prolonged hyperglycemia; and increased serum lactate, pyruvate, total ketone bodies, and nonesterified fatty acids. Such consequences can be attributed to a greater morbidity for neonates in the NICU. Several experimental studies revealed a significant decrease in these responses when adequate analgesia was used before the painful procedure. One study showed that the standardization of postoperative pain management strategies for infants in the NICU led to the following improvements: (1) decreased length of time to extubation, (2) decreased length of stay, (3) better fluid management, and (4) reduced side effects of opioids. The authors also noted improved pain management documentation, decreased cost, and decreased nursing time (Furdon, Eastman, Benjamin, et al., 1998) (see Atraumatic Care box).

ATRAUMATIC CARE

Use of Opioids and Extubation Practice

Traditional belief holds that the continued use of opioids for neonates in the postoperative period results in prolonged intubation. Consequently traditional practice is to discontinue all opioids several hours before and after extubation, thus preventing pain relief. Furdon, Eastman, Benjamin, et al. (1998) found that continuous opioid infusion in infants without an underlying pulmonary or neurologic pathologic condition actually shortened the time to extubation and caused no problems of respiratory depression that required reintubation. Evidence suggests that the use of preemptive analgesia with a continuous infusion of low-dose morphine reduces the incidence of poor neurologic outcomes in preterm neonates who require ventilatory support.

COMMON PAIN STATES

Pain in Primary Care

In normative problems such as teething; during immunizations and vaccinations; and in common childhood illnesses such as otitis media, pharyngitis, and viral infections, pain is the presenting symptom that can be distressing (Schechter, 2003). The inflammation or irritation of the gingiva as the tooth erupts is responsible for discomfort during teething. Teething infants show more mouthing and drooling than nonteething infants. A topical anesthetic such as benzocaine, cold or frozen teething rings, and hard crackers or bread can alleviate pain during teething.

Injections from immunizations, IM antibiotics in the ED or health care provider's office, and blood draws are common sources of pain in children (Schechter, 2003). The immunization schedule for infants and young children requires at least 19 injections in the first 6 years of childhood; children receive four or five injections at multiple visits. Potential complications to needlesticks include fibrosis, contracture, abscess, and nerve injury. Factors that affect the incidence of complication are the injection site, the injectate itself (lower pH causing more burning and stinging), needle length, and frequency of injection. Warming the injectate, using lidocaine as a diluent, and applying ice and pressure to the site immediately before the procedure may reduce the discomfort associated with IM injections. Topical analgesia such as EMLA, LMX, amethocaine, cold sprays, and iontophoresis (see Evidence-Based Practice boxes) and cognitive-behavioral techniques (distraction, bubbles, parental presence, age-appropriate explanations, kaleidoscopes, music, stories) have been used to minimize pain, stress, fear, distress, and anxiety during injections. If multiple injections are required, parents have reported that simultaneous administration is less painful and less traumatic for their children than sequential administration.

In patients with otitis media the incidence of pain is lower in those who received ibuprofen 3 times a day when compared with those children who received acetaminophen or who did not receive either ibuprofen or acetaminophen (Bertin, Pons, d'Athis, et al., 1996). Warm compresses using oatmeal or warm stones have also been found to be effective for otitis media. Local anesthetic combinations such as Auralgan (antipyrine, benzocaine, and oxyquinoline

EVIDENCE-BASED PRACTICE

Analgesic Patches: Synera to Decrease Pain During Painful Procedures

Ask the Question

Do topical analgesic patches (e.g., lidocaine-tetracaine [Synera, S-Caine]) offer additional advantages (less time, ease of use, lower cost, higher effectiveness, decreased anxiety) in relieving pain during peripheral intravenous (PIV) cannulation in children compared with lidocaine cream (LMX) and buffered lidocaine via injection?

Search for the Evidence

Search Strategies

English research-based publications on lidocaine-tetracaine patches for venipuncture without time limitation were included. Exclusions included epidural use, dermatologic procedures, and S-Caine Peel.

Databases Used

Cochrane Collaboration Database, Joanna Briggs Institute, National Guideline Clearinghouse (AHRQ), PubMed, SUMSearch, CINAHL, Scopus, Micromedex, UpToDate, BestBETs, manufacturer's websites (Endo Pharmaceuticals, ZARS Pharma)

Critically Analyze the Evidence

Studies evaluated effectiveness of Synera patch in decreasing pain during painful procedures.

- Synera is as effective as EMLA (a eutectic mix of lidocaine and prilocaine) in a much shorter time frame with fewer adverse reactions in adults (Sawyer, Febbraro, Masud, et al., 2009).
- Synera reduced PIV cannulation pain and did not alter the success rate in children 3 to 17 years old (Singer, Taira, Chisena, et al., 2008).
- Median self-reported pain using a visual analog scale or Wong-Baker FACES scale was significantly lower when the Synera patch was placed over the antecubital or hand vein vs. the placebo patch ($p = 0.04$) (Singer, Taira, Chisena, et al., 2008).
- A 20-minute application of the S-Caine patch (Synera) was effective in lessening pain in children scheduled for vascular access (Sethna, Verghese, Hannallah, et al., 2005).
- Synera pain patch significantly reduced pain compared with placebo (median Oucher scores of 0 vs. 60; $p < 0.001$); 59% of children in the pain patch group reported no pain compared with 20% in the placebo group (Sethna, Verghese, Hannallah, et al., 2005).
- Mild skin erythema (<38%) and edema (<2%) occurred with similar frequencies between the groups (Sethna, Verghese, Hannallah, et al., 2005).

Apply the Evidence: Nursing Implications

There is *good evidence* with *strong recommendation* for using Synera patches to decrease pain during painful procedures (Guyatt, Oxman, Vist, et al., 2008). Synera use during PIV cannulation in children 3 years and older decreases pain. It should not be used in children with sensitivity to lidocaine, tetracaine, para-aminobenzoic acid (PABA), or amide- or ester-type anesthetics. Use with caution in patients with hepatic impairment and those receiving class I antiarrhythmic drugs (e.g., tocainide and mexiletine) and do not apply to broken skin. Use the patch immediately after opening the pouch; do not cut or remove any layers of the patch; and ensure that the holes on the patch are not covered by clothing. Do not keep the patch on longer than 20 to 30 minutes. As with all transdermal patches containing medication, after use fold the adhesive together and dispose of used patches in a location out of the reach of children. Do not use in a magnetic resonance imaging suite.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe the use of Synera to decrease pain during painful procedures.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by using Synera patches to decrease pain during painful procedures.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate strengths and weakness of evidence for use of Synera patches to decrease pain during painful procedures.

*Adapted from the QSEN at www.qsen.org.

sulfate dissolved in dehydrated glycerine) have been demonstrated to provide greater relief than olive oil drops to the ear (Hoberman, Paradise, Reynolds, et al., 1997).

In children with pharyngitis, spontaneous pain resolved in 80% of children who received ibuprofen during the first 48 hours, 70% of children who received acetaminophen, and 55% of children who received neither ibuprofen nor acetaminophen (Bertin, Pons, d'Athis, et al., 1996). In patients who had culture-positive streptococcal pharyngitis, those who received IM injection of a steroid such as dexamethasone or betamethasone were able to achieve pain relief within 6 hours compared with those who did not receive either one (Marvez-Valls, Ernst, Gray, et al., 1998). Parents have also reported using salt water gargles, lozenges, and local anesthetic sprays for alleviation of their child's pain in acute pharyngitis.

Viral infections of the mouth such as primary herpetic gingivostomatitis (herpes simplex virus 1) and herpangina ulcers (coxsackievirus A) are extremely painful; if inadequately treated the pain can inhibit oral intake in children. Viscous lidocaine can be swished and spit by children older than 3 years of age or applied with cotton-tipped applicator in children younger than 3 years. A

EVIDENCE-BASED PRACTICE

Needle-Free Injection System: J-Tip to Administer Buffered Lidocaine

Ask the Question

In pediatrics are needle-free injection systems (e.g., J-Tip) effective and safe in relieving pain during peripheral intravenous (PIV) cannulation?

Search for the Evidence

Search Strategies

English-language research-based publications on jet injectors for delivery of lidocaine during PIV cannulation without time limitation were included. Exclusions included dental products, insulin, growth factor, and medications other than lidocaine.

Databases Used

Cochrane Collaboration Database, Joanna Briggs Institute, National Guideline Clearinghouse (AHRQ), PubMed, SUMSearch, CINAHL, Scopus, UpToDate, BestBETs, manufacturers' or distributors' websites (National Medical Products, Bioject, and Injex)

Critically Analyze the Evidence

- J-Tip is superior in pain prevention compared with lidocaine cream (LMX) or EMLA (a eutectic mix of lidocaine and prilocaine) (Jimenez, Bradford, Seidel, et al., 2006; Spanos, Booth, Koenig, et al., 2008).
- J-Tip with 0.2 mL of 1% buffered lidocaine provided greater anesthesia than a 30-minute application of LMX in children ages 8 to 15 years undergoing 22- or 24-gauge peripheral intravenous (PIV) catheter insertion (Spanos, Booth, Koenig, et al., 2008).
- Visual analog scale (VAS) scores were significantly different immediately after PIV catheter insertion (17.3 for J-Tip vs. 44.6 for LMX; $p < 0.001$). Blinded reviewer VAS scores were not statistically significant (21.7 for J-Tip vs. 31.9 for LMX; $p = 0.23$) (Spanos, Booth, Koenig, et al., 2008).
- J-Tip did not alter the insertion site or affect the success of PIV access on the first attempt; multiple injections could be performed if necessary without causing lidocaine toxicity (Spanos, Booth, Koenig, et al., 2008).
- J-Tip with 0.25 mL of 1% buffered lidocaine provided greater anesthesia than application of 2.5 g of EMLA in a study of 116 children ages 7 to 19 years undergoing PIV catheter insertion (Jimenez, Bradford, Seidel, et al., 2006).
- Subjects' self-report median pain ratings of PIV cannulation using a 0 to 10 VAS were 0 for J-Tip and 3 for EMLA ($p = 0.0001$ for patients receiving EMLA ≥60 minutes before cannulation and $p = 0.0013$ for those receiving EMLA <60 minutes before) (Jimenez, Bradford, Seidel, et al., 2006).
- More pain scores were favorable for the J-Tip application (84% reported no pain at the time of injection) compared with EMLA application (61% reported pain at time of Tegaderm dressing removal; $p = 0.004$) (Jimenez, Bradford, Seidel, et al., 2006).
- J-Tip with 0.2 mL of 1% buffered lidocaine was no more effective than jet-delivered placebo (preservative-free normal saline) during PIV cannulation but may provide superior analgesia compared with no local anesthetic pretreatment (Auerbach, Tunik, and Mojica, 2009).
- Children 5 to 18 years of age received either J-Tip (0.2 mL of buffered 1% lidocaine) or jet-delivered placebo (0.2 mL of preservative-free normal saline) 60 seconds before PIV cannulation in an emergency department. Subjects reported pain on injection and on PIV cannulation using a 100-mm color analog scale (Auerbach, Tunik, and Mojica, 2009).
- Mean needle insertion pain score for jet lidocaine, 28 mm, was similar to the mean score for placebo, 34 mm, and lower than the no-device group, 52 mm; most patients reported that they would request this device for future PIV access (Auerbach, Tunik, and Mojica, 2009).

Apply the Evidence: Nursing Implications

There is *good evidence* with a *strong recommendation* for using J-Tip to administer buffered lidocaine (Guyatt, Oxman, Vist, et al., 2008). J-Tip with 0.2 mL of buffered lidocaine 1% decreases pain during PIV insertion. It is recommended to wait 1 minute after administration before attempting PIV insertion. J-Tip should not be used to administer buffered lidocaine in children with a known hypersensitivity to lidocaine or other amide-type local anesthetics such as prilocaine, mepivacaine, bupivacaine, or etidocaine.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

2% viscous lidocaine solution contains 100 mg/5 mL lidocaine hydrochloride; dosages of more than 5 mg/kg every 3 hours can be potentially toxic in small children (Gonzales-Del-Rey, Wason, and Druckenbrod, 1994). Parents need careful instructions to place an accurate amount of lidocaine in the child's mouth. Benzocaine has also been used, and methemoglobinemia has been reported as a rare side effect associated with its administration in younger children. "Magic mouthwash" preparation has ingredients that adhere to the lesion and provide pain relief. It usually consists of equal parts of diphenhydramine, viscous lidocaine, and aluminum and

EVIDENCE-BASED PRACTICE

Buffered Lidocaine for Pain Reduction During Peripheral Intravenous Access in Children

Ask the Question

In children is buffered lidocaine an appropriate anesthetic for reducing pain during peripheral intravenous (PIV) access?

Search for the Evidence

Search Strategies

Search criteria included English-language publications within the past 5 years, research-based articles (level 3 or lower) on children undergoing PIV access. Two of the articles reviewed were more than 5 years old but were included based on the limited literature in this area.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Joanna Briggs Institute, National Guideline Clearinghouse (AHQR), TRIP Database, PedsCCM, BestBETs

Critically Analyze the Evidence

- Patients' comfort and satisfaction were improved when the pH of lidocaine solution was increased; it is recommended to increase pH of lidocaine solution using bicarbonate immediately before administration (Cepeda, Tzortzopoulou, Thackrey, et al., 2010).
- Buffered lidocaine vs. liposomal lidocaine cream (LMX) was evaluated before PIV access in children (4 to 17 years of age; 61% female). Both interventions decreased pain; no significant differences in pain levels between buffered lidocaine and LMX groups were noted. The LMX group stated that the pain came with the removal of the occlusive dressing from the site (Luhmann, Hurt, Shootman, et al., 2004).
- PIV access without buffered lidocaine was significantly more painful than PIV access with buffered lidocaine in children (Fein, Boardman, Stevenson, et al., 1998).
- Subcutaneous lidocaine vs. no pain-control measures was evaluated in children younger than 2 years of age before PIV access in the emergency department; no significant differences in pain levels were found (Sacchetti and Carraccio, 1996).
- PIV access without lidocaine was significantly more painful than PIV access with lidocaine regardless of catheter size (Klein, Shugerman, Leigh-Taylor, et al., 1995).

Apply the Evidence: Nursing Implications

There is *good evidence* with a *strong recommendation* (Guyatt, Oxman, Vist, et al., 2008) for using buffered lidocaine as a pain reduction measure in children before PIV access. Buffered lidocaine should be used in children older than 2 years of age. It has an immediate time of onset and a duration of about 1 hour and can be injected at multiple sites. The following dosage is recommended: 0.1 to 0.5 mL buffered 1% lidocaine to a maximum of 0.45 mL/kg/dose; can repeat dose after 2 hours. Buffered lidocaine should not be used within 2 hours before vesicants or with abraded skin. There is a possibility of some vasoconstriction with its use, which may increase the difficulty of PIV access. An "extra stick" and ineffective buffered lidocaine administration may result in pain during both local administration and PIV access. Expertise in administering buffered lidocaine is an important factor related to its effectiveness.

magnesium hydroxide (Maalox); equal parts of diphenhydramine and attapulgite suspension (Kaopectate); or a sucralfate suspension plus diphenhydramine and attapulgite suspension solutions that coat the lesions.

Painful and Invasive Procedures

Several painful and invasive procedures require the administration of anesthetics and analgesics. For circumcision pain caudal or penile blocks are used before the procedure; then parents are instructed how to apply lidocaine gels for the first 24 to 36 hours after the circumcision. For open wounds bupivacaine may be instilled with or without epinephrine onto the dressing applied to skin to minimize pain for up to 48 hours after the procedure. For graft donor sites analgesia is maintained by using a foam dressing soaked with bupivacaine (0.25%, 2 mg/kg; 0.8 mL/kg) applied to the donor surface. A continuous infusion of 0.25% bupivacaine at 1 to 3 mL/hr via a standard 18-gauge epidural catheter is then curled on the outer or inner surface of the foam (Cousins and Power, 2003). Wound perfusion of bupivacaine is useful for iliac crest bone graft donor sites (used for alveolar bone grafting in some techniques of

cleft palate repair). A standard 18-gauge epidural catheter is also used with a very low infusion rate (1 to 3 mL/hr) of bupivacaine. For minor and some intermediate procedures, the local anesthetic infiltration with bupivacaine is commonly used. Some examples of these procedures include surface wounds and tunneling procedures in the anesthetized child requiring inguinal surgery; insertion of ventriculoperitoneal shunts, central venous lines, or central venous catheter-reservoir systems; and similar procedures.

Nitrous oxide, which is taken up rapidly and eliminated by the lungs, is highly insoluble in the blood and delivered quickly to the brain to produce an analgesic effect equivalent to that of IV morphine. After approximately 2 minutes of inhalation, maximum pain relief can be achieved. The child breathes via face mask, nasal mask, or mouthpiece. It is not suitable for children younger than 3 years old and works best for children older than 5 years of age. Nitrous oxide inhalations are used frequently for a wide variety of procedures that require potent analgesia for a short time such as suture insertion or removal, dressing removal or changes (including burns), drain or catheter removal, venipuncture or cannulation, lumbar puncture, physical therapy, and biopsies (skin, muscle, renal, or bone marrow). However, the use of nitrous oxide is contraindicated in children with pneumothorax, bowel obstruction, abnormal airway, recent head injury (especially with an intracranial air pocket), chronic respiratory disease with air trapping or bullous changes in the lung, and some types of uncorrected congenital heart disease (such as pulmonary hypertension). Nitrous oxide may lead to expansion of air pockets in confined spaces (chest, cranial cavities, bowel lumens) and create an increased pressure and tension effect. Tension pneumothorax, ischemia or shift of intracranial contents, and bowel distention with risk of perforation could occur. In addition, because nitrous oxide produces a degree of sedation and potentiates the sedative effects of other central nervous system depressants, caution is required when concurrently giving opioids, benzodiazepines, antihistamines, and similar drugs. Inspired concentrations of up to 50% nitrous oxide used for less than 30 minutes do not affect airway reflexes. Only trained personnel may administer nitrous oxide and monitor the child (Cousins and Power, 2003).

Postoperative Pain

Pain associated with surgery to the chest (e.g., repair of congenital heart defects, chest trauma) or abdominal regions (e.g., appendectomy, cholecystectomy, splenectomy) may result in pulmonary complications. Pain leads to decreased muscle movement in the thorax and abdominal area and decreased tidal volume, vital capacity, functional residual capacity, and alveolar ventilation. The patient is unable to cough and clear secretions, and the risk for complications such as pneumonia and atelectasis is high. Severe postoperative pain also results in sympathetic overactivity, which leads to increases in heart rate, peripheral resistance, blood pressure, and cardiac output. The patient eventually experiences an increase in cardiac demand and myocardial oxygen consumption and a decrease in oxygen delivery to the tissues.

The basis for good postoperative pain control in children is preemptive analgesia. Preemptive analgesia involves administration of medications (e.g., local and regional anesthetics, analgesics) before the child experiences the pain or before surgery is performed so the sensory activation and changes in the pain pathways of the peripheral and central nervous system can be controlled. Preemptive analgesia has been demonstrated to lower postoperative pain, analgesic requirement, hospital stay, and complications after surgery and minimize the risks for peripheral and central nervous system sensitization that can lead to persistent pain (Cousins and Power, 2003).

A combination of medications (multimodal or balanced analgesia) is used for postoperative pain and may include nonsteroidal antiinflammatory drugs (NSAIDs), local anesthetics, nonopioids, and opioid analgesics to achieve optimum relief and minimize side effects. Opioids administered around the clock (ATC) during the first 48 hours or via patient-controlled analgesia (PCA) are commonly prescribed after surgery. The duration of use is frequently limited to days because the cause of pain usually resolves. The combination of the IV NSAID ketorolac and morphine using a PCA device is frequently prescribed after thoracic surgery. Morphine delivered by PCA leads to a lower total dosage of opioid analgesia when compared with the administration of intermittent doses of analgesic as required. After bowel surgery a mixture of local anesthetics (bupivacaine) and a low-dose opioid (fentanyl) delivered by epidural route improves the rate of recovery and minimizes the gastrointestinal effects (e.g., bowel stasis, nausea, vomiting). Once bowel function has been restored, oral opioids such as immediate- and controlled-release preparations are preferred in older children. Controlled-release opioids facilitate ATC dosing and improve sleep. They are also associated with lower incidence of nausea, sedation, and breakthrough pain.

Burn Pain

Because burn pain has multiple components, involves repeated manipulations over the injured painful sites, and has changing pattern over time, it is difficult and challenging to control. It includes a constant background pain that is felt at the wound sites and surrounding areas and can be exacerbated (breakthrough pain) by movements such as changing position, turning in bed, walking, or even breathing. Areas of normal skin that have been harvested for skin grafts (donor sites) also elicit pain. Pain is commonly experienced with intense tingling or itching sensations when skin grafting is required. During the healing process, when the tissue and nerve regenerate, the necrotic tissue **(eschar)** is excised until viable tissue is reached. The healing process may last for months to years. Pain or paresthetic sensations (e.g., itching, tingling, cold sensations) may persist. In addition, discomfort may be associated with immobilization of limbs in splints or garments and multiple surgical interventions such as skin grafting and reconstructive surgery (Choiniere, 2003).

Multiple therapeutic procedures are carried out during the course of treatment. These procedures (i.e., dressing changes, wound debridement and cleansing, physical therapy sessions) occur daily or even several times a day. Providing proper analgesia without interfering with the patient's awareness during and after the procedure is the biggest challenge in the management of burn pain. Fentanyl or alfentanil has a major advantage over morphine because of the short duration. Fentanyl can prevent oversedation following the procedure. For less painful procedures premedication with oral morphine, oral ketamine, or milder opioids 15 minutes before the procedure may be sufficient. Depending on the patient's anxiety level, a benzodiazepine (e.g., lorazepam) before the procedure may be beneficial. For longer procedures morphine is the mainstay of treatment. Some patients may require moderate-to-deep sedation and analgesia. Oral oxycodone with midazolam and acetaminophen, in addition to nitrous oxide, may be needed. IV ketamine administered at subtherapeutic doses has been one of the most extensively used anesthetics for burn patients. The dysphoria and unpleasant reactions associated with ketamine administration may be minimized with premedication with a benzodiazepine. If

ketamine is used with either morphine or fentanyl, the regimen could have opioid-sparing actions and reduce the opioid-related side effects.

Psychologic interventions can also be helpful in the treatment of burn pain. These interventions include hypnosis, relaxation training (breathing exercises, progressive muscle relaxation), biofeedback, stress inoculation training, cognitive-behavioral strategies (guided imagery, distraction, coping skills), and group and individual psychotherapy. They can be used alone or in combination. All of these techniques can help the patient relax and maintain a sense of control (Choiniere, 2003). A major disadvantage of these interventions is that they require time and discipline and often patients are too stressed, fatigued, disoriented, or sick to engage in them.

Recurrent Headaches

Recurrent headaches in children can have several causes, including tension, dental braces, imbalance or weakness of eye muscles causing deviation in alignment and refractive errors, sequelae to accidents, sinusitis and other cranial infection or inflammation, increased intracranial pressure, epileptic attacks, drugs, obstructive sleep apnea and, rarely, hypertension. Other causes may include arteriovenous malformations, disturbances in cerebrospinal fluid flow or absorption, intracranial hemorrhages, ocular and dental diseases, bacterial infections, and brain tumors. Severe pain is the most disturbing symptom in migraine. Tension-type headache is usually mild or moderate, often producing a pressing feeling in the temples like a "tight band around the head." Continuous, daily, or near-daily headache with no specific cause occurs in a small subgroup of children. In epilepsy headaches commonly occur immediately before, during, or after a seizure attack.

Treatment of recurrent headaches requires an understanding of the antecedents and consequences of headache pain. A headache diary can allow the child to record the time of onset, activities before the onset, any worries or concerns as far back as 24 hours before the onset, severity and duration of pain, pain medications taken, and activity pattern during headache episodes. The headache diary allows ongoing monitoring of headache activity, indicates the effects of interventions, and guides treatment planning.

There are two main approaches to management of headache using behavioral approaches: (1) teaching patients self-control skills to prevent headache (biofeedback techniques and relaxation training), and (2) modifying behavior patterns that increase the risk of headache occurrence or reinforce headache activity (cognitive-behavioral stress-management techniques). Biofeedback is a technology-based form of relaxation therapy and can be useful in assessing and reinforcing learning of relaxation skills such as progressive muscle relaxation, deep breathing, and imagery. Children as young as 7 years of age have been taught these skills and with 2 or 3 weeks of practice are able to decrease the time needed to achieve relaxation.

To modify behavior patterns that increase the risk of headache occurrence or reinforce headache activity, the nurse instructs parents to avoid giving excessive attention to their child's headache and to respond matter-of-factly to pain behavior and requests for special attention (Holden, Deichmann, and Levy, 1999). Parents are taught to assess whether school or social performance demands are being avoided because of headache. They are taught to focus attention on adaptive coping such as the use of relaxation techniques and maintenance of normal activity patterns. When using cognitive-behavioral stress-management techniques, the parents identify negative thoughts and situations that may be associated with increased risk for headache. The child is then taught to activate positive thoughts and engage in adaptive behavior appropriate to the situation.

Recurrent Abdominal Pain

Recurrent abdominal pain (RAP) or functional abdominal pain is defined as pain that occurs at least once per month for 3 consecutive months, accompanied by pain-free periods, and is severe enough that it interferes with a child's normal activities. Management of RAP is highly individualized to reflect the causes of the pain and the psychosocial needs of the child and family. A clear understanding of the child's characteristics (anxiety, physical health, temperament, coping skills, experience, learned response, depression), child's disability (school attendance, activities with family, social interactions, pain behaviors), environmental factors (family attitudes and behavioral patterns, school environment, community, friendships), and the pain stimulus (disease, injury, stress) is important in planning management strategies (Collins and Weisman, 2003).

Before any workup of the pain, the nurse informs the family that RAP is common in children and only 10% of children with RAP have an identifiable organic cause for their pain symptom. Medical workup is dictated by the child's symptoms and signs in combination with knowledge about common organic causes of RAP. If an organic cause is found, it is treated appropriately. Even if no organic cause is found, the nurse needs to communicate to the child and family a belief that the pain is real. Usually the abdominal pain goes away; however, even if problems are identified, they may not be the actual cause, and pain may persist, be replaced by another symptom, or go away on its own. The management of plan includes regular follow-up at a 3- to 4-month intervals, a list of symptoms that call for earlier contact, and biobehavioral pain-management techniques. The goal is to minimize the impact that the pain has on the child's activities and the family's life (Collins and Weisman, 2003).

Case reports have demonstrated the effectiveness of implementing a time-out procedure, token systems, and positive reinforcement based on operant theory treatment modalities. Stress-management and cognitive-behavioral strategies have also been reported to be successful. Parent training in how to avoid positive reinforcement of sick behaviors and focus on rewarding healthy behaviors is important. Over the course of several sessions parents are educated about RAP, how to distinguish between sick and well behaviors, a reward system for well behaviors, and the importance of reinforcing relaxation and stressing the teaching of coping skills to children for pain management. Treatment may consist of a varying number of sessions over 1 to 6 months and include various components such as monitoring symptoms, limited parent attention, relaxation training, increased dietary fiber, and requirements of school attendance. Response rates are 25% without abdominal pain and 56% to 75% improvements in symptoms (Collins and Weisman, 2003). The use of cognitive-behavioral therapy has been documented to reduce or eliminate pain in children with RAP and highlights the involvement of parents in supporting their child's self-management behavior. No negative side effects of symptom substitution occurred with the interventions. One study demonstrated that the combination of self-regulation and cognitive-behavioral interventions along with fiber intervention is more effective for treating RAP than using fiber alone (Weydert, Ball, and Davis, 2003).

Pain with Sickle Cell Disease

A painful episode is the most frequent cause for ED visits and hospital admissions among children with sickle cell disease. The acute

painful episode in sickle cell disease is the only pain syndrome in which opioids are considered the major therapy and are started in early childhood and continued throughout adult life. A source of frustration for patients and clinicians is that the most current analgesic regimens are inadequate in controlling some of the most severe painful episodes. A multidisciplinary approach that involves both pharmacologic and nonpharmacologic modalities (cognitive-behavioral intervention, heat, massage, physical therapy) is needed but not often implemented. The goals of treatment of the acute episode may not be to take all the pain away, which is usually impossible, but to make the pain tolerable to the patient until the episode resolves and increase function and patient participation in activities of daily living (Benjamin, Dampier, Jacox, et al., 1999; Max, Payne, Edwards, et al., 1999).

Individuals coming to an ED for acute painful episodes usually have exhausted all home care options or outpatient therapy (Benjamin, Dampier, Jacox, et al., 1999; Max, Payne, Edwards, et al., 1999). The nurse should ask patients what the usual medication, dosage, and side effects were in the past; about the usual medication taken at home; and about medication taken since the onset of present pain. The patient may be on long-term opioid therapy at home and therefore may have developed some degree of tolerance. A different potent opioid or a larger dose of the same medication may be indicated. Because mixed opioid-agonist-antagonists (e.g., pentazocine, nalbuphine, butorphanol) may precipitate withdrawal syndromes, these should be avoided if patients were taking long-term opioids at home. A "passport" card with patient information about the diagnosis, previous complications, suggested pain management regimen, and name and contact information of the primary hematologist would be helpful for parents and would facilitate management of pain in the ED.

The patient is admitted for inpatient management of severe pain if adequate relief is not achieved in the ED (Benjamin, Dampier, Jacox, et al., 1999; Max, Payne, Edwards, et al., 1999). For severe pain IV administration with bolus dosing and continuous infusion using a PCA device may be necessary. Patients requiring more than 5 to 7 days of opioids should have tapering doses to avoid the physiologic symptoms of withdrawal (dysphoria, nasal congestion, diarrhea, nausea and vomiting, sweating, and seizures). Appropriate weaning of the PCA schedules starts with reduction of the continuous infusion rate before discontinuation while the patient can continue to use demand doses for analgesia. Morphine-equivalent equianalgesic conversions may be used to convert continuous infusion rates to equivalent oral analgesics. Doses of long-acting oral analgesics such as sustained-release oral morphine may also be used to replace continuous-infusion dosing. The demand doses can be reduced subsequently if analgesia remains adequate.

Some patients whose pain is managed poorly try to persuade medical staff to give them more analgesic, engage in clock watching, and request specific medications or dosages. These patients are often perceived as manipulative and demanding. Because patients with sickle cell disease have lifelong experiences with pain, they are knowledgeable about the medications and doses that are effective (Benjamin, Dampier, Jacox, et al., 1999; Max, Payne, Edwards, et al., 1999). Therefore the nurse should respect their requests for specific medications and doses and not interpret them as indications of drug-seeking behavior.

Patients who are administered doses of opioids that are inadequate to relieve their pain or whose doses are not tapered after a course of treatment may develop **iatrogenic** pseudoaddiction (Elander, Lusher, Bevan, et al., 2004), which resembles addiction. Pseudoaddiction or clock-watching behavior may be resolved by communicating with patients to ensure accurate assessment, involving them in decisions about their pain management, and administering adequate opioid doses (Elander, Lusher, Bevan, et al., 2004).

Cancer Pain

Pain is the most prevalent symptom (84.4%) and was rated as moderate to severe (86.6%) and highly distressing (52.8%) in children with cancer (Collins, Byrnes, Dunkel, et al., 2000). Pain is present before diagnosis and treatment and may resolve after initiation of anticancer therapy. However, treatment-related pain is a common occurrence. Pain may be related to an operation; mucositis; a phantom limb; infection; chemotherapy; and procedures such as bone marrow aspiration, needle puncture, and lumbar puncture (Collins, Byrnes, Dunkel, et al., 2000). Tumor-related pain frequently occurs when the child relapses or when tumors become resistant to treatment. Intractable pain may occur in patients with solid tumors that metastasize to the central or peripheral nervous system. In young adult survivors of childhood cancer, chronic pain conditions may develop, including complex regional pain syndrome of the lower extremity, phantom limb pain, avascular necrosis, mechanical pain related to bone that failed to unite after tumor resection, and postherpetic neuralgia.

Oral mucositis (ulceration of the oral cavity and throat) may occur in 40% of patients undergoing chemotherapy or radiotherapy and in 76% of patients undergoing bone marrow transplant (Berger, Henderson, Nadoolman, et al., 1995). No present therapy adequately relieves the pain of these lesions. Antihistamines, local anesthetics, and opioids provide only temporary relief, may block taste perception, or may produce additional side effects such as lethargy and constipation. Initial treatment includes single agents (saline, opioids, sodium bicarbonate, hydrogen peroxide, sucralfate suspension, clotrimazole, nystatin, viscous lidocaine, amphotericin B, dyclonine) or mouthwash mixtures using a combination of agents (lidocaine, diphenhydramine, Maalox or Mylanta, nystatin). The mucositis after bone marrow transplantation may be prolonged, continuously intense, exacerbated by mouth care and swallowing, or worse during waking hours. The patient may be unable to eat or swallow. Morphine administered as a continuous infusion or delivered by PCA device may be required until mucositis is resolved (Collins and Weisman, 2003).

Other treatment-related pain includes (1) abdominal pain after allogeneic bone marrow transplantation, which may be associated with acute graft-versus-host disease; (2) abdominal pain associated with typhlitis (infection of the cecum), which occurs when the patient is immunocompromised; (3) phantom sensations and phantom limb pain after an amputation; (4) peripheral neuropathy after administration of vincristine; and (5) medullary bone pain, which may be associated with administration of granulocyte colony–stimulating factor (Collins and Weisman, 2003).

Almost 40% of all pain episodes in children with cancer may be attributed to procedures (Ljungman, Gordh, Sorensen, et al., 1999, 2000, 2001; Ljungman, Kreuger, Andreasson, et al., 2000). Survivors of childhood cancer describe vivid memories of their experience with repeated painful procedures during treatment. These procedures include needle puncture for IM chemotherapy (L-asparaginase), IV lines, port access and blood draws, lumbar puncture, bone marrow aspiration and biopsy, removal of central venous catheters, and other invasive diagnostic procedures. Fear and anxiety related to these procedures may be minimized with parent and child preparation. The preparation starts with obtaining information from the parent about the child's coping styles, explaining

the procedure, and enlisting their support, followed by an age-appropriate explanation to the child. Topical analgesics (cold sprays, EMLA, amethocaine gels), as discussed previously, have been effective in providing analgesia before needle procedures.

Lumbar puncture for administration of chemotherapy (cytarabine, methotrexate) and collection of cerebrospinal fluid may lead to a leak at the puncture site and low intracranial pressure (Collins and Weisman, 2003). Some children may experience postdural puncture headache, which may be treated by administering nonopioid analgesics and placing the patient in the supine position for 1 hour after the procedure. The pain related to bone marrow aspiration is caused by the insertion of a large needle into the posterior iliac space and the unpleasant sensation experienced at the time of marrow aspiration. Nonpharmacologic strategies such as cognitive-behavioral therapy, guided imagery, relaxation, music therapy, hypnosis, conscious sedation, and general anesthesia have been proven effective in decreasing pain and distress during the procedure.

Morphine is the most widely used opioid for moderate-to-severe pain and may be administered via the oral (including sustained-release formulations such as MS Contin and Kadian), IV, subcutaneous, epidural, and intrathecal routes. When dose-limiting side effects of morphine develop, hydromorphone has been reported to be effective in several studies of children with cancer (Drake, Longworth, and Collins, 2004). In a study of children and adolescents with mucositis after bone marrow transplantation, which compared morphine to hydromorphone using PCA, hydromorphone was tolerated well and had a potency ratio of approximately 6:1 relative to morphine (Drake, Longworth, and Collins, 2004).

The most common clinical syndrome of neuropathic pain is painful peripheral neuropathy caused by chemotherapeutic agents, particularly vincristine and cisplatin, and rarely cytarabine (Collins and Weisman, 2003). Withdrawal of the chemotherapy may resolve the neuropathy over weeks to months, or it may persist even after withdrawal. **Neuropathic pain** is associated with at least one of the following: (1) pain that is described as electric or shocklike, stabbing, or burning; (2) signs of neurologic involvement (paralysis, neuralgia, pain hypersensitivity) other than those associated with the progression of the tumor; and (3) the location of the solid organ cancer consistent with neurologic damage that could give rise to neuropathic pain. Dying children with cancer who experience neuropathic pain have higher baseline requirements of morphine and require more rapid increases of morphine than dying children without neuropathic pain (Dougherty and DeBaun, 2003). Children with neuropathic pain often require massive opioid infusion (3 mg/kg/hr of IV morphine dose equivalent or approximately 100-fold greater than standard starting infusion rates). An epidural or subarachnoid infusion may be initiated if the patient experiences dose-limiting side effects of opioids or if pain was resistant to opioids.

Tricyclic antidepressants (amitriptyline, desipramine) and anticonvulsants (gabapentin, carbamazepine) have demonstrated effectiveness in neuropathic cancer pain. Randomized controlled trials showed that 60% to 70% of patients with neuropathic pain achieve relief with tricyclic antidepressants (Sindrup, Otto, Finnerup, et al., 2005). The tricyclic antidepressants have many actions that could be involved in their pain-relieving effect and have been considered the mainstay of therapy for neuropathic pain (Sindrup, Otto, Finnerup, et al., 2005).

Klepstad, Borchgrevink, Hval, et al. (2001) reported the pain experience of a 12-year-old girl with severe neuropathic pain caused by a cervical spinal tumor. Two weeks after resection of the tumor, the child experienced increased pain in her neck, which was superficial and distributed in the dermatomes below the cervical medullary lesion. Pain was provoked by touch and did not decrease in intensity despite a subcutaneous infusion of morphine at 160 mg/24 hr. The child screamed from increased pain when her parents or siblings tried to comfort her with bodily contact. Pain was relieved after administration of 7.5-to-10 mg IV ketamine. Ketamine is an *N*-methyl-D-aspartate (NMDA) antagonist, which has undesirable side effects (sedation, nausea, dissociative reactions, muteness, dizziness, and visual distortions) and short duration of action (Sang, 2000). After administration of ketamine the child was able to tolerate touch without pain paroxysms. A continuous IV infusion was eventually initiated for convenience, and benzodiazepines were added to avoid the psychomimetic effects associated with ketamine. More recently Finkel, Pestieau, and Quezado (2007) used subanesthetic doses of ketamine to treat 11 children and adolescents who were on high doses of opioids and had uncontrolled cancer pain. Ketamine appeared to improve pain control and have an opioid-sparing effect. Members of a pain-management consulting service directed and titrated the ketamine to address symptoms. The ketamine dosage range used (0.1 to 1 mg/kg/hr) was low-dose and is lower than that used for anesthetic purposes. Lorazepam (0.025 mg/kg every 12 hours) was administered concurrently during ketamine treatment. Heart rate, noninvasive blood pressure, respiratory rate, and oxygen saturation are monitored continuously.

Although ketamine is frequently used to ensure analgesia and sedation during painful procedures in children, its long-term use for the treatment of neuropathic pain in children has not been studied systematically and is not of clinical benefit for all patients (Klepstad, Borchgrevink, Hval, et al., 2001). In randomized studies of patients with chronic neuropathic pain, only some had a beneficial response to ketamine (Haines and Gaines, 1999; Max, Byas-Smith, Gracely, et al., 1995; Mitchell, 2001). Other NMDA antagonists (dextromethorphan, memantine) are available for clinical use, but no reports on their use in children with neuropathic pain related to cancer have been documented.

Pain and Sedation in End-of-Life Care

Many patients require doses of opioids that make them sedated but arousable as their disease progresses (cancer, human immunodeficiency virus, cystic fibrosis, neurodegenerative disease) at the end of life. Comfort can be achieved with a combination of opioids and adjuvant analgesics in most situations. Parents need reassurance that the opioids are treating pain but not causing the child's death and that the child's advancing disease is the cause of death.

A small group of patients have intolerable side effects or inadequate analgesia despite extremely aggressive use of medications to relieve pain and side effects. Continuous sedation may be a means of relieving suffering when there is no feasible or acceptable means of providing analgesia that preserves alertness. A continuing high-dose infusion of opioids along with sedation is prescribed to reduce the possibility that a child might experience unrelieved pain but be too sedated to report it. Sedation in these situations is widely regarded as providing comfort, not euthanasia. Clinicians and ethicists have a range of views regarding assisted suicide and euthanasia, but they all agree that no child or parent should choose death because of inadequate efforts to relieve pain and suffering (Berde and Collins, 2003).

KEY POINTS

- Although the ability to measure pain in children has improved dramatically in recent years, assessment of pain in children continues to be complex and challenging.
- Behavioral assessment is useful for measuring pain in infants and preverbal children who do not have the language skills to communicate that they are in pain or when mental clouding and confusion limit a child's ability to communicate.
- Physiologic measures are not able to distinguish between physical responses to pain and other forms of stress to the body.
- The number of pain measurement tools that are available for use in infants and young children has increased dramatically and adds a layer of complexity to the assessment of pain in children.
- Important components of assessment include the onset of pain; pain duration or pattern; effectiveness of the current treatment; factors that aggravate or relieve the pain; other symptoms and complications concurrently felt; and interference with the child's mood, function, and interactions with family.
- The administration of sucrose with and without nonnutritive sucking has a calming and pain-relieving effect for invasive procedures in neonates.
- One of the most significant improvements in the ability to provide atraumatic care to children is the anesthetic cream LMX or EMLA.
- Nonopioids, including acetaminophen (Tylenol, paracetamol) and NSAIDs, are suitable for mild-to-moderate pain; opioids are needed for moderate-to-severe pain.
- Several drugs known as coanalgesics or adjuvant analgesics may be used alone or with opioids to control pain symptoms and opioid side effects.
- A significant advance in the administration of IV, epidural, or subcutaneous analgesics is the use of PCA.
- Although respiratory depression is the most feared side effect of opioids, constipation is a common and sometimes serious side effect that decreases peristalsis and increases anal sphincter tone.
- Several harmful effects occur with unrelieved pain, particularly when pain is prolonged.
- Surgery and traumatic injuries (i.e., fractures, dislocations, strains, sprains, lacerations, burns) generate a *catabolic state* as a result of increased secretion of catabolic hormones and lead to alterations in blood flow, coagulation, fibrinolysis, substrate metabolism, and water and electrolyte balance and increase the demands on the cardiovascular and respiratory systems.
- Because burn pain has multiple components, involves repeated manipulations over the injured painful sites, and has changing pattern over time, it is difficult and challenging to control.
- Treatment of recurrent headaches requires an understanding of the antecedents and consequences of headache pain.
- RAP or functional abdominal pain is defined as pain that occurs at least once per month for 3 consecutive months accompanied by pain-free periods and is severe enough that it interferes with a child's normal activities.
- A painful episode is the most frequent cause for ED visits and hospital admissions among children with sickle cell disease.
- Pain is the most prevalent symptom reported by children with cancer.
- Injections from immunizations, IM antibiotics in the ED or health care provider's office, and blood draws are common sources of pain in children.
- For nonpainful procedures such as radiologic imaging studies, several medications are used to sedate, minimize anxiety, and induce amnesia.
- Several painful and invasive procedures require the administration of anesthetics and analgesics.

CHAPTER

31

The Infant and Family

David Wilson

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify the major biologic, psychosocial, cognitive, and social developments during the first year of life.
- Relate parent-child attachment, separation anxiety, and stranger fear to developmental achievements during infancy.
- Provide anticipatory guidance to parents regarding common parental concerns during infancy.
- Provide anticipatory guidance to parents regarding recommendations for feeding infants.
- Outline immunization requirements during infancy, early childhood, and adolescence.
- List general contraindications, precautions, and administration routes for immunizations.
- Provide anticipatory guidance to parents regarding injury prevention based on the infant's developmental achievements.
- Provide principles of anticipatory guidance in the care of the family with an infant who is experiencing colic.
- Plan nursing care that meets the physical and emotional needs of the child and family with growth failure.
- Provide nursing care that meets the immediate and long-term needs of the family who lost a child from sudden infant death syndrome.
- Provide anticipatory guidance for the prevention of sudden infant death syndrome.
- Identify the needs of the family whose child is home-monitored for apnea.

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

Biologic Development

At no other time in life are physical changes and developmental achievements as dramatic as during infancy. All major body systems undergo progressive maturation, and there is concurrent development of skills that increasingly allow infants to respond to and cope with the environment. Acquisition of these fine and gross motor skills occurs in an orderly head-to-toe and center-to-periphery (cephalocaudal and proximodistal) sequence.

Proportional Changes

Growth is very rapid during the first year, especially the initial 6 months. Infants gain 150 to 200 g (5 to 7 oz) weekly until approximately age 5 to 6 months, when the birth weight has at least doubled. An average weight for a 6-month-old child is 7.26 kg (16 lb). Weight gain slows during the second 6 months. By 1 year of age, the infant's birth weight has tripled, for an average weight of 9.75 kg (21.5 lb). *Height* increases by 2.5 cm (l in) a month during the first 6 months and also slows during the second 6 months. Increases in length occur in sudden spurts, rather than in a slow, gradual pattern. Average height is 65 cm (25.5 inches) at 6 months and 74 cm (29 inches) at 12 months. By 1 year, the birth length has increased by almost 50%. This increase occurs mainly in the trunk, rather than in the legs, and contributes to the infant's characteristic physique.

Head growth is also rapid. During the first 6 months, head circumference increases approximately 1.5 cm (0.6 inch) a month, but the rate of increase falls to only 0.5 cm (0.2 inch) monthly during the second 6 months. The average size is 43 cm (17 inches) at 6 months and 46 cm (18 inches) at 12 months. By 1 year, head size has increased by almost 33%. Closure of the cranial sutures occurs, with the posterior fontanel closing by 6 to 8 weeks of age and the anterior fontanel closing by 12 to 18 months of age (the average age being 14 months).

Expanding head size reflects the growth and differentiation of the *nervous system*. By the end of the first year, the brain has increased in weight about 2.5 times. Maturation of the brain is exhibited in the dramatic developmental achievements of infancy (Table 31-1). Primitive reflexes are replaced by voluntary, purposeful movement, and new reflexes that influence motor development appear.

Text continued on p. 869

TABLE 31-1 GROWTH AND DEVELOPMENT DURING INFANCY

AGE (MO)	PHYSICAL	GROSS MOTOR	FINE MOTOR	SENSORY	VOCALIZATION	SOCIALIZATION/ COGNITION
1	Weight gain of 150-200 g (5-7 oz) weekly for first 6 mo Height gain of 2.5 cm (1 inch) monthly for first 6 mo Head circumference increases by 1.5 cm (5/10 inch) monthly for first 6 mo Primitive reflexes present and strong Doll's eye reflexes and dance reflex fading Obligatory nose breathing (most infants)	Assumes flexed position with pelvis high but knees not under abdomen when prone (at birth, knees flexed under abdomen)* Can turn head from side to side when prone; lifts head momentarily from bed (see Fig. 31-3, *A*)* Has marked head lag, especially when pulled from lying to sitting position (see Fig. 31-2, *A*) Holds head momentarily parallel and in midline when suspended in prone position Assumes asymmetric tonic neck reflex position when supine When held in standing position, body is limp at knees and hips In sitting position, back is uniformly rounded, absence of head control	Hands predominantly closed Grasp reflex strong Hand clenches on contact with rattle	Able to fixate on moving object in range of 45 degrees when held at a distance of 20-25 cm (8-10 inches) Visual acuity approaches 20/100† Follows light to midline Quiets when hears a voice	Cries to express displeasure Makes small, throaty sounds Makes comfort sounds during feeding	Is in sensorimotor phase—stage I, use of reflexes (birth–1 mo), and stage II, primary circular reactions (1-4 mo) Watches parent's face intently as parent talks to infant
2	Posterior fontanel closed Crawling reflex disappears	Assumes less flexed position when prone—hips flat, legs extended, arms flexed, head to side* Less head lag when pulled to sitting position (see Fig. 31-2, *B*) Can maintain head in same plane as rest of body when held in ventral suspension When prone, can lift head almost 45 degrees off table When moved to sitting position, head is held up but bends forward (see Fig. 31-5, *B*) Assumes asymmetric tonic neck reflex position intermittently	Hands often open Grasp reflex fading	Binocular fixation and convergence to near objects beginning When supine, follows dangling toy from side to point beyond midline Visually searches to locate sounds Turns head to side when sound is made at level of ear	Vocalizes, distinct from crying* Crying becomes differentiated Coos Vocalizes to familiar voice	Demonstrates social smile in response to various stimuli*

Continued

TABLE 31-1 GROWTH AND DEVELOPMENT DURING INFANCY—cont'd

AGE (MO)	PHYSICAL	GROSS MOTOR	FINE MOTOR	SENSORY	VOCALIZATION	SOCIALIZATION/ COGNITION
3	Primitive reflexes fading	Able to hold head more erect when sitting, but still bobs forward Has only slight head lag when pulled to sitting position Assumes symmetric body positioning Able to raise head and shoulders from prone position to a 45- to 90-degree angle from table; bears weight on forearms When held in standing position, able to bear slight fraction of weight on legs Regards own hand	Actively holds rattle but will not reach for it* Grasp reflex absent Hands kept loosely open Clutches own hand; pulls at blankets and clothes	Follows object to periphery (180 degrees)* Locates sound by turning head to side and looking in same direction* Begins to have ability to coordinate stimuli from various sense organs	Squeals aloud to show pleasure* Coos, babbles, chuckles Vocalizes when smiling "Talks" a great deal when spoken to Less crying during periods of wakefulness	Displays considerable interest in surroundings Ceases crying when parent enters room Can recognize familiar faces and objects, such as feeding bottle Shows awareness of strange situations
4	Drooling begins Moro, tonic neck, and rooting reflexes have disappeared*	Has almost no head lag when pulled to sitting position (see Fig. 31-2, *C*)* Balances head well in sitting position (see Fig. 31-5, *C*)* Back less rounded, curved only in lumbar area Able to sit erect if propped up Able to raise head and chest off surface to angle of 90 degrees (see Fig. 31-3, *B*) Assumes predominant symmetric position Rolls from back to side*	Inspects and plays with hands; pulls clothing or blanket over face in play* Tries to reach objects with hand but overshoots Grasps object with both hands Plays with rattle placed in hand, shakes it, but cannot pick it up if dropped Can carry objects to mouth	Able to accommodate to near objects Binocular vision fairly well established Can focus on a 1.25 cm (½-inch) block Beginning eye-hand coordination	Makes consonant sounds *n, k, g, p, b* Laughs aloud* Vocalization changes according to mood	Is in stage III, secondary circular reactions Demands attention by fussing; becomes bored if left alone Enjoys social interaction with people Anticipates feeding when sees bottle or mother if breastfeeding Shows excitement with whole body, squeals, breathes heavily Shows interest in strange stimuli Begins to show memory
5	Beginning signs of tooth eruption as bumps on gums are palpable Birth weight doubles	No head lag when pulled to sitting position When sitting, able to hold head erect and steady Able to sit for longer periods when back is well supported Back straight When prone, assumes symmetric positioning with arms extended Can turn over from abdomen to back* When supine, puts feet to mouth	Able to grasp objects voluntarily* Uses palmar grasp, bidextrous approach Plays with toes Takes objects directly to mouth Holds one cube while regarding a second one	Visually pursues a dropped object Is able to sustain visual inspection of an object Can localize sounds made below ear	Squeals Makes cooing vowel sounds interspersed with consonant sounds (e.g., *ah-goo*)	Smiles at mirror image Pats bottle or breast with both hands More enthusiastically playful, but may have rapid mood swings Is able to discriminate strangers from family Vocalizes displeasure when object is taken away Discovers parts of body

TABLE 31-1 GROWTH AND DEVELOPMENT DURING INFANCY—cont'd

AGE (MO)	PHYSICAL	GROSS MOTOR	FINE MOTOR	SENSORY	VOCALIZATION	SOCIALIZATION/ COGNITION
6	Growth rate may begin to decline Weight gain of 90-150 g (3-5 oz) weekly for next 6 mo Height gain of 1.25 cm (0.5 inch) monthly for next 6 mo Teething may begin with eruption of two lower central incisors* Chewing and biting occur*	When prone, can lift chest and upper abdomen off surface, bearing weight on hands (see Fig. 31-3, *C*) When about to be pulled to a sitting position, lifts head Sits in high chair with back straight Rolls from back to abdomen When held in standing position, bears almost all of weight Hand regard absent	Resecures a dropped object Drops one cube when another is given Grasps and manipulates small objects Holds bottle Grasps feet and pulls to mouth	Adjusts posture to see an object Prefers more complex visual stimuli Can localize sounds made above ear Will turn head to the side, then look up or down	Begins to imitate sounds* Babbling resembles one-syllable utterances—*ma, mu, da, di, hi** Vocalizes to toys, mirror image Takes pleasure in hearing own sounds (self-reinforcement)	Recognizes parents; begins to fear strangers Holds arms out to be picked up Has definite likes and dislikes Begins to imitate (cough, protrusion of tongue) Excites on hearing footsteps Laughs when head is hidden in a towel Briefly searches for a dropped object (object permanence beginning)* Frequent mood swings—from crying to laughing with little or no provocation
7	Sits alone without support	When supine, spontaneously lifts head off surface Sits, leaning forward on hands (see Fig. 31-5, *D*)* When prone, bears weight on one hand Sits erect momentarily Bears full weight on feet (see Fig. 31-6, *A*) When held in standing position, bounces actively	Transfers objects from one hand to the other (see Fig. 31-5, *E*)* Has unidextrous approach and grasp Holds two cubes more than momentarily Bangs cube on table Rakes at a small object	Can fixate on very small objects* Responds to own name Localizes sound by turning head in a curving arch Beginning awareness of depth and space Has taste preferences	Produces vowel sounds and chained syllables—*baba, dada, kaka** Vocalizes four distinct vowel sounds "Talks" when others are talking	Increasing fear of strangers; shows signs of fretfulness when parent disappears* Imitates simple acts and noises Tries to attract attention by coughing or snorting Plays peekaboo Demonstrates dislike of food by keeping lips closed Exhibits oral aggressiveness in biting and mouthing Demonstrates expectation in response to repetition of stimuli
8	Begins to show regular patterns in bladder and bowel elimination Parachute reflex appears (see Fig. 31-4) Eruption of upper central incisors	Sits steadily unsupported (see Fig. 31-5, *E*)* Readily bears weight on legs when supported; may stand holding onto furniture Adjusts posture to reach an object	Has beginning pincer grasp using index, fourth, and fifth fingers against lower part of thumb Releases objects at will Rings bell purposely Retains two cubes while regarding third cube Secures an object by pulling on a string Reaches persistently for toys out of reach		Makes consonant sounds *t, d, w* Listens selectively to familiar words Utterances signal emphasis and emotion Combines syllables, such as *dada,* but does not ascribe meaning to them	Increasing anxiety over loss of parent, particularly mother, and fear of strangers Responds to word "no" Dislikes dressing, undressing, and diaper change

Continued

TABLE 31-1 GROWTH AND DEVELOPMENT DURING INFANCY—cont'd

AGE (MO)	PHYSICAL	GROSS MOTOR	FINE MOTOR	SENSORY	VOCALIZATION	SOCIALIZATION/ COGNITION
9	Eruption of upper lateral incisor may begin	Creeps on hands and knees Sits steadily on floor for prolonged time (10 min) Recovers balance when leaning forward but cannot do so when leaning sideways Pulls self to standing position and stands holding onto furniture (see Fig. 31-6, *B* and *C*)*	Uses thumb and index fingers in crude pincer grasp (see Fig. 31-1)* Preference for use of dominant hand now evident Grasps third cube Compares two cubes by bringing them together	Localizes sounds by turning head diagonally and directly toward sound Depth perception increasing	Responds to simple verbal commands Comprehends "no-no"	Parent (mother) is increasingly important for own sake Shows increasing interest in pleasing parent Begins to show fears of going to bed and being left alone Puts arms in front of face to avoid having it washed
10	Labyrinth-righting reflex is strongest—when infant is in prone or supine position, is able to raise head	Can change from prone to sitting position Stands while holding onto furniture, sits by falling down Recovers balance easily while sitting While standing, lifts one foot to take a step (see Fig. 31-6, *D*)	Crude release of an object beginning Grasps bell by handle		Says "dada," "mama" with meaning* Comprehends "bye-bye" May say one word (e.g., "hi," "bye," "no")	Inhibits behavior to verbal command of "no-no" or own name Imitates facial expressions; waves bye-bye Extends toy to another person but will not release it Develops object permanence* Repeats actions that attract attention and cause laughter Pulls clothes of another to attract attention Plays interactive game such as pat-a-cake Reacts to adult anger; cries when scolded Demonstrates independence in dressing, feeding, locomotive skills, and testing of parents Looks at and follows pictures in a book
11	Eruption of lower lateral incisor may begin	When sitting, pivots to reach toward back to pick up an object Cruises or walks holding onto furniture or with both hands held*	Explores objects more thoroughly (e.g., clapper inside bell) Has neat pincer grasp Drops object deliberately for it to be picked up Puts one object after another into a container (sequential play) Able to manipulate an object to remove it from tight-fitting enclosure		Imitates definite speech sounds	Experiences joy and satisfaction when a task is mastered Reacts to restrictions with frustration Rolls ball to another on request Anticipates body gestures when a familiar nursery rhyme or story is being told (e.g., holds toes and feet in response to "This little piggy went to market") Plays game up-down, "so big," or peekaboo Shakes head for "no"

TABLE 31-1 GROWTH AND DEVELOPMENT DURING INFANCY—cont'd

AGE (MO)	PHYSICAL	GROSS MOTOR	FINE MOTOR	SENSORY	VOCALIZATION	SOCIALIZATION/ COGNITION
12	Birth weight tripled* Birth length increased by 50%* Head and chest circumference equal (head circumference 46 cm [18 inches]) Has total of six to eight deciduous teeth Anterior fontanel almost closed Landau reflex fading Babinski reflex disappears Lumbar curve develops; lordosis evident during walking	Walks with one hand held* Cruises well May attempt to stand alone momentarily; may attempt first step alone* Can sit down from standing position without help	Releases cube in cup Attempts to build two-block tower but fails Tries to insert a pellet into a narrow-necked bottle but fails Can turn pages in a book, many at a time	Discriminates simple geometric forms (e.g., circle) Amblyopia may develop with lack of binocularity Can follow rapidly moving object Controls and adjusts response to sound; listens for sound to recur	Says three to five words besides "dada," "mama"* Comprehends meaning of several words (comprehension always precedes verbalization) Recognizes objects by name Imitates animal sounds Understands simple verbal commands (e.g., "Give it to me," "Show me your eyes")	Shows emotions such as jealousy, affection (may give hug or kiss on request), anger, fear Enjoys familiar surroundings and explores away from parent Is fearful in strange situation; clings to parent May develop habit of "security blanket" or favorite toy Has increasing determination to practice locomotor skills Searches for an object even if it has not been hidden, but searches only where object was last seen*

*Milestones that represent essential integrative aspects of development that lay the foundation for the achievement of more advanced skills.
†Degree of visual acuity varies according to vision measurement procedure used.

Because of the complexity of the developmental process during the first 12 months, Table 31-1 is presented to help organize and clarify the data already discussed. Although all milestones are important, some represent essential integrative aspects of development that lay the foundation for achievement of more advanced skills. These essential milestones are designated by an asterisk in the table. The table represents the average monthly age at which various skills are attained. It must be remembered that although the sequence is the same, the rate will vary among children.

The *chest* assumes a more adult contour, with the lateral diameter becoming larger than the anteroposterior diameter. The chest circumference approximately equals the head circumference by the end of the first year. The heart grows less rapidly than the rest of the body. Its weight is usually doubled by 1 year of age; in comparison, body weight triples during the same period. The size of the heart is still large in relation to the chest cavity; its width is approximately 55% of the chest width.

Maturation of Systems

Other organ systems also change and grow during infancy. The *respiratory* rate slows somewhat (see Appendix C) and is relatively stable. Respiratory movements continue to be abdominal. Several factors predispose the infant to more severe and acute respiratory problems. The close proximity of the trachea to the bronchi and its branching structures rapidly transmits infectious agents from one anatomic location to another. The short, straight eustachian tube closely communicates with the ear, allowing infection to ascend from the pharynx to the middle ear. In addition, the inability of the immune system to produce sufficient immunoglobulin A (IgA) in the mucosal lining provides less protection against infection in infancy than during later childhood.

The *heart rate* slows (see Appendix C), and the rhythm is often *sinus dysrhythmia* (i.e., rate increases with inspiration and decreases with expiration). Blood pressure also changes during infancy (see Appendix C). Systolic pressure rises during the first 2 months as a result of the increasing ability of the left ventricle to pump blood into the systemic circulation. Diastolic pressure decreases during the first 3 months and then gradually rises to values close to those at birth. Fluctuations in blood pressure occur during varying states of activity and emotion.

Significant *hematopoietic changes* occur during the first year (see Appendix B). Fetal hemoglobin (HgbF) is present in large quantities for the first 5 months, with adult hemoglobin steadily increasing through the first half of infancy. Fetal hemoglobin has a shorter life span than adult hemoglobin; therefore there is an increased turnover of these cells and a gradual decrease in hemoglobin. This process results in a *physiologic anemia* around 3 to 6 months of age. High levels of HgbF depress the production of erythropoietin, a hormone released by the kidney that stimulates red blood cell production. Hemoglobin levels decrease to a certain point at which tissue oxygenation needs stimulate erythropoietin, and erythropoiesis resumes, forming new red blood cells.

Maternally derived iron stores are present for the first 5 to 6 months and gradually diminish, which also accounts for lowered hemoglobin levels toward the end of the first 6 months. The occurrence of physiologic anemia is not affected by an adequate supply of iron. However, when erythropoiesis is stimulated, iron supplies are necessary for the formation of hemoglobin.

The *digestive processes* are immature at birth. Although term newborn infants have some limitations in digestive function, human milk has properties that partially compensate for decreased digestive enzymatic activity, thus enabling breastfed infants to receive optimal nutrition during the first several months of life. Saliva is secreted in small amounts, but the majority of the digestive processes do not begin functioning until age 3 months, when drooling is common because of the poorly coordinated swallowing reflex. The enzyme *amylase* (also called *ptyalin*) is present in small amounts but usually has little effect on the foodstuffs because of the small amount of time the food stays in the mouth. Gastric digestion in the stomach consists primarily of the action of hydrochloric acid and rennin, an enzyme that acts specifically on the casein in milk to cause the formation of curds (i.e., coagulated semisolid particles of milk). The curds cause the milk to be retained in the stomach long enough for digestion to occur.

Digestion also takes place in the duodenum, where pancreatic enzymes and bile begin to break down protein and fat. Secretion of the pancreatic enzyme *amylase,* which is needed for digestion of complex carbohydrates, is deficient until about the fourth to sixth month of life. *Lipase* is also limited, and infants do not achieve adult levels of fat absorption until 4 to 5 months of age. *Trypsin* is secreted in sufficient quantities to catabolize protein into polypeptides and some amino acids.

The immaturity of the digestive processes is evident in the appearance of stools. During infancy, solid foods (e.g., peas, carrots, corn, and raisins) are passed incompletely broken down in the feces. An excess quantity of fiber easily disposes the child to loose, bulky stools. During infancy, the stomach enlarges to accommodate a greater volume of food. By the end of the first year, the infant is able to tolerate three meals a day and an evening bottle and may have one or two bowel movements daily. With any type of gastric irritation, however, the infant is vulnerable to diarrhea, vomiting, and dehydration (see Chapter 41).

The *liver* is the most immature of all the gastrointestinal organs throughout infancy. The ability to conjugate bilirubin and secrete bile is achieved after the first couple of weeks of life. However, the capacities for gluconeogenesis, formation of plasma protein and ketones, storage of vitamins, and deaminization of amino acids remain relatively immature for the first year of life.

Maturation of the suckling, sucking, and swallowing reflexes and the eruption of teeth (see Teething, p. 881) parallel the changes in the gastrointestinal tract and prepare the infant for the introduction of solid foods.

The immunologic system undergoes numerous changes during the first year. Full-term newborns receive significant amounts of maternal immunoglobulin G (IgG), which, for approximately 3 months, confers immunity against antigens to which their mothers were exposed. During this time, infants begin to synthesize IgG; approximately 40% of adult levels are reached by 1 year of age. Significant amounts of immunoglobulin M (IgM) are produced at birth, and adult levels are reached by 9 months of age. Secretory IgA is not present at birth but is found in saliva and tears by 2 to 5 weeks.

Prebiotic oligosaccharides found in breast milk produce probiotic bacteria such bifidobacteria and lactobacilli, which in turn stimulate synthesis and secretion of secretory IgA (sIgA). Secretory IgA is present in large amounts in colostrum; IgA confers protection to the mucous membranes of the gastrointestinal tract (Blackburn, 2013; Lawrence and Lawrence, 2011) against many bacteria, such as *Escherichia coli,* and viruses, such as rubella, poliovirus, and the enteroviruses. The development of the mucosa-associated lymphoid tissue occurs during infancy; in part, this system is believed to prevent colonization and passage of bacteria across the infant's mucosal barrier (Lawrence and Lawrence, 2011). The function and quantity of T-lymphocytes, lymphokines, interferon-γ, interleukins, tumor necrosis factor-α, and complement are reduced in early infancy, thus preventing optimal response to certain bacteria and viruses. The production of IgA and immunoglobulins D and E (IgD and IgE) is much more gradual, and maximum levels are not attained until early childhood. Probiotics may have a significant role in helping the gastrointestinal tract establish a "good" bacterial colonization in the gut to prevent many illnesses, including antibiotic-induced diarrhea and possibly *Helicobacter pylori* gastritis (Thomas, Greer, American Academy of Pediatrics [AAP], et al., 2010).

There is evidence that vernix caseosa, a white oily substance that coats the term infant's body and is often found in abundance in creases of the axilla and groin, has innate immunologic properties that serve to protect the newborn from infection (Narendran and Hoath, 2006). Vernix also appears to have a role in maintaining the integrity of the stratum corneum and facilitating acid mantle development (Hoath, Pickens, and Visscher, 2006). The epidermis of the full-term infant undergoes maturation during the first month of life; the newborn's skin acts as a barrier to infection, assists in thermal regulation, and prevents transepidermal water loss in term infants.

During infancy, *thermoregulation* becomes more efficient; the ability of the skin to contract and of muscles to shiver in response to cold increases. The peripheral capillaries respond to changes in ambient temperature to regulate heat loss. The capillaries constrict in response to cold, conserving core body temperature and decreasing potential evaporative heat loss from the skin surface. The capillaries dilate in response to heat, decreasing internal body temperature through evaporation, conduction, and convection. Shivering *(thermogenesis)* causes the muscles and muscle fibers to contract, generating metabolic heat that is distributed throughout the body. Increased adipose tissue during the first 6 months insulates the body against heat loss.

A shift in the *total body fluid* occurs. At birth, 75% of the term infant's body weight is water, with a large percentage being extracellular fluid (ECF). As the percentage of body water decreases, so does the amount of ECF—from 40% at term to 20% in adulthood. The high proportion of ECF, which is composed of blood plasma, interstitial fluid, and lymph, predisposes the infant to a more rapid loss of total body fluid and, consequently, dehydration. The loss of 5% to 10% of the term newborn's initial birth weight in the first 5 days of life is attributed to ECF compartment contraction, enhanced renal tubular function, and rapidly increasing glomerular filtration rate.

The immaturity of the *renal structures* also predisposes the infant to dehydration. Complete maturity of the kidney occurs during the latter half of the second year, when the cuboidal epithelium of the glomeruli becomes flattened. Before this time, the glomeruli's filtration capacity is reduced. Urine is voided frequently and has a low specific gravity (i.e., 1.000 to 1.010). At term, most infants produce and excrete approximately 15 to 60 mL/kg/24 hr, and an output of less than 0.5 mL/kg/hr after 48 hours of age is considered to be oliguria (Blackburn, 2013).

Auditory acuity is at adult levels during infancy. Visual acuity begins to improve, and binocular fixation is established. Binocularity, or the fixation of two ocular images into one cerebral picture (fusion), begins to develop by 6 weeks of age and should be well established by age 4 months. Depth perception (stereopsis) begins

FIG 31-1 Crude pincer grasp at 8 to 10 months. (Photo by Paul Vincent Kuntz, Texas Children's Hospital, Houston, TX.)

to develop by age 7 to 9 months but may not be fully mature until 2 to 3 years of age, thus increasing the infant's and younger toddler's risk for falling.

Fine Motor Development

Fine motor behavior includes the use of the hands and fingers in the prehension (grasp) of an object. Grasping occurs during the first 2 to 3 months as a reflex and gradually becomes voluntary. At 1 month of age, the hands are predominantly closed, and by 3 months, they are mostly open. By this time, infants demonstrate a desire to grasp an object but they "grasp" it more with the eyes than with the hands. If a rattle is placed in the hand, the infant will actively hold onto it. By 4 months of age, the infant regards both a small pellet and the hands and then looks from the object to the hands and back again. By 5 months, the infant is able to voluntarily grasp an object.

Gradually the palmar grasp (using the whole hand) is replaced with a pincer grasp (using the thumb and index finger). The infant uses a crude pincer grasp by 8 to 9 months of age and has progressed to a neat pincer grasp by 11 months (Fig. 31-1).

By 6 months of age, infants have increased manipulative skill: they hold their bottle, grasp their feet and pull them to their mouth, and feed themselves a cracker. By 7 months, they transfer objects from one hand to the other, use one hand for grasping, and hold a cube in each hand simultaneously. They enjoy banging objects and will explore the movable parts of a toy.

By 10 months of age, the pincer grasp is sufficiently established to enable infants to pick up a raisin and other finger foods. They can deliberately let go of an object and will offer it to someone. By 11 months, they put objects into a container and like to remove them. By age 1 year, infants try to build a tower of two blocks but fail.

Gross Motor Development

Head Control. The full-term newborn can momentarily hold the head in midline and parallel when the body is suspended ventrally and can lift and turn the head from side to side when prone. This is not the case when the infant is lying prone on a pillow or soft surface; infants do not have the head control to lift their head out of the depression of the object and therefore risk possible suffocation in the prone position early in infancy (see Sudden Infant Death Syndrome, p. 910). Marked head lag is evident when the infant is pulled from a lying to a sitting position. By 3 months of age, infants can hold their head well beyond the plane of the body. By 4 months of age, infants can lift the head and front portion of the chest approximately 90 degrees above the table, bearing their weight on the forearms. Only slight head lag is evident when the infant is pulled from a lying to a sitting position, and by 4 to 6 months, head control is well established (Figs. 31-2 and 31-3).

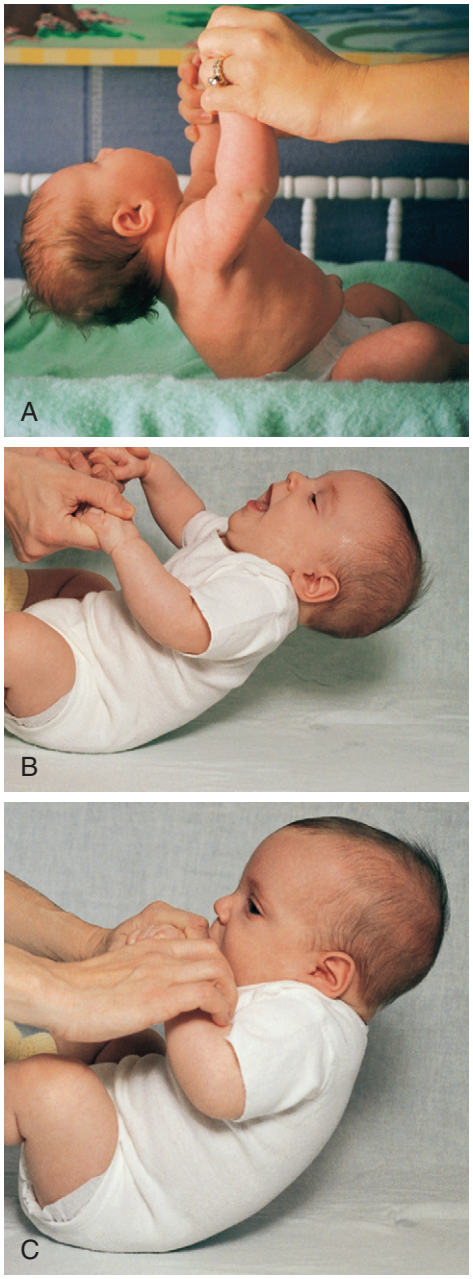

FIG 31-2 Head control while pulled to sitting position. **A,** Complete head lag at 1 month. **B,** Partial head lag at 2 months. **C,** Almost no head lag at 4 months.

! NURSING ALERT

An infant who displays head lag at 6 months of age should have a developmental and neurologic evaluation.

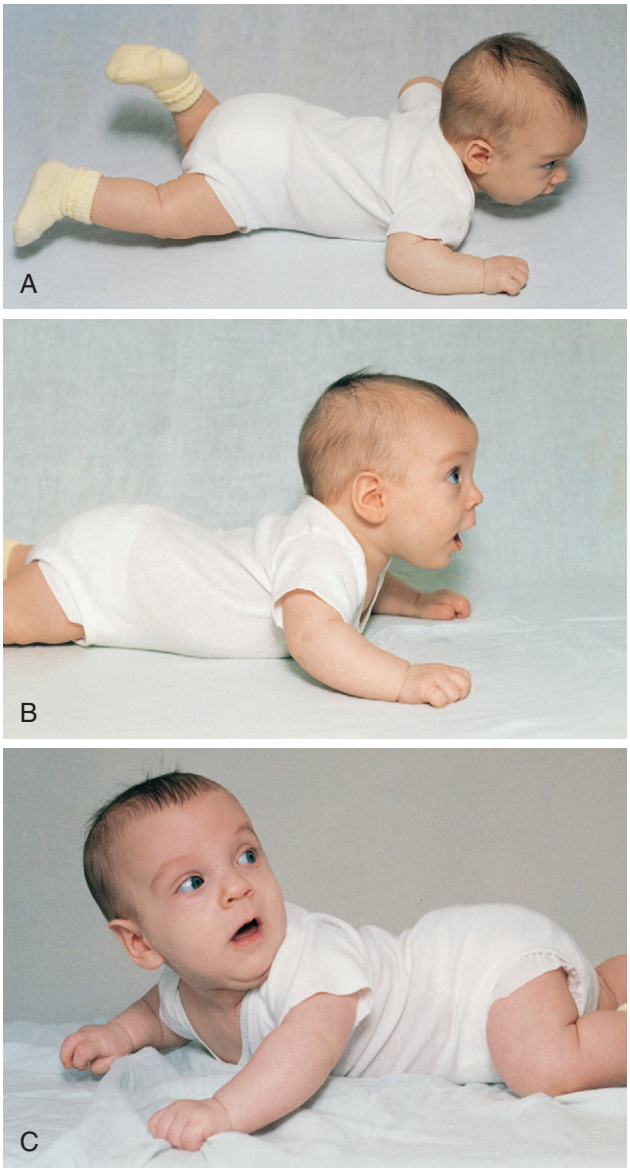

FIG 31-3 Head control while prone. **A,** Infant momentarily lifts head at 1 month. **B,** Infant lifts head and chest 90 degrees and bears weight on forearms at 4 months. **C,** Infant lifts head, chest, and upper abdomen and can bear weight on hands at 6 months. Note how this position facilitates turning from abdomen to back.

Rolling Over. Newborns may roll over accidentally because of their rounded back. The ability to willfully turn from the abdomen to the back occurs at 5 months, and the ability to turn from the back to the abdomen occurs at 6 months. Infants put to sleep on their sides may easily roll over to a prone (face-down) position, thus placing them at higher risk for sudden infant death syndrome (SIDS). It is therefore important to place infants in a supine position for sleep. While the infant is awake, a prone position (tummy time) is acceptable to enhance achievement of milestones such as head control, crawling, creeping, and turning over. It is noteworthy that the parachute reflex (Fig. 31-4), a protective response to falling, appears at 7 months.

Sitting. The ability to sit follows progressive head control and straightening of the back (Fig. 31-5). For the first 2 to 3 months, the back is uniformly rounded. The convex cervical curve forms at approximately 3 to 4 months of age, when head control is established. The convex lumbar curve appears when the child begins to sit, at about age 4 months. As the spinal column straightens, the infant can be propped in a sitting position. By age 7 months, infants can sit alone, leaning forward on their hands for support. By age 8 months, they can sit well while unsupported and begin to explore their surroundings in this position rather than in a lying position. By 10 months, they can maneuver from a prone to a sitting position.

FIG 31-4 Parachute reflex. Infant extends arms to protect from falling. (Photo by Paul Vincent Kuntz, Texas Children's Hospital, Houston, TX.)

! NURSING ALERT

In the first several months, before the infant can roll over, the head should be positioned on alternating sides to prevent positional plagiocephaly (when asleep or awake in the supine position).

Locomotion. Locomotion involves acquiring the ability to bear weight, propel forward on all four extremities, stand upright with support, and, finally, walk alone (Fig. 31-6). Following a cephalocaudal pattern, infants 4 to 6 months old have increasing coordination in their arms. Initial locomotion results in infants propelling themselves backward by pushing with the arms. By 6 to 7 months of age, they are able to bear all their weight on their legs with assistance. *Crawling* (propelling forward with belly on floor) progresses to *creeping* (on hands and knees with belly off floor) by 9 months. At this time, they stand while holding onto furniture and can pull themselves to the standing position but they are unable to maneuver back down except by falling, usually on their bottom. By 11 months, they walk while holding onto furniture or with both hands held, and by age 1 year, they may be able to walk with one hand held. A number of infants attempt their first independent steps by their first birthday. Although there is considerable variation among infants for the achievement of these milestones, they provide guidelines for early intervention.

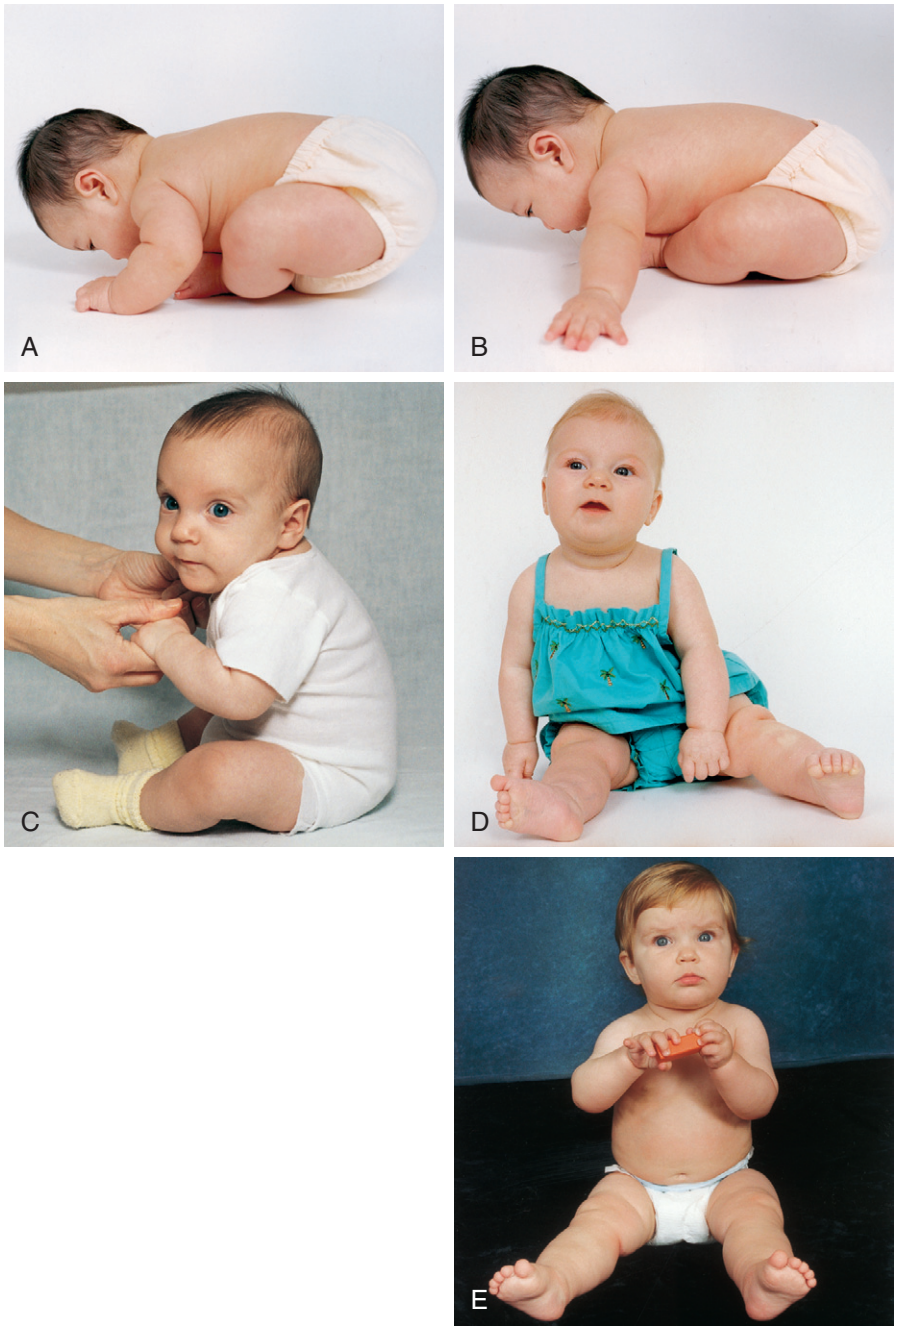

FIG 31-5 Development of sitting. **A,** Back is completely rounded and infant has no ability to sit upright at 1 month. **B,** At 2 months, infant exhibits more control; back is still rounded, but infant can sit up momentarily with some head control. **C,** Back is rounded only in lumbar area and infant is able to sit erect with good head control at 4 months. **D,** Infant can sit alone, leaning on hands for support, at 7 months. **E,** Infant sits without support at 8 months. Note the transferring of objects that occurs beginning at 7 months. (Photos by Paul Vincent Kuntz, Texas Children's Hospital, Houston, TX.)

! NURSING ALERT

An infant who does not pull to a standing position by 11 to 12 months of age should be further evaluated for possible developmental dysplasia of the hip (see Chapter 48).

Psychosocial Development

Developing a Sense of Trust (Erikson)

Erikson's (1963) phase I (birth to 1 year) is concerned with *acquiring a sense of trust* while *overcoming a sense of mistrust.* The trust that develops is a trust of self, of others, and of the world. Infants "trust" that their feeding, comfort, stimulation, and caring needs will be met. The crucial element for the achievement of this task is the quality of both the parent-child (or caregiver-child) relationship and

FIG 31-6 Development of locomotion. **A,** Infant bears full weight on feet by 7 months. **B,** Infant can maneuver from sitting to kneeling position. **C,** Infant can stand holding onto furniture at 9 months. **D,** While standing, infant takes deliberate step at 10 months. **E,** Infant crawls with abdomen on floor and pulls self forward, and then, **F,** creeps on hands and knees at 9 months. (Photos by Paul Vincent Kuntz, Texas Children's Hospital, Houston, TX.)

the care the infant receives. The provision of food, warmth, and shelter by itself is inadequate for the development of a strong sense of self. The infant and parent must jointly learn to satisfactorily meet their needs in order for mutual regulation of frustration to occur. When this synchrony fails to develop, mistrust is the eventual outcome.

Failure to learn *delayed gratification* leads to mistrust. Mistrust can result from either too much or too little frustration. If parents always meet their children's needs before the children signal their readiness, infants will never learn to test their ability to control the environment. If the delay is prolonged, infants experience constant frustration and eventually mistrust others in their efforts to satisfy them. Therefore consistency of care is essential.

The trust acquired in infancy provides the foundation for all succeeding phases. Trust allows infants a feeling of physical comfort and security, which assists them in experiencing unfamiliar situations with a minimum of fear. Erikson has divided the first year of life into two oral/social stages. During the first 3 to 4 months, food intake is the most important social activity in which the infant engages. The newborn can tolerate little frustration or delay of gratification. Primary narcissism (total concern for oneself) is at its height. However, as bodily processes such as vision, motor movements, and vocalization become better controlled, infants use more advanced behaviors to interact with others. For example, rather than cry, infants may put their arms up to signify a desire to be held.

The next social modality involves a mode of reaching out to others through *grasping.* Grasping is initially reflexive, but even as a reflex, it has a powerful social meaning for the parents. The reciprocal response to the infant's grasping is the parents' holding on and touching. There is pleasurable tactile stimulation for both the child and the parents.

Tactile stimulation is extremely important in the total process of acquiring trust. The degree of mothering skill, the quantity of food, or the length of sucking does not determine the quality of the experience. Rather, it is the overall quality of the interpersonal relationship that influences the infant's formulation of trust.

During the second stage, the more active and aggressive modality of *biting* occurs. Infants learn that they can hold onto what is their own and can more fully control their environment. During this stage, infants may be confronted with one of their first conflicts. If they are breastfeeding, they quickly learn that biting causes the mother to become upset and withdraw the breast. Yet biting also brings internal relief from teething discomfort and a sense of power or control.

This conflict may be solved in a variety of ways. The mother may wean the infant from the breast and begin bottle-feeding, or the infant may learn to bite substitute "nipples," such as a pacifier, and retain pleasurable breastfeeding. The successful resolution of this conflict strengthens the mother-child relationship because it occurs at a time when infants are recognizing the mother as the most significant person in their life.

Cognitive Development

Sensorimotor Phase (Piaget)

The theory most commonly used to explain *cognition,* or the ability to know, is that of Piaget (1952). The period from birth to 24 months is termed the *sensorimotor phase* and is composed of six stages; however, because this discussion is concerned with ages birth to 12 months, only the first four stages are discussed. The last two stages occur during the toddler period of 12 to 24 months and are discussed in Chapter 32.

During the sensorimotor phase, infants progress from reflex behaviors to simple repetitive acts to imitative activity. Three crucial events take place during this phase. The first event involves *separation,* in which infants learn to separate themselves from other objects in the environment. They realize that others besides themselves control the environment and that certain readjustments must take place for mutual satisfaction to occur. This coincides with Erikson's concept of the formation of trust.

The second major accomplishment is achieving the concept of **object permanence,** or the realization that objects that leave the visual field still exist. A typical example of the development of object permanence is when infants are able to pursue objects they observe being hidden under a pillow or behind a chair (Fig. 31-7). This skill develops at approximately 9 to 10 months of age, which corresponds to the time of increased locomotion skills.

The last major intellectual achievement of this period is the ability to use *symbols,* or *mental representation.* The use of symbols allows the infant to think of an object or situation without actually experiencing it. The recognition of symbols is the beginning of the understanding of time and space.

Piaget's first stage, from birth to 1 month, is identified by the infant's *use of reflexes.* At birth, the infant's individuality and temperament are expressed through the physiologic reflexes of sucking, rooting, grasping, and crying. The repetitious nature of the reflexes is the beginning of associations between an act and a sequential response. When infants cry because they are hungry, a nipple is put in the mouth and they suck, feel satisfaction, and sleep. They are assimilating this experience while perceiving auditory, tactile, and visual cues. This experience of perceiving certain patterns, or "ordering," provides a foundation for the subsequent stages.

FIG 31-7 Nine-month-old infant actively searches for object hidden behind pillow. (Photo by Paul Vincent Kuntz, Texas Children's Hospital, Houston, TX.)

The second stage, *primary circular reactions,* marks the beginning of the replacement of reflexive behavior with voluntary acts. During the period from 1 to 4 months, activities such as sucking or grasping become deliberate acts that elicit certain responses. The beginning of accommodation is evident. Infants incorporate and adapt their reactions to the environment and recognize the stimulus that produced a response. Previously they would cry until the nipple was brought to the mouth. Now they associate the nipple with the sound of the parent's voice. They accommodate this new piece of information and adapt by ceasing to cry when they hear the voice—before receiving the nipple. What is taking place is a realization of causality and a recognition of an orderly sequence of events. The environment is taken in with all of the senses and with whatever motor ability is present.

The *secondary circular reactions* stage is a continuation of primary circular reactions and lasts until 8 months of age. In this stage, the primary circular reactions are repeated and prolonged for the response that results. Grasping and holding now become shaking, banging, and pulling. Shaking is performed to hear a noise, not solely for the pleasure of shaking. The quality and quantity of an act become evident. More or less shaking produces different responses. Understanding of causality, time, deliberate intention, and separateness from the environment begins to develop.

Three new processes of human behavior occur. *Imitation* requires the differentiation of selected acts from several events. By the second half of the first year, infants can imitate sounds and simple gestures. *Play* becomes evident as they take pleasure in performing an act after they have mastered it. Many of the infant's waking hours are absorbed in sensorimotor play. *Affect* (the outward manifestation of emotion and feeling) is seen as infants begin to develop a sense of permanency. During the first 6 months, infants believe that an object exists only for as long as they can visually perceive it. In other words, out of sight, out of mind. Affect in relation to external objects is evident when the object continues to be present or remembered

even though it is beyond the range of perception. Object permanence is a critical component of parent-child attachment and is seen in the development of separation anxiety at 6 to 8 months of age (see p. 877).

During the fourth sensorimotor stage, *coordination of secondary schemas and their application to new situations,* infants use previous behavioral achievements primarily as the foundation for adding new intellectual skills to their expanding repertoire. This stage is largely transitional. Increasing motor skills allow for greater exploration of the environment. They begin to discover that hiding an object does not mean that it is gone but that removing an obstacle will reveal the object. This marks the beginning of intellectual reasoning. Furthermore, they can experience an event by observing it and they begin to associate symbols with events (e.g., "bye-bye" with "Mommy goes to work"), but the classification is purely their own. In this stage, they learn from the object itself; this is in contrast to the second stage, in which infants learn from the type of interaction between objects or individuals. Intentionality is further developed in that infants now actively attempt to remove a barrier to the desired (or undesired) action (see Fig. 31-7). If something is in their way, they attempt to climb over it or push it away. Previously, an obstacle would cause them to give up any further attempt to achieve the desired goal.

Development of Body Image

The development of body image parallels sensorimotor development. Infants' kinesthetic and tactile experiences are the first perceptions of their body, and the mouth is the principal area of pleasurable sensations. Other parts of the body are primarily objects of pleasure—the hands and fingers to suck and the feet to play with. As physical needs are met, they feel comfort and satisfaction with their body. Messages conveyed by the caregivers reinforce these feelings. For example, when infants smile, they receive emotional satisfaction from others who smile back.

Achieving the concept of object permanence is basic to the development of self-image. By the end of the first year, infants recognize that they are distinct from their parents. At the same time, they have increasing interest in their image, especially in the mirror (Fig. 31-8). As motor skills develop, they learn that parts of the body are useful; for example, the hands bring objects to the mouth and the legs help them move to different locations. All of these achievements transmit messages to them about themselves. Therefore it is important to transmit positive messages to infants about their bodies.

Social Development

Infants' social development is initially influenced by their reflexive behavior, such as the grasp, and eventually depends primarily on the interaction between them and the principal caregivers. **Attachment** to the parent is increasingly evident during the second half of the first year. In addition, tremendous strides are made in communication and personal-social behavior. Whereas crying and reflexive behavior are methods to meet one's needs in the neonatal period, the social smile is an early step in social communication. This has a profound effect on family members and is a tremendous stimulus for evoking continued responses from others. By 4 months, infants laugh aloud.

Play is a major socializing agent and provides stimulation needed to learn from and interact with the environment. By age 6 months, infants are personable. They play games such as peekaboo when their head is hidden in a towel, they signal their desire to be picked up by extending their arms, and they show displeasure when a toy is removed or their face is washed.

FIG 31-8 Nine-month-old infant enjoying own image in mirror.

Attachment

The importance of human physical contact to infants cannot be overemphasized. Parenting is not an instinctual ability but, instead, a learned, acquired process. The attachment of parent and child, which begins before birth, assumes even more importance at birth and continues during the first year. In the following discussion of attachment, the term *mother* is used in the broad context of the consistent caregiver with whom the child relates more than anyone else. However, in society's changing social climate and gender-role stereotypes, this person may very well be the father or a grandparent. Studies on paternal-infant attachment demonstrate that stages similar to those in maternal attachment occur and that fathers are often more involved in child care when mothers are employed (although many mothers continue to do the majority of infant care). Additional research has shown that inexperienced, first-time fathers are as capable as experienced fathers of developing a close attachment with their infants. Studies of fathers of high risk infants demonstrate that fathers experience feelings of love and affection toward their offspring during the newborn period; fathers in one study verbalized more positive feelings of love and affection toward the newborn when they were able to have close physical contact such as holding the child (Sullivan, 1999). The father has also been reported to have a significant role in supporting the mother in the perinatal period; fathers of high risk infants reported concern about their mates' well-being in addition to the status of the ill infant (Lundqvist and Jakobsson, 2003). Research demonstrates that fathers develop feelings of attachment with their offspring and that their relationship with the infant is an important factor in the mother's emotional well-being. With many single-parent families in existence, a grandmother (or other significant caregiver) may become the primary caregiver. It is important for nurses to recognize that infant-parent attachments may be present or absent in situations wherein caregiver roles are less well defined by those involved.

When the infant is not provided a safe haven and consistent and loving care, an *insecure attachment* develops; such infants do not feel they can trust the world in which they live. This insecure attachment may result in psychosocial difficulties as the child grows and may

persist even into adulthood. Insecure attachment may also exist in homes where there is domestic violence and maternal postnatal depression.

Attachment progresses during infancy, with the child assuming an increasingly significant role. Two components of cognitive development are required for attachment: (1) the ability to discriminate the mother from other individuals, and (2) the achievement of object permanence. Both of these processes prepare the infant for an equally important aspect of attachment: separation from the parent. Separation-individuation should occur as a harmonious, parallel process with emotional attachment.

During the formation of attachment to the parent, the infant progresses through four distinct but overlapping stages. For the first few weeks, infants respond indiscriminately to anyone. Beginning at approximately 8 to 12 weeks of age, they cry, smile, and vocalize more to the mother than to anyone else but continue to respond to others, whether familiar or not. At approximately 6 months of age, infants show a distinct preference for the mother. They follow her more, cry when she leaves, enjoy playing with her more, and feel most secure in her arms. About 1 month after showing attachment to the mother, many infants begin attaching to other members of the family, most often the father.

Infants acquire other developmental behaviors that influence the attachment process. These include:

- Differential crying, smiling, and vocalization (more to the mother than to anyone else)
- Visual-motor orientation (looking more at the mother, even if she is not close)
- Crying when the mother leaves the room
- Approaching through locomotion (crawling, creeping, or walking)
- Clinging (especially in the presence of a stranger)
- Exploring away from the mother while using her as a secure base

Reactive attachment disorder (RAD) is a psychologic and developmental problem that stems from maladaptive or absent attachment between the infant and parent and may persist into childhood and even adulthood (Zeanah and Gleason, 2010). Infants at risk for RAD include those who have been victims of physical or sexual abuse or neglect; infants exposed to parental alcoholism, mental illness, and substance abuse; and infants who have experienced the absence of a consistent primary caregiver as a result of foster care, institutionalization, parental abandonment, or parental incarceration. RAD is a form of extreme insecure attachment. Historically, two different patterns of RAD were described: the emotionally withdrawn–inhibited pattern and an indiscriminate-disinhibited pattern (Zeanah and Fox, 2004). Recently Zeanah and Gleason (2010) have proposed classifying these two subtypes into separate disorders: disinhibited social engagement disorder of childhood and reactive attachment disorder of infancy or early childhood. These researchers postulate that children who experience grossly inadequate child care will develop severe attachment disorder. Signs of RAD are usually seen before the age of 5 years in infants who had insecure attachments to the mother or other primary caregiver. The child may manifest behaviors such as not being cuddly with parents, failing to make eye contact with significant others, having poor impulse control, and being destructive to self and others. Maltreated and orphaned children may be diagnosed with this complex disorder. Without early intervention, some of these children fail to develop a conscience and suffer from an antisocial personality disorder that may lead to criminal acts. Children with autism or other pervasive developmental disorders have behaviors that are categorically different from those with RAD (Zeanah and Gleason, 2010).

Separation Anxiety. Between ages 4 and 8 months, the infant progresses through the first stage of separation-individuation and begins to have some awareness of self and mother as separate beings. At the same time, object permanence is developing and the infant is aware that the parent can be absent. Therefore **separation anxiety** develops and is manifested through a predictable sequence of behaviors.

During the early second half of the first year, infants protest when placed in their crib, and a short time later they object when the mother leaves the room. Infants may not notice the mother's absence if they are absorbed in an activity. However, when they realize her absence, they protest. From this point on, they become very alert to her activities and whereabouts. By 11 to 12 months, they are able to anticipate her imminent departure by watching her behaviors and they begin to protest before she leaves. At this point, many parents learn to postpone alerting the child to their departure until just before leaving.

Stranger Fear. As infants demonstrate attachment to one person, they correspondingly exhibit less friendliness to others. Between ages 6 and 8 months, fear of strangers and stranger anxiety become prominent and are related to infants' ability to discriminate between familiar and unfamiliar people. Behaviors such as clinging to the parent, crying, and turning away from the stranger are common (Fig. 31-9).

Language Development

The infant's first means of verbal communication is crying. Crying as a biologic sign conveys a message of urgency and signals displeasure, such as hunger. However, crying is also a social event that affects the development of the parent-infant relationship—either by its absence, which usually has a positive effect on parents, or its presence, which may involve a negative response or persuade parents to minister to the child's physical or emotional needs.

In the first few weeks of life, crying has a reflexive quality and is mostly related to physiologic needs. Infants cry for 1 to 1.5 hours a day up to 3 weeks of age and then build up to 2 and even 4 hours by 6 weeks. Crying tends to decrease by 12 weeks of age. It is thought

FAMILY-CENTERED CARE

Child's Developing Language Skills

During the acquisition of new language skills the child temporarily may stop using other recently learned sounds or words. This is often distressing for parents, who have waited in anticipation for the words "dada" or "mama," because these sounds are commonly replaced by other vocalizations and may not be repeated for several weeks. Nurses can reassure parents that the child will again say these special words, and with increased meaning.

that the increase in crying for no apparent reason during the first few months may be related to the discharge of energy and the maturational changes in the central nervous system. During the end of the first year, infants cry for attention; from fear (especially stranger fear); and from frustration, usually in response to their developing but inadequate motor skills.

! NURSING ALERT

Be alert to parents' reports about maternal postpartum depression and infant crying, since these concerns may indicate a stressed mother-infant relationship.

Vocalizations heard during crying eventually become syllables and words (e.g., the "mama" heard during vigorous crying). Infants vocalize as early as 5 to 6 weeks of age by making small throaty sounds. By 2 months, they make single vowel sounds such as *ah, eh,* and *uh.* By 3 to 4 months, the consonants *n, k, g, p,* and *b* are added and the infants coo, gurgle, and laugh aloud. By 8 months, they imitate sounds; add the consonants *t, d,* and *w;* and combine syllables (e.g., "dada") but they do not ascribe meaning to the word until 10 to 11 months of age (see Family-Centered Care box). By 9 to 10 months, they comprehend the meaning of the word "no" and obey simple commands. By age 1 year, they can say three to five words with meaning.

Play

Play during infancy represents the various social modalities observed during cognitive development. Infants' activity is primarily narcissistic and revolves around their own body. As discussed under Development of Body Image (p. 876), body parts are primarily objects of play and pleasure.

During the first year, play becomes more sophisticated and interdependent. From birth to 3 months, infants' responses to the environment are global and largely undifferentiated. Play is dependent; pleasure is demonstrated by a quieting attitude (1 month), a smile (2 months), or a squeal (3 months). From 3 to 6 months, infants show more discriminate interest in stimuli and begin to play alone with a rattle or a soft stuffed toy or with someone else. There is much more interaction during play. By 4 months of age, they laugh aloud, show a preference for certain toys, and become excited when food or a favorite object is brought to them. They recognize an image in a mirror, smile at it, and vocalize to it.

By 6 months to 1 year, play involves sensorimotor skills. Actual games such as peekaboo and pat-a-cake are played. Verbal repetition and imitation of simple gestures occur in response to demonstration. Play is much more selective, not only in terms of specific toys but also in terms of "playmates." Although play is solitary or one-sided, infants choose with whom they will interact. At 6 to 8 months, they usually refuse to play with strangers. Parents are definite favorites, and infants know how to attract their attention. At 6 months, they extend the arms to be picked up; at 7 months, cough or squeal to make their presence known; at 10 months, pull the parent's clothing; and at 12 months, call them by name. This represents a tremendous advance from the newborn, who signaled biologic needs by crying to express displeasure.

Stimulation is as important for psychosocial growth as food is for physical growth. Knowledge of developmental milestones allows nurses to guide parents regarding proper play for infants. It is not sufficient to place a mobile over a crib and toys in a play yard for a child's optimal social, emotional, and intellectual development. Likewise, the television or recorded videos, for the most part, do not provide infants with appropriate sensory stimulation, do not increase language skills, and should therefore be restricted in children younger than 2 years (AAP Council on Communications and Media, 2011). Play must provide interpersonal contact and recreational and educational stimulation. Infants need to be *played with,* not merely *allowed to play.* Although the type of play infants engage in is called *solitary,* this is a figurative, not literal, term to denote one-sided play. The type of toys given to the child is much less important than the quality of personal interaction that occurs.

Temperament

The infant's temperament or behavioral style influences the type of interaction that occurs between the child and parents, especially the mother, and other family members (see general discussion of temperament in Chapter 28). In assessments of a child's temperament, it is the parents' perception of the child and the degree of fit between their expectations and the child's actual temperament that are important. The more dissonance, or lack of harmony, between the child's temperament and the parent's ability to accept and deal with the behavior, the more risk for subsequent parent-child conflicts.

Although most behavioral researchers agree that there is a strong biologic component to temperament, researchers also suggest that temperament may be modified by the environment, particularly the family (Wilson, White, Cobb, et al., 2000). Family interaction with the infant is perceived as a circular process wherein each family member affects each other and the family as a unit. With these concepts in mind, the nurse has an important role in helping the family understand the infant's temperament as it relates to family dynamics and the eventual well-being of the child and family unit (Wilson, White, Cobb, et al., 2000).

Some researchers speculate that infant temperament may contribute to maternal depression. Indeed, when reciprocity is lacking between the infant and the mother or when the infant's behavior does not meet maternal expectations, there is increased risk for discord. Beck's (2001) meta-analysis found that infant temperament was a mild risk factor for postpartum depression, whereas self-esteem, marital status, socioeconomic status, and unplanned or unwanted pregnancy were much more significant in predicting maternal depression. Fragmented maternal sleep rather than infant temperament was positively correlated to maternal depression in another study (Goyal, Gay, and Lee, 2009). Others (McGrath, Records, and Rice, 2008) found that depressed mothers (vs. nondepressed mothers) rated their infant's temperament at 2 and 6 months of age as more difficult. The researchers stress that depressed

mothers need to be identified and assisted in making the transition to motherhood and in developing synchronicity with their newborn infants. Researchers have correlated fussy infant temperament with the introduction of early complementary feedings (at 3 months of age) (Wasser, Bentley, Borja, et al., 2011) and feeding infants foods that may contribute to obesity (Vollrath, Tonstad, Rothbart, et al., 2011).

The Revised Infant Temperament Questionnaire (RITQ) (Carey and McDevitt, 1978) can be used as a screening tool with parents. The questionnaire focuses on nine temperament variables, but the 95 questions relate specifically to activities such as sleeping, feeding, playing, diapering, and dressing. The scores from the RITQ help identify the child's temperamental style. Use of the RITQ is well accepted by parents and should be accompanied by an adequate explanation of the results. In discussing the results, the nurse should avoid descriptors such as *difficult* and describe such infants in terms such as *intense* or *less predictable.* The Early Infancy Temperament Questionnaire is a 76-item parent questionnaire that was adapted from the RITQ to specifically evaluate temperament characteristics of infants 1 to 4 months old, whereas the RITQ is best suited for infants 4 months old and older (Medoff-Cooper, Carey, and McDevitt, 1993).

With knowledge of the infant's temperament, nurses are better able to (1) provide parents with background information that will help them see their child in a better perspective, (2) offer a more organized picture of their child's behavior and possibly reveal distortions in their perceptions of the behavior, and (3) guide parents regarding appropriate childrearing techniques. Appropriate counseling based on awareness of the child's temperament can greatly enhance the quality of interaction between parents and infant. Even just letting parents know that "difficult" traits are innate can relieve feelings of guilt and incompetence.

Knowledge of the developmental sequence allows the nurse to assess normal growth and minor or abnormal deviations. It also helps parents gain realistic expectations of their child's ability and provides guidelines for suitable play and stimulation. Parents who lack knowledge of child growth and development may set inappropriate behavioral expectations for their child. Emphasizing the child's developmental rather than chronologic age strengthens the parent-child relationship by fostering trust and lessening frustration. Therefore thorough understanding and appreciation of children's growth and development are essential.

Coping with Concerns Related to Normal Growth and Development

Separation and Stranger Fear

A number of fears can appear during infancy. However, the fear that causes parents the most concern is fear related to strangers and separation. Although erroneously interpreted by some as a sign of undesirable, antisocial behavior, stranger fear and separation anxiety are important components of a strong, healthy, parent-child attachment. Nevertheless, this period can present difficulties for the parent and child. Parents may experience guilt at having to leave the infant because he or she violently protests being separated from the parents. To accustom the infant to new people, parents are encouraged to have close friends or relatives visit often. This provides other persons with whom the child is comfortable and who can give parents time for themselves.

Infants also need opportunities to safely experience strangers. Usually toward the end of the first year, infants begin to venture away from the parent and demonstrate curiosity about strangers. If allowed to explore at their own rate, many infants eventually "warm up." If parents hold the child away from their face, the infant can observe while maintaining close physical contact.

The best approach for the stranger (who may be the nurse) is to talk softly; meet the child at eye level (to appear smaller); maintain a safe distance from the infant; and avoid sudden, intrusive gestures, such as holding the arms out and smiling broadly.

Parents also may wonder whether they should encourage the child's clinging, dependent behavior, especially if there is pressure from others who view this as "spoiling." Parents need to be reassured that such behavior is healthy, desirable, and necessary for the child's optimal emotional development. If parents can reassure the infant of their presence, the infant will learn to realize that they are still there even if not physically present. Talking to infants when leaving the room, allowing them to hear one's voice on the telephone, and using transitional objects (e.g., a favorite blanket or toy) reassure them of the parent's continued presence.

Alternative Child Care Arrangements

For many parents, especially working mothers, locating safe and competent child care facilities for the infant is an increasingly difficult problem—one that is compounded by the number of mothers working outside the home. Over the past 40 years, there has been a marked shift in child care arrangements; whereas the majority of children are cared for in group centers or other settings, an increasing number of children are being cared for in home settings.

The basic types of care are (1) in-home care, either in the parents' or caregivers' home (family day care) and (2) center-based care, usually in a day care center. *In-home care* may consist of a full-time baby-sitter who lives in the home, a full-time baby-sitter who comes to the home, cooperative arrangements such as exchange baby-sitting, and family day care. A licensed *small family child day care home* typically provides care and protection for up to six children for part of a day and does not include informal arrangements such as exchange baby-sitting or caregivers in the child's own home. The six children include the family day care provider's own children younger than 5 years living in the home. *Large family child day care homes* may provide care for eight to twelve children. Unfortunately, many family child day care homes operate without a license and may care for large numbers of infants without adequate staff and facilities.

Child center-based care usually refers to a licensed day care facility that provides care for six or more children for 6 or more hours a day. *Work-based group care* is another option that is becoming increasingly popular as employers recognize the benefit of providing high-quality and convenient child care to their employees. *Sick-child care* may also be available for times when the child is ill. Such programs are often located in community hospitals or in work settings.

Nurses may fulfill a unique role in guiding parents in locating suitable facilities that have a well-qualified staff. State licensing agencies can help parents identify day care centers that accept children of specific age-groups and that are convenient to home and work. Their records are available to the public and provide reports from the health, safety, and fire departments; periodic evaluations from the licensing agency; complaints filed against the center; and qualifications of the center's employees. State-licensed programs are supposed to abide by established standards, which represent the minimum requirements and safeguards; however, enforcement of the standards is sometimes inadequate. Early childhood programs may also belong to a voluntary accreditation system, the National

Association for the Education of Young Children, which serves as a model for optimal care.*

The same attention should be applied to locating competent baby-sitters. References from other parents are essential, and there is no substitute for observing the interaction between the individual and the child. Although very young infants need little if any preparation for the introduction of a new caregiver, older infants may benefit from a gradual placement to reduce stranger anxiety. At all times the parent should have the right to visit the child, and regular conferences should be established to review the child's progress. Some child care centers provide a service whereby the parent may log on to the Internet from work and view the child's activity at the center for reassurance that the child is well.

Important areas for parents to evaluate are the center's daily program, teacher qualifications, nurturing qualities of caregivers, child-to-staff ratio, discipline policy, environmental safety precautions, provision of meals, sanitary conditions, adequate indoor and outdoor space per child, and fee schedule. Although fees vary considerably, a program that charges a minimum fee may also be providing minimum services. Parents should arrange to meet the director and some of the employees, especially those who would be caring for the child. Resources to familiarize parents with characteristics of quality child care and checklists to systematically evaluate the center and compare it with other facilities can help parents make successful choices.

One of the areas that is increasingly important in selecting child care is the center's health practices; however, parents often do not check the center for health and safety features. Evidence shows that children, especially those younger than 3 years in day care centers, have more illnesses—especially diarrhea, otitis media, respiratory tract infections (especially if the caregiver smokes), hepatitis A, meningitis, and cytomegalovirus—than children cared for in their home. The strongest predictor of risk for illness is the number of unrelated children in the room. Proactive infection control measures and education of staff have been effective in reducing the incidence of upper respiratory tract infections, diarrhea, and rotavirus. It has been reported that families who have children in out-of-home child care lose an estimated 13 days of work per year as a result of infections (Brady, 2005). Parents should inquire about the center's policy regarding the attendance and care of sick children. Parents with children in day care or even in-home care need to discuss safe sleep positions and environments for infants in order to prevent SIDS (Matthews and Moore, 2013).

Limit Setting and Discipline

As infants' motor skills advance and mobility increases, parents face the need to set safe limits to protect the child and establish a positive and supportive parent-child relationship (see Nurse's Role in Injury Prevention, p. 903). Although there are numerous disciplinary techniques, some are more appropriate for this age than others. An effective approach used in disciplining a child is the use of "time-out." The important principle to consider is that the place for time-out needs to be commensurate with the child's abilities. For example, the play yard is better for most infants than a chair. Although parents may be concerned with instituting discipline during infancy, it is important to stress that the earlier effective disciplinary methods are employed, the easier it is to continue these approaches.

Parents must recognize the child's cognitive and behavioral limitations; adequate protection from hazards must be implemented because infants and toddlers do not understand a cause-effect relationship between dangerous objects and physical harm. Children will innately test limits and explore during the exploratory phase of growth; instead of discouraging exploration, parents should provide safe alternatives, put away dangerous household items, and provide consistent discipline and nurturing.

Effective teaching for injury prevention optimally begins in infancy by helping parents understand the nature of their child's normal development. It must be reiterated continually that infants cry because a need is not being met, not to intentionally irritate an adult. The fussy or irritable infant is a potential victim of shaken baby syndrome (or other bodily harm), since adults and caregivers may not understand the nature of the infant's crying.*

Thumb-Sucking and Use of a Pacifier

Sucking is the infant's chief pleasure and may not be satisfied by breastfeeding or bottle-feeding. It is such a strong need that infants who are deprived of sucking, such as those with a cleft lip repair, will suck on their tongues. Some newborns are born with sucking blisters on their hands from in utero sucking activity.

Problems arise when parents are overly concerned about the sucking of the fingers, thumb, or pacifier and attempt to restrain this natural tendency. Before giving advice, nurses should investigate the parents' feelings and base guidance on this information.

Pacifier use, particularly in the early days after birth and in the birth hospital, has gained considerable attention in the scientific literature. Biancuzzo (2003) suggests that it cannot be stated with absolute certainty that pacifier use is bad in every situation but warns of a potential harm in the use of pacifiers based on available evidence. Furthermore, she cautions health care workers to be informed regarding potential harm in pacifier use and to inform parents of the potential. Lawrence and Lawrence (2011), as well as other experts in breastfeeding, recommend that health care workers not introduce pacifiers to breastfed infants unless the parent requests it. Pacifier use is not recommended as part of the Baby-Friendly Hospital Initiative. O'Connor, Tanabe, Siadaty, et al. (2009) reviewed 29 studies and concluded that pacifier use did not adversely affect breastfeeding duration or exclusivity. They further concluded that pacifier use and shortened breastfeeding in many studies likely represented a number of other complex factors such as breastfeeding difficulties or intent to wean.

Pacifier use has been associated with an increased risk for otitis media in several studies (Niemelä, Pihakari, Pokka, et al., 2000; Rovers, Numans, Langenbach, et al., 2008). The American Academy of Pediatrics (AAP) and American Academy of Family Physicians recommend use of pacifier during the first 6 months because of the benefit in regard to pain management and prevention of sudden infant death syndrome (SIDS) but recommend the child be weaned from the pacifier during the second 6 months of life

*Information about accreditation criteria and procedures of the National Academy for Early Childhood Program Accreditation/NAEYC is available from the National Association for the Education of Young Children, 1313 L St. NW, Suite 500, Washington, DC 20005; 800-424-2460 or 202-232-8777; www.naeyc.org. These criteria are excellent guidelines for evaluating child care facilities. (Sexton and Natale, 2009). Pacifier use during painful procedures in neonates has been shown to produce an analgesic effect when combined with a concentrated sucrose solution (Carbajal, 2005) (see Chapter 30).

A review of studies by the Joanna Briggs Institute (2005) found an association between pacifier use in infancy and a reduction in breastfeeding and exclusive breastfeeding. However, the authors concluded that pacifier use did not cause a reduction in breastfeeding; rather, it was a "marker for socioeconomic, demographic, psychosocial and cultural factors that determine pacifier use and breastfeeding." In addition, the researchers examined studies related to pacifier use and prevention of SIDS; infants put to sleep with a pacifier had a *reduced* risk for SIDS. Because of the limited number of studies correlating pacifier use and increased risk for infections or dental malocclusion, the authors were unable to make any recommendations for or against pacifier use in relation to these practices (Joanna Briggs Institute, 2005).

A recent Cochrane review found that pacifier use in full-term healthy infants, started from birth or after lactation was established, did not significantly affect the prevalence or duration of exclusive and partial breastfeeding up to 4 months of age (Jaafar, Jahanafar, Angolkar, et al., 2011).

The AAP Task Force on Sudden Infant Death Syndrome (2005), recommends limited pacifier use in infants, citing the strong evidence for pacifier use and its protective effect in SIDS reduction. The exact mechanism involved in the protection for SIDS is not known. Still, pacifier use should not replace actual feeding or suckling; prohibiting pacifier use will not ensure an increase in the length of breastfeeding; and there should be an emphasis on allowing the infant to control the pace, frequency, and termination of feeding rather than allowing the pacifier (or anything else) to become the focus of the interaction.

To decrease dependence on nonnutritive sucking in young infants, sucking pleasure can be increased by prolonging feeding time. Also, the parent's excessive use of the pacifier to calm the child should be explored. It is not unusual for parents to place a pacifier in the infant's mouth as soon as crying begins, thus reinforcing a pattern of distress-relief.

If the child uses a pacifier, stress safety considerations in purchasing one. During infancy and early childhood there is no need to restrain nonnutritive sucking of the fingers. Malocclusion may occur if thumb-sucking persists past approximately 4 years of age, or when the permanent teeth erupt. Some parents may perceive pacifiers as less damaging because they are discarded by 2 to 3 years of age, whereas thumb-sucking may persist well into school-age years. Both pacifier use and thumb-sucking may also have significant cultural variations. Thumb-sucking reaches its peak at age 18 to 20 months and is most prevalent when the child is hungry, tired, or feeling insecure. Persistent thumb-sucking in a listless, apathetic child always warrants investigation. It may be a sign of an emotional problem between parent and child or of boredom, isolation, and lack of stimulation.

At the time of this writing, there is no evidence that pacifier use and nonnutritive sucking in *preterm infants* have any effect on the initiation and length of breastfeeding. Nonnutritive sucking should not be withheld from preterm infants, especially when used in conjunction with concentrated sucrose for pain management.

Teething

One of the more difficult periods in the infant's (and parents') life is the eruption of the deciduous (primary) teeth, often referred to as *teething*. The age of tooth eruption shows considerable variation among children, but the order of their appearance is fairly regular and predictable (Fig. 31-10). The first primary teeth to erupt are the lower central incisors, which appear at approximately 6 to 10 months of age (average 8 months). These are followed closely by the upper central incisors. The following is a quick guide to assessment of deciduous teeth during the first 2 years:

Age of the child in months – 6 = Number of teeth.

For example, 8 months of age – 6 = 2 teeth at this time.

Teething is a physiologic process; some discomfort is common as the crown of the tooth breaks through the periodontal membrane. Some children show minimal evidence of teething, such as drooling, gum rubbing, increased finger sucking, or biting on hard objects. Others are very irritable, have difficulty sleeping, and refuse to eat solid foods. Generally, signs of illness such as fever, vomiting, or diarrhea are not symptoms of teething but of illness and may warrant further investigation. Because teething pain is a result of inflammation, cold is soothing. Giving the child a cold teething ring helps relieve the inflammation (do not freeze liquid-filled teething rings). Several nonprescription topical anesthetic ointments are available, such as Baby Ora-Jel, although parents and health care workers should be aware of the risks of using topical anesthetic products (absorption rates vary in infants) (Markman, 2009). The active ingredient in most of them is benzocaine, which may rarely cause methemoglobinemia. If such products are used, parents are advised to apply them correctly. In the event of persistent irritability that affects sleeping and feeding, systemic analgesics such as acetaminophen or ibuprofen can be given (if age appropriate) for no more than 3 days (Anderson, 2004); however, parents should know

that this is a temporary measure and should contact the practitioner if symptoms persist or if the child's condition changes.

The use of teething powders or procedures such as cutting or rubbing the gums with salicylates (aspirin) are discouraged, since ingestion of the powder, infection or irritation of the tissue, and ingestion or aspiration of the aspirin can occur. Hard candy may cause accidental choking or aspiration and should be avoided at this age.

PROMOTING OPTIMAL HEALTH DURING INFANCY

Nutrition

Ideally, discussion of optimal nutrition should begin prenatally with a discussion regarding maternal intake of adequate nutrition in the form of a balanced diet and adequate amounts of protein, vitamins, and minerals, all of which have an impact on the growing fetus. Nurses should encourage and provide information for parents to discuss the options of breastfeeding or bottle-feeding the infant well in advance of the birth date. The choice for either is highly individual and is discussed in Chapter 24. This section is concerned primarily with infant nutrition during the months when growth needs and developmental milestones ready the child for the introduction of solid foods.

Despite adequate availability of optimal nutrient sources, health care experts are concerned that infants are not fed appropriately. Infants may be given solid foods when their digestive system is not ready to completely absorb such foods. In addition, drinks that are inappropriate for growing infants may be given in place of enriched infant milk and may only provide "empty" calories and contribute to childhood and adult cardiovascular disease or obesity and place the infant at risk for iron deficiency anemia, vitamin D deficiency, and rickets. A survey of infant feeding practices found that about 40% of infants had consumed infant cereal, fruit, or vegetables by 4 months of age, despite recommendations that such foods not be introduced until 4 to 6 months (Grummer-Strawn, Scanlon, and Fein, 2008). In the same study, 50% of infants were consuming cake, fried potatoes, candy, and cookies by age 12 months. There is some preliminary evidence that accelerated weight gain in the first 6 months of life may be correlated with obesity later in life (Taveras, Rifas-Shiman, Belfort, et al., 2009). Infant health practices, including nutrition, may have a far-reaching, long-term impact on the child's life. Growth and development could be negatively affected, as could the risk for acquiring certain chronic health conditions. Nurses must be proactive in teaching parents what constitutes appropriate infant nutrition and nutritional habits, which provide the child with an optimal opportunity to grow and develop into a healthy child and adult.

The First 6 Months

Human milk is the most desirable complete diet for the infant during the first 6 months. The healthy term infant receiving breast milk from a well-nourished mother usually requires no specific vitamin and mineral supplements, with a few exceptions. Daily supplements of vitamin D and vitamin B_{12} may be indicated if the mother's intake of these vitamins is inadequate. The AAP (2008) recommends that all infants (including those exclusively breastfed) receive a daily supplement of 400 international units (IU) of vitamin D beginning in the first few days of life to prevent rickets and vitamin D deficiency. Vitamin D supplementation should occur until the infant is consuming at least 1 L/day (or 1 quart/day) of vitamin D–fortified formula (AAP, 2008). Non-breastfed infants who are taking less than 1 L/day of vitamin D–fortified formula should also receive a daily vitamin D supplement of 400 IU (see Safety Alert). If the infant is being exclusively breastfed after 4 months (when fetal iron stores are depleted), iron supplementation (1 mg/kg/day) is recommended until appropriate iron-containing complementary foods such as iron-fortified cereal are introduced (Baker, Greer, and AAP Committee on Nutrition, 2010) (see Community Focus box). Infants, whether breastfed or bottle-fed, do not require additional fluids, especially water or juice, during the first 4 months of life. Excessive intake of water in infants may result in water intoxication and hyponatremia.

COMMUNITY FOCUS

Administration of Oral Iron Supplements

- Ideally, iron supplements should be administered between meals for greater absorption.
- Liquid iron supplements may stain the teeth; therefore administer with a dropper toward the back of the mouth (side). In older children, administer liquid iron supplements through a straw or rinse mouth thoroughly after ingestion.
- Avoid administration of liquid iron supplements with whole cow's milk or milk products because these bind free iron and prevent absorption.
- Educate parents that iron supplements will turn stools black or tarry green.
- Iron supplements may cause transient constipation. Caution parents not to switch to a low-iron–containing formula or whole milk, which are poor sources of iron and may lead to iron deficiency anemia (see Iron Deficiency Anemia, Chapter 43).
- In older children, follow liquid iron supplement with a citrus fruit or juice drink (no more than 3-4 oz).
- Avoid administration of iron supplements with foods or drinks that bind iron and prevent absorption (see p. 935).

SAFETY ALERT

There are reports of accidental overdoses of liquid vitamin D in infants because of packaging errors; the syringe for liquid administration may not be labeled clearly for 400 IU. Nurses should educate parents to read the syringe and to avoid administering more than 400 IU of vitamin D (FDA Consumer Health Information, 2010).

Employed mothers can continue breastfeeding with guidance and encouragement.* Mothers are encouraged to set realistic goals for employment and breastfeeding, with accurate information regarding the costs, risks, and benefits of available feeding options. Barriers encountered by working breastfeeding mothers include lack of employer or co-worker support, unavailable or inadequate facilities for pumping and storing milk, lack of time to express milk while at work, and real or perceived low milk supply (Johnston and Esposito, 2007; Rojjanasrirat, 2004; Shealey, Li, Benton-Davis, et al., 2005). Important themes that emerged in the study by Rojjanasrirat (2004) of working breastfeeding mothers included support (emotional, informational, and instrumental), attitude, and psychologic distress. Johnston and Esposito (2007) found flexible scheduling and increased paid maternity leave time (at least 12 weeks vs. 10 weeks) to be key to encouraging mothers to continue breastfeeding.

*See also *The CDC Guide to Breastfeeding Interventions* (Shealy, Li, Benton-Davis, et al., 2005), which includes information for working and breastfeeding, www.cdc.gov/breastfeeding/pdf/breastfeeding_interventions.pdf.

Many mothers may find that a program of breast pumping when away from home and bottle-feeding the infant the expressed milk with or without formula supplementation is successful. Expressed breast milk may be stored in the refrigerator (4° C [39° F]) without danger of bacterial contamination for up to 5 days (Lawrence and Lawrence, 2011). Although feeding the infant at home may occur on a demand basis, pumping milk away from home may be needed every 3 to 4 hours to maintain adequate supply. Breast milk may be expressed by hand or pump (manual or electric) and stored in an appropriate air-tight glass or plastic container. Expressed breast milk may be frozen (−18° C [0° F] or lower) for up to 6 months (depending on the type of freezer used), but care should be taken to prevent freezer burn (see Lawrence and Lawrence, 2011, for further guidelines on storing and freezing human milk).

In addition to efficient breast pumping, mothers also need child care by a trusted individual or agency and support and assistance from significant others. As with all breastfeeding mothers, these women must have proper nutrition and rest for adequate lactation. Maternal fatigue is considered the biggest threat to successful breastfeeding in employed mothers.

! NURSING ALERT

Warming expressed milk in a microwave decreases the availability of antiinfective properties and vitamin C and causes a separation of milk layers, which affects fat content (Lawrence and Lawrence, 2011). To prevent oral burns from uneven warming of the milk, breast milk should never be thawed or rewarmed in a microwave oven. To thaw the frozen milk, either place container under a lukewarm water bath (<40.5° C [105° F]) or place in refrigerator overnight.

An acceptable alternative to breastfeeding is commercial iron-fortified formula. Like human milk, it supplies all nutrients needed by the infant for the first 6 months. Unmodified whole cow's milk, low-fat cow's milk, skim milk, other animal milks, and imitation milk drinks are not acceptable as a major source of nutrition for infants because of their limited digestibility, increased risk for contamination, and lack of components needed for appropriate growth. Whole milk can cause iron deficiency anemia in infants, possibly as a result of occult gastrointestinal blood loss. Pasteurized whole cow's milk is deficient in iron, zinc, and vitamin C and has a high renal solute load, which makes it undesirable for infants younger than 12 months (AAP, 2009).

! NURSING ALERT

Neither infant formula nor breast milk should be warmed in a microwave oven because this may cause oral burns as a result of uneven heating in the container; the bottle or container may remain cool while hot spots develop in the formula (Food and Drug Administration [FDA], 2012; Morin, 2009a).

! NURSING ALERT

Dietary fat in infants younger than 6 months should not be restricted unless on specific medical advice. Substituting skim or low-fat milk is unacceptable, since the essential fatty acids are inadequate and the solute concentration of protein and electrolytes, such as sodium, is too high.

The amount of formula per feeding and the number of feedings per day vary among infants. Infants being fed on demand usually determine their own feeding schedule, but some infants may need a more planned schedule based on average feeding patterns to ensure sufficient nutrients. In general, the number of feedings decreases from six at 1 month of age to four or five at 6 months. Regardless of the number of feedings, the total amount of formula ingested will usually level off at about 32 ounces (946 mL) per day.

CULTURAL COMPETENCE

Multicultural Feeding Practices

Cultural beliefs and values often influence infant feeding practices. Health care professionals may benefit from understanding the multicultural feeding practices that parents choose for their infant. Traditional feeding practices include offering a variety of liquids or foods, such as sugared wine, water, or honey during the first few days of life and thereafter.

Honey should be avoided in the first 12 months because of the risk for botulism (see Chapter 49); a pacifier should not be coated with honey to encourage the infant to take it. Socializing the infant to food flavors of the family's culture is common in addition to continuing breastfeeding for 2 to 4 years (see Cultural Competence box).

Bottled water for mixing powdered or concentrated formula is a relatively safe alternative to tap water if available tap water has a high content of contaminants such as lead. Do not assume, however, that bottled water is sterile unless specifically stated on the container. Fluoridated bottled water is not necessary for mixing powdered formula unless the local water source is low in fluoride, in which case fluoride supplementation is recommended after age 6 months (see Dental Health, p. 885).

The addition of solid foods before 4 to 6 months of age is not recommended. During the early months, solid foods are not compatible with the ability of the gastrointestinal tract and infant's nutritional needs. Feeding solids to young infants exposes them to food antigens that may produce food protein allergy. There is ample evidence that early introduction of foods other than maternal milk in the first 6 months of life predisposes children to an increased risk for food allergy development; foods known to be allergenic (e.g., peanuts, eggs, fish, seafood) should be introduced later than 12 months according to the child's risk for atopy (AAP, 2009).

Developmentally, infants are not ready for solid food. The extrusion (protrusion) reflex is strong and often causes them to push food out of the mouth. Infants instinctively suck when given food. Because of their limited motor abilities, infants are unable to deliberately push food away or avoid feeding. Therefore early introduction of solids is a type of forced feeding that may lead to excessive weight gain and increased predisposition to allergies and iron deficiency anemia. Parents should be cautioned concerning the use of juices and nonnutritive drinks such as fruit-flavored drinks or carbonated beverages (soda or pop) during this period. Many juices and nonnutritive drinks, although readily available to consumers, do not provide sufficient and appropriate caloric intake for infants younger than 12 months; such drinks may replace the nutrients in breast milk or formula and lead to growth or health problems. Fruit juices are not required in the first 6 months; there are no studies demonstrating benefits of giving fruit juice to infants.

The World Health Organization growth charts released in 2006 are now recommended as reference growth charts in children 0 to 59 months of age (Grummer-Strawn, Reinold, Krebs, et al., 2010) (cdc.gov/growthcharts/who_charts.htm).

The Second 6 Months

During the second half of the first year, human milk or formula should optimally continue to be the primary source of nutrition.

Fluoride supplementation should begin, depending on the infant's intake of fluoride (in formula mixed with tap water or bottled water [containing fluoride] as appropriate) (see Dental Health, p. 885). If breastfeeding is discontinued, a commercial iron-fortified formula should be substituted. Follow-up or transition formulas marketed for older infants offer no special advantages over other infant formulas and provide excessive protein (AAP, 2009).

The major change in feeding habits is the addition of solid foods to the infant's diet. Physiologically and developmentally, the infant 4 to 6 months of age is in a transition period. By this time, the gastrointestinal tract has matured sufficiently to handle more complex nutrients and is less sensitive to potentially allergenic foods. Tooth eruption is beginning and facilitates biting and chewing. The extrusion reflex has disappeared, and swallowing is more coordinated to allow the infant to accept solids easily. Head control is well developed, which permits infants to sit with support and purposely turn the head away to communicate lack of interest in food. Voluntary grasping and improved eye-hand coordination gradually allow infants to pick up finger foods and feed themselves. Their increasing sense of independence is evident in their desire to hold the bottle and try to "help" during feeding.

Selection and Preparation of Solid Foods

The choice of solid foods to introduce first is variable but should meet the reasons for feeding solids, such as supplying nutrients not found in formula or breast milk. Iron-fortified infant cereal is generally introduced first because of its high iron content (7 mg/3 tbsp of prepared dry cereal). Commercially prepared ready-to-serve dry cereals for infants include rice, barley, oatmeal, and high-protein cereals; rice is usually suggested as an initial food because of its easy digestibility and low allergenic potential. Cereals such as cream of farina should not be used, since infant commercial cereals are a better source of iron. Some of the commercial baby cereals are combined with fruit. There is little nutritional benefit from these preparations, and they are more expensive. New foods should be added one at a time; therefore parents should avoid cereal combinations when beginning a new grain.

Infant cereal (iron fortified) may be mixed with expressed breast milk or water until whole milk is given. After 6 months of age, small amounts of 100% fruit juices can be mixed with the dry cereal; the vitamin C content of the juice enhances the absorption of iron in the cereal. Because of their benefit as a source of iron, infant cereals should be continued until the child is 18 months of age.

Fruit juice can be offered from a cup for its rich source of vitamin C and as a substitute for milk for one feeding a day. Large quantities of certain juices (e.g., apple, pear, prune, sweet cherry, peach, grape) should be avoided because they may cause abdominal pain, diarrhea, or bloating in some children. Avoid fruit-flavored drinks, which may be marketed as juices but contain high concentrations of complex sugars. White grape juice (no more than 5 oz/day) may be better absorbed and safe for infants this age without causing gastrointestinal distress. The AAP (2009) recommends that fruit juice intake not exceed 4 to 6 ounces per day and that juices not be given to infants younger than 4 to 6 months. Because vitamin C is naturally destroyed by heat, juice is not warmed. Juice containers are always kept covered and refrigerated to prevent further vitamin loss.

The addition of other foods is arbitrary. A common sequence is to introduce strained fruits followed by vegetables and, finally, meats; however, some clinicians prefer to add vegetables before fruit. If foods are introduced early, citrus fruits, meats, and eggs are delayed until after 6 months of age because of their potential to result in allergy. At 6 months, foods such as a cracker or zwieback can be offered as finger and teething foods. By 8 to 9 months, junior foods and nutritious finger foods such as firmly cooked vegetable, raw pieces of fruit, or cheese can be given. By 1 year, well-cooked table foods are served.

The introduction of solid foods into the infant's diet at this age is primarily for taste and chewing experience, not for growth. The majority of the infant's caloric needs are derived from the primary milk source (human or formula); therefore solids should not be perceived as a substitute for milk until the child is older than 12 months. Portion sizes may vary according to the infant's taste. In general, 1 tablespoon per year of age (i.e., ½ to ¾ tablespoon for most infants younger than 12 months) is adequate for most infants. In most cases, 2 tablespoons may be served, but because of the infant's focus on the texture and feel of the food, smaller amounts will be consumed. Another reason for smaller portions is the concern over feeding habits in early childhood and obesity; early feeding of smaller portions may help prevent the "clean your plate" or "eat all your food or you can't get down from the table" concepts, which are known to contribute to overeating in later life. The addition of solid foods to the exclusively breastfed infant's diet does not significantly increase overall caloric intake or weight gain.

Commercially prepared baby foods are the most common type of food served to infants in the United States. They are convenient but sometimes contain added salt or sugar and can be relatively expensive. An alternative is to prepare baby foods at home, which is a simple and inexpensive process. Fruits and vegetables can be steamed in a small amount of water and pureed in a blender or food processor. Many of them, such as ripe banana, can be mashed fine with a fork. Fruits such as apples or pears require little or no water in the cooking process. Vegetables such as carrots, potatoes, or string beans require additional water in the cooking and blending process.

In general, low-calorie milk and foods should be avoided in infants and toddlers unless a strict medically prescribed diet is required. The infant's growth during this phase is crucial to future health status. Although saturated fat restriction is desirable after 2 years of age, the AAP (2009) cautions against excessive restriction of dietary fat in infancy. One suggestion is to limit the *amount* (serving size) of dietary fat in foods provided rather than eliminate them altogether, especially during infancy. However, it is important to recognize that certain types of dietary fat are unacceptable for infants; fried potatoes, candy, ice cream, cake, soda pop and other sweetened drinks, and other such items are not appropriate for infants and may contribute to childhood cardiovascular disease and obesity.

Parents are cautioned to avoid reliance on food supplements marketed as iron- or vitamin-fortified as primary sources of minerals. Instead, encourage parents to offer the child a variety of fruits, vegetables, and whole grains, including those known to naturally be rich in iron (Fox, Reidy, Novak, et al., 2006).

Introduction of Solid Foods

When the spoon is first introduced, infants often push it away and appear dissatisfied. Patience and skill are required to overcome this initial response. A small-bowled, straight, long-handled spoon, similar to a demitasse spoon, allows a small portion of food to be placed toward the back of the tongue. Food that is placed on the front of the tongue and pushed out is simply scooped up and refed. As infants become accustomed to the spoon, they more eagerly accept the food and eventually will open the mouth in anticipation (or keep it closed in dislike). Because the first introduction of food is a new experience, spoon feeding should be attempted after

PATIENT TEACHING

Introducing Solid Foods to Infants

- Introduce solids when infant is hungry.
- Begin spoon-feeding by pushing food to back of tongue because of infant's natural tendency to thrust the tongue forward.
- Use a small spoon with a straight handle; begin with 1 or 2 teaspoons of food; gradually increase to a couple of tablespoons per feeding.
- Introduce one food at a time, usually at intervals of 4 to 7 days, to allow for identification of food allergies.
- As the amount of solid food increases, decrease the quantity of milk to prevent overfeeding.
- Do not introduce foods by mixing them with formula in the bottle.

ingestion of some breast milk or formula to associate this activity with a pleasurable and satisfying experience. Trying to introduce a food *after* the entire milk feeding is usually useless because the infant is satiated and has no inclination to try something new.

After several spoon feedings, food can be introduced at the beginning of a meal. It is best to introduce many foods during the first year, when the infant is more likely to eat them because of a hearty appetite resulting from a rapid growth rate. During the toddler years, eating becomes less of an adventure and strong food preferences become evident.

One food item is introduced at intervals of 4 to 7 days to allow for identification of food allergies. New foods are fed in small amounts, from 1 teaspoon to a few tablespoons. As the amount of solid food increases, the quantity of milk is decreased to less than 1 L daily to prevent overfeeding.

Because feeding is a learning process as well as a means of nutrition, new foods are given alone to allow the child to learn new tastes and textures. Food should not be mixed in the bottle and fed through a nipple with a large hole; this deprives the child of the pleasure of learning new tastes and of developing a discriminating palate. It can also cause problems with poor chewing of food later in life because of lack of experience. Guidelines for the introduction of new foods are given in the Patient Teaching box.

The infant's first, second, and often twentieth try at self-feeding or cup feeding is a sloppy experience. Finger foods such as soft fruits or vegetables are just as good as playthings as food; they can be squeezed, smeared, squashed, and thoroughly painted on oneself, others, and the surrounding environment. However, all of this is part of learning, and mastery follows many accidents.

Parents are encouraged to interpret the infant's signals of discomfort and intervene in ways other than through feeding. Crying, fussiness, and sucking do not necessarily indicate hunger. Rocking, stroking, holding, and offering a toy or a pacifier may be more appropriate than automatically responding with food.

Weaning

Defined as the process of giving up one method of feeding for another, *weaning* usually refers to relinquishing the breast or bottle for a cup. In Western societies this is generally regarded as a major task for infants and is often seen as a potentially traumatic experience. It is psychologically significant because the infant is required to give up a major source of oral pleasure and gratification. Other cultural groups define weaning in relation to significant life events (e.g., teething) or reaching a specific age. No one time for weaning is best for every child, but generally, most infants show signs of readiness during the second half of the first year. It is recommended that weaning be accomplished with the infant's needs as a guide (Lawrence and Lawrence, 2011).

Infants have learned that good things come from a spoon. Their increasing desire for freedom of movement may lessen their desire to be held close for feedings. They are acquiring more control over their actions and can easily manipulate a cup to their lips (even if it is held upside down!). Imitation becomes a powerful motivator by age 8 or 9 months, and they enjoy using a cup or glass like others do. Weaning should be gradual, replacing one bottle-feeding or breastfeeding at a time. The nighttime feeding is usually the last feeding to be discontinued. It is advisable never to begin allowing a child to take a bottle of milk to bed; this is a major cause of early childhood caries in deciduous teeth. If breastfeeding is terminated before 5 or 6 months of age, weaning should be to a bottle to provide for the infant's continued sucking needs. If breastfeeding is discontinued later, weaning can be directly to a cup, especially by age 12 to 14 months. Any sweet liquid, such as fruit juice, should be given in a cup.

Sleep and Activity

Sleep patterns vary among infants, with active infants typically sleeping less than placid children. Generally, by 3 to 4 months of age, most infants have developed a nocturnal pattern of sleep that lasts 9 to 11 hours. The total daily sleep is approximately 15 hours. In a study of Swiss children, Iglowstein, Jenni, Molinari, et al. (2003) found that the average number of hours of sleep in 6-month-olds was 14.2 hours. Consolidation of nocturnal sleep hours occurred during the first 12 months with decreasing daytime sleep and increasing nighttime sleep (approximately 11.7 hours) by 1 year of age. The number of naps per day varies, but infants may take one or two naps by the end of the first year. Breastfed infants usually sleep for shorter periods, with more frequent waking, especially during the night, compared with bottle-fed infants (Quillin and Glenn, 2004); average total sleep for 4-week-old infants in this study was 14 hours. Because of the trend toward breastfeeding, sleep norms such as those previously described, which were based primarily on bottle-fed infants, may not be relevant.

Most infants are naturally active and need no encouragement to be mobile. Problems can arise when devices such as play yards, strollers, commercial swings, and mobile walkers are used excessively. These items restrict movement and prevent infants from exploring and developing gross motor skills. Contrary to popular belief, mobile walkers do not enhance coordination and are dangerous if tipped over or placed near stairs (see also Sleep Problems in Chapter 32).

Dental Health

Good infant dental hygiene begins with appropriate maternal dental health before and during the pregnancy and counseling during early infancy regarding dietary intake for the promotion of optimal oral hygiene. Parents are counseled early regarding feeding practices that increase the risk for poor dental health. Some of these, as previously mentioned, include propping the milk bottle, giving the milk bottle in the bed, or giving fruit juices in a bottle, especially before 6 months of age. These contribute to enamel erosion and **early childhood caries** (previously called *baby bottle tooth decay*). Parents should also be made aware that dental caries is contagious and can be prevented with optimal oral hygiene starting in infancy (Peterson-Sweeney and Stevens, 2010).

Once the primary teeth erupt, cleaning should begin. The teeth and gums are initially cleaned by wiping with a damp cloth;

toothbrushing is too harsh for the tender gingiva. The caregiver can stabilize the infant by cradling the child with one arm and using the free hand to cleanse the teeth. Oral hygiene can be made pleasant by singing or talking to the infant. It is recommended that the infant have a brief oral health examination by 6 months of age from a qualified pediatric health care practitioner; infants at high risk for caries are identified, and oral health counseling is implemented. It is also recommended that the infant have an established dental home by 1 year of age (American Academy of Pediatric Dentistry, 2012). It is generally recommended that a small, soft-bristled toothbrush be used as more teeth erupt and the infant adjusts to the routine of cleaning. Water is preferred to toothpaste, which the infant will swallow (and if the toothpaste is fluoridated, the infant may ingest excessive amounts of fluoride). The American Academy of Pediatric Dentistry (2012) recommends a "smear" of toothpaste for children younger than 2 years and a pea-size amount for those 2 to 5 years old.

Fluoride, an essential mineral for building caries-resistant teeth, is needed beginning at 6 months of age if the infant does not receive water with adequate fluoride content. The AAP (2009) recommends that children 6 months to 3 years of age take 0.25 mg fluoride daily if water fluoride content is less than 0.3 ppm. The fluoride dosage has been decreased from earlier recommendations because of an increased occurrence of dental fluorosis from excessive fluoride ingestion. If bottled water is used to reconstitute powdered or concentrated formula, it should either be fluoride-free or contain low levels of fluoride.

Dietary considerations are also important because habits begun during infancy tend to continue into later years. Avoid foods with concentrated sugar (sucrose) in the infant's diet. Parents should be counseled regarding the detrimental effects of frequent and prolonged bottle-feeding or breastfeeding during sleep, when the milk or other fluid, such as juice, bathes the teeth, causing early childhood caries.

Immunizations

One of the most dramatic advances in pediatrics has been the decline of infectious diseases during the twentieth century because of the widespread use of immunization for preventable diseases. However, childhood vaccines have been widely criticized in recent years, and fear related to vaccine components has prompted some families to avoid childhood vaccines. In addition, many of the diseases for which children are vaccinated are rarely seen on a large-scale basis, leading some parents to believe that such vaccines are no longer necessary in the twenty-first century. The Internet provides a variety of information suggesting parents avoid childhood vaccines; a number of "vaccine myths" exist, which are based on erroneous information. The nurse is in an optimal position to provide parents with accurate information regarding childhood illnesses and available vaccines; the parent must then make an informed decision regarding the child's vaccinations. Nurses should address parents' concerns about childhood vaccines and avoid judgmental attitudes regarding the parents' decision to not vaccinate children.

Although many of the immunizations can be given to individuals of any age, the recommended primary schedule begins during infancy and, with the exception of boosters, is completed during early childhood. Therefore the discussion of childhood immunizations for diphtheria, tetanus, pertussis; polio; measles, mumps, rubella; *Haemophilus influenzae* type b; hepatitis A virus (HAV), hepatitis B virus (HBV); pneumococcus; influenza; meningococcus; and chickenpox is included in this chapter. Selected vaccines generally reserved for children considered at high risk for the disease are discussed here and as appropriate throughout the text. (See also Communicable Diseases, Chapter 33, for a discussion of several of the diseases for which vaccines are available.)

Schedule for Immunizations

In the United States, two organizations—the Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention (CDC) and the Committee on Infectious Diseases of the American Academy of Pediatrics (AAP)—govern the recommendations for immunization policies and procedures. In Canada, recommendations are from the National Advisory Committee on Immunization under the authority of the Minister of Health and Public Health Agency of Canada. The policies of each committee are *recommendations,* not rules, and they change as a result of advances in the field of immunology. Pediatric nurses must stay informed of the latest advances and changes in policy.

In the United States, the recommended age for beginning primary immunizations of infants is within 2 weeks of birth or, in special circumstances, at birth (Figs. 31-11 and 31-12). Infants born preterm should receive the full dose of each vaccine at the appropriate chronologic age. Recommended schedules for children not immunized during infancy are available at the Centers for Disease Control and Prevention (CDC) website *www.cdc.gov/vaccines/recs/schedules/child-schedule.htm.* Immunization schedules for Canadian children are available from the Public Health Agency of Canada (*http://www.phac-aspc.gc.ca/im/is-cv/index-eng.php*).

Children who began primary immunizations at the recommended age but fail to receive all of the doses do not need to begin the series again but, instead, receive only the missed doses. For situations in which there is doubt that the child will return for immunization according to the optimal schedule, the following vaccines can be administered simultaneously:

- HepA (HAV)
- HepB (HBV)
- DTaP (diphtheria, tetanus, acellular pertussis)
- IPV (inactivated poliovirus)
- MMR (measles, mumps, rubella)
- Varicella
- Hib (*Haemophilus influenzae* type b)

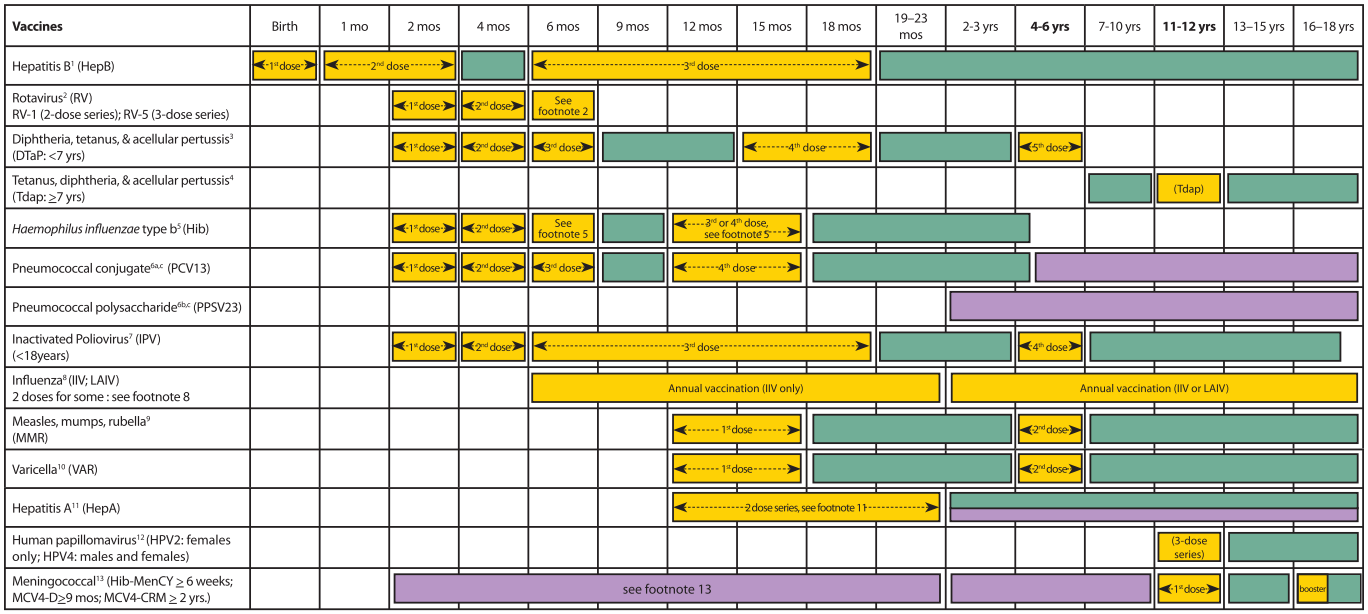
Parenteral vaccines are given in separate syringes in different injection sites (AAP Committee on Infectious Diseases, 2012).

Recommendations for Routine Immunizations*

Hepatitis A Virus. Hepatitis A has been recognized as a significant child health problem, particularly in communities with unusually high infection rates. HAV is spread by the fecal-oral route and from person-to-person contact, by ingestion of contaminated food or water, and rarely by blood transfusion. The illness has an abrupt onset, with fever, malaise, anorexia, nausea, abdominal discomfort, dark urine, and jaundice being the most common clinical signs of infection. In children younger than 6 years, who represent approximately one third of all cases of hepatitis A, the disease may be asymptomatic, and jaundice is rarely evident.

*Because of constant changes in the pharmaceutical industry, trade names of single and combination vaccines in this section may differ from those currently available. The reader is encouraged to access the vaccine page of the Center for Biologics Evaluation and Research (CBER) of the Food and Drug Administration for the latest licensed vaccine trade names: http://www.fda.gov/BiologicsBloodVaccines/default.htm.

These recommendations must be read with the footnotes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars in Figure 1. To determine minimum intervals between doses, see the catch-up schedule (Figure 2). School entry and adolescent vaccine age groups are in bold.



This schedule includes recommendations in effect as of January 1, 2013. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. The use of a combination vaccine generally is preferred over separate injections of its equivalent component vaccines. Vaccination providers should consult the relevant Advisory Committee on Immunization Practices (ACIP) statement for detailed recommendations, available online at http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow vaccination should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (http://www.vaers.hhs.gov) or by telephone (800-822-7967).Suspected cases of vaccine-preventable diseases should be reported to the state or local health department. Additional information, including precautions and contraindications for vaccination, is available from CDC online (http://www.cdc.gov/vaccines) or by telephone (800-CDC-INFO [800-232-4636]).

This schedule is approved by the Advisory Committee on Immunization Practices (http://www.cdc.gov/vaccines/acip/index.html), the American Academy of Pediatrics (http://www.aap.org), the American Academy of Family Physicians (http://www.aafp.org), and the American College of Obstetricians and Gynecologists (http://www.acog.org).

NOTE: The above recommendations must be read along with the footnotes of this schedule.

Footnotes — Recommended immunization schedule for persons aged 0 through 18 years—United States, 2013

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/pubs/acip-list.htm.

1. **Hepatitis B (HepB) vaccine. (Minimum age: birth)**
   Routine vaccination:
   At birth
   - Administer monovalent HepB vaccine to all newborns before hospital discharge.
   - For infants born to hepatitis B surface antigen (HBsAg)–positive mothers, administer HepB vaccine and 0.5 mL of hepatitis B immune globulin (HBIG) within 12 hours of birth. These infants should be tested for HBsAg and antibody to HBsAg (anti-HBs) 1 to 2 months after completion of the HepB series, at age 9 through 18 months (preferably at the next well-child visit).
   - If mother's HBsAg status is unknown, within 12 hours of birth administer HepB vaccine to all infants regardless of birth weight. For infants weighing <2,000 grams, administer HBIG in addition to HepB within 12 hours of birth. Determine mother's HBsAg status as soon as possible and, if she is HBsAg-positive, also administer HBIG for infants weighing ≥2,000 grams (no later than age 1 week).

   Doses following the birth dose
   - The second dose should be administered at age 1 or 2 months. Monovalent HepB vaccine should be used for doses administered before age 6 weeks.
   - Infants who did not receive a birth dose should receive 3 doses of a HepB-containing vaccine on a schedule of 0, 1 to 2 months, and 6 months starting as soon as feasible. See Figure 2.
   - The minimum interval between dose 1 and dose 2 is 4 weeks and between dose 2 and 3 is 8 weeks. The final (third or fourth) dose in the HepB vaccine series should be administered no earlier than age 24 weeks, and at least 16 weeks after the first dose.
   - Administration of a total of 4 doses of HepB vaccine is recommended when a combination vaccine containing HepB is administered after the birth dose.

   Catch-up vaccination:
   - Unvaccinated persons should complete a 3-dose series.
   - A 2-dose series (doses separated by at least 4 months) of adult formulation Recombivax HB is licensed for use in children aged 11 through 15 years.
   - For other catch-up issues, see Figure 2.
2. **Rotavirus (RV) vaccines. (Minimum age: 6 weeks for both RV-1 [Rotarix] and RV-5 [RotaTeq]).**
   Routine vaccination:
   - Administer a series of RV vaccine to all infants as follows:
     1. If RV-1 is used, administer a 2-dose series at 2 and 4 months of age.
     2. If RV-5 is used, administer a 3-dose series at ages 2, 4, and 6 months.
     3. If any dose in series was RV-5 or vaccine product is unknown for any dose in the series, a total of 3 doses of RV vaccine should be administered.

   Catch-up vaccination:
   - The maximum age for the first dose in the series is 14 weeks, 6 days.
   - Vaccination should not be initiated for infants aged 15 weeks 0 days or older.
   - The maximum age for the final dose in the series is 8 months, 0 days.
   - If RV-1(Rotarix) is administered for the first and second doses, a third dose is not indicated.
   - For other catch-up issues, see Figure 2.
3. **Diphtheria and tetanus toxoids and acellular pertussis (DTaP) vaccine. (Minimum age: 6 weeks)**
   Routine vaccination:
   - Administer a 5-dose series of DTaP vaccine at ages 2, 4, 6, 15–18 months, and 4 through 6 years. The fourth dose may be administered as early as age 12 months, provided at least 6 months have elapsed since the third dose.

   Catch-up vaccination:
   - The fifth (booster) dose of DTaP vaccine is not necessary if the fourth dose was administered at age 4 years or older.
   - For other catch-up issues, see Figure 2.
4. **Tetanus and diphtheria toxoids and acellular pertussis (Tdap) vaccine. (Minimum age: 10 years for Boostrix, 11 years for Adacel).**
   Routine vaccination:
   - Administer 1 dose of Tdap vaccine to all adolescents aged 11 through 12 years.
   - Tdap can be administered regardless of the interval since the last tetanus and diphtheria toxoid-containing vaccine.
   - Administer one dose of Tdap vaccine to pregnant adolescents during each pregnancy (preferred during 27 through 36 weeks gestation) regardless of number of years from prior Td or Tdap vaccination.

   Catch-up vaccination:
   - Persons aged 7 through 10 years who are not fully immunized with the childhood DTaP vaccine series, should receive Tdap vaccine as the first dose in the catch-up series; if additional doses are needed, use Td vaccine. For these children, an adolescent Tdap vaccine should not be given.
   - Persons aged 11 through 18 years who have not received Tdap vaccine should receive a dose followed by tetanus and diphtheria toxoids (Td) booster doses every 10 years thereafter.
   - An inadvertent dose of DTaP vaccine administered to children aged 7 through 10 years can count as part of the catch-up series. This dose can count as the adolescent Tdap dose, or the child can later receive a Tdap booster dose at age 11–12 years.
   - For other catch-up issues, see Figure 2.
5. ***Haemophilus influenzae* type b (Hib) conjugate vaccine. (Minimum age: 6 weeks)**
   Routine vaccination:
   - Administer a Hib vaccine primary series and a booster dose to all infants. The primary series doses should be administered at 2, 4, and 6 months of age; however, if PRP-OMP (PedvaxHib or Comvax) is administered at 2 and 4 months of age, a dose at age 6 months is not indicated. One booster dose should be administered at age 12 through15 months.
   - Hiberix (PRP-T) should only be used for the booster (final) dose in children aged 12 months through 4 years, who have received at least 1 dose of Hib.

FIG 31-11 Recommended immunization schedule for persons ages 0 through 18 years. (From Centers for Disease Control and Prevention: *Recommended immunization schedules for persons aged 0 through 18 years—United States,* 2013.)

Continued

For further guidance on the use of the vaccines mentioned below, see: http://www.cdc.gov/vaccines/pubs/acip-list.htm.

Catch-up vaccination:
- If dose 1 was administered at ages 12-14 months, administer booster (as final dose) at least 8 weeks after dose 1.
- If the first 2 doses were PRP-OMP (PedvaxHIB or Comvax), and were administered at age 11 months or younger, the third (and final) dose should be administered at age 12 through 15 months and at least 8 weeks after the second dose.
- If the first dose was administered at age 7 through 11 months, administer the second dose at least 4 weeks later and a final dose at age 12 through 15 months, regardless of Hib vaccine (PRP-T or PRP-OMP) used for first dose.
- For unvaccinated children aged 15 months or older, administer only 1 dose.
- For other catch-up issues, see Figure 2.

Vaccination of persons with high-risk conditions:
- Hib vaccine is not routinely recommended for patients older than 5 years of age. However one dose of Hib vaccine should be administered to unvaccinated or partially vaccinated persons aged 5 years or older who have leukemia, malignant neoplasms, anatomic or functional asplenia (including sickle cell disease), human immunodeficiency virus (HIV) infection, or other immunocompromising conditions.

6a. Pneumococcal conjugate vaccine (PCV). (Minimum age: 6 weeks)

Routine vaccination:
- Administer a series of PCV13 vaccine at ages 2, 4, 6 months with a booster at age 12 through 15 months.
- For children aged 14 through 59 months who have received an age-appropriate series of 7-valent PCV (PCV7), administer a single supplemental dose of 13-valent PCV (PCV13).

Catch-up vaccination:
- Administer 1 dose of PCV13 to all healthy children aged 24 through 59 months who are not completely vaccinated for their age.
- For other catch-up issues, see Figure 2.

Vaccination of persons with high-risk conditions:
- For children aged 24 through 71 months with certain underlying medical conditions (see footnote 6c), administer 1 dose of PCV13 if 3 doses of PCV were received previously, or administer 2 doses of PCV13 at least 8 weeks apart if fewer than 3 doses of PCV were received previously.
- A single dose of PCV13 may be administered to previously unvaccinated children aged 6 through 18 years who have anatomic or functional asplenia (including sickle cell disease), HIV infection or an immunocompromising condition, cochlear implant or cerebrospinal fluid leak. See MMWR 2010;59 (No. RR-11), available at http://www.cdc.gov/mmwr/pdf/rr/rr5911.pdf.
- Administer PPSV23 at least 8 weeks after the last dose of PCV to children aged 2 years or older with certain underlying medical conditions (see footnotes 6b and 6c).

6b. Pneumococcal polysaccharide vaccine (PPSV23). (Minimum age: 2 years)

Vaccination of persons with high-risk conditions:
- Administer PPSV23 at least 8 weeks after the last dose of PCV to children aged 2 years or older with certain underlying medical conditions (see footnote 6c). A single revaccination with PPSV should be administered after 5 years to children with anatomic or functional asplenia (including sickle cell disease) or an immunocompromising condition.

6c. Medical conditions for which PPSV23 is indicated in children aged 2 years and older and for which use of PCV13 is indicated in children aged 24 through 71 months:
- Immunocompetent children with chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma if treated with high-dose oral corticosteroid therapy), diabetes mellitus; cerebrospinal fluid leaks; or cochlear implant.
- Children with anatomic or functional asplenia (including sickle cell disease and other hemoglobinopathies, congenital or acquired asplenia, or splenic dysfunction);
- Children with immunocompromising conditions: HIV infection, chronic renal failure and nephrotic syndrome, diseases associated with treatment with immunosuppressive drugs or radiation therapy, including malignant neoplasms, leukemias, lymphomas and Hodgkin disease; or solid organ transplantation, congenital immunodeficiency.

7. Inactivated poliovirus vaccine (IPV). (Minimum age: 6 weeks)

Routine vaccination:
- Administer a series of IPV at ages 2, 4, 6–18 months, with a booster at age 4–6 years. The final dose in the series should be administered on or after the fourth birthday and at least 6 months after the previous dose.

Catch-up vaccination:
- In the first 6 months of life, minimum age and minimum intervals are only recommended if the person is at risk for imminent exposure to circulating poliovirus (i.e., travel to a polio-endemic region or during an outbreak).
- If 4 or more doses are administered before age 4 years, an additional dose should be administered at age 4 through 6 years.
- A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.
- If both OPV and IPV were administered as part of a series, a total of 4 doses should be administered, regardless of the child's current age.
- IPV is not routinely recommended for U.S. residents aged 18 years or older.
- For other catch-up issues, see Figure 2.

8. Influenza vaccines. (Minimum age: 6 months for inactivated influenza vaccine [IIV]; 2 years for live, attenuated influenza vaccine [LAIV])

Routine vaccination:
- Administer influenza vaccine annually to all children beginning at age 6 months. For most healthy, nonpregnant persons aged 2 through 49 years, either LAIV or IIV may be used. However, LAIV should NOT be administered to some persons, including 1) those with asthma, 2) children 2 through 4 years who had wheezing in the past 12 months, or 3) those who have any other underlying medical conditions that predispose them to influenza complications. For all other contraindications to use of LAIV see MMWR 2010; 59 (No. RR-8), available at http://www.cdc.gov/mmwr/pdf/rr/rr5908.pdf.
- Administer 1 dose to persons aged 9 years and older.

For children aged 6 months through 8 years:
- For the 2012–13 season, administer 2 doses (separated by at least 4 weeks) to children who are receiving influenza vaccine for the first time. For additional guidance, follow dosing guidelines in the 2012 ACIP influenza vaccine recommendations, MMWR 2012; 61:613–618, available at http://www.cdc.gov/mmwr/pdf/wk/mm6132.pdf.
- For the 2013–14 season, follow dosing guidelines in the 2013 ACIP influenza vaccine recommendations.

9. Measles, mumps, and rubella (MMR) vaccine. (Minimum age: 12 months for routine vaccination)

Routine vaccination:
- Administer the first dose of MMR vaccine at age 12 through 15 months, and the second dose at age 4 through 6 years. The second dose may be administered before age 4 years, provided at least 4 weeks have elapsed since the first dose.
- Administer 1 dose of MMR vaccine to infants aged 6 through 11 months before departure from the United States for international travel. These children should be revaccinated with 2 doses of MMR vaccine, the first at age 12 through 15 months (12 months if the child remains in an area where disease risk is high), and the second dose at least 4 weeks later.
- For vaccination of persons with primary and secondary immunodeficiencies, see Table 13, "Vaccination of persons with primary and secondary immunodeficiencies," in General Recommendations on Immunization (ACIP), available at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr6002a1.htm; and American Academy of Pediatrics. Immunization in Special Clinical Circumstances. In: Pickering LK, Baker CJ, Kimberlin DW, Long SS eds. Red book: 2012 report of the Committee on Infectious Diseases. 29th ed. Elk Grove Village, IL: American Academy of Pediatrics.
- Administer 2 doses of MMR vaccine to children aged 12 months and older, before departure from the United States for international travel. The first dose should be administered on or after age 12 months and the second dose at least 4 weeks later.

Catch-up vaccination:
- Ensure that all school-aged children and adolescents have had 2 doses of MMR vaccine; the minimum interval between the 2 doses is 4 weeks.

10. Varicella (VAR) vaccine. (Minimum age: 12 months)

Routine vaccination:
- Administer the first dose of VAR vaccine at age 12 through 15 months, and the second dose at age 4 through 6 years. The second dose may be administered before age 4 years, provided at least 3 months have elapsed since the first dose. If the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid.

Catch-up vaccination:
- Ensure that all persons aged 7 through 18 years without evidence of immunity (see MMWR 2007;56 [No. RR-4], available at http://www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have 2 doses of varicella vaccine. For children aged 7 through 12 years the recommended minimum interval between doses is 3 months (if the second dose was administered at least 4 weeks after the first dose, it can be accepted as valid); for persons aged 13 years and older, the minimum interval between doses is 4 weeks.

11. Hepatitis A vaccine (HepA). (Minimum age: 12 months)

Routine vaccination:
- Initiate the 2-dose HepA vaccine series for children aged 12 through 23 months; separate the 2 doses by 6 to 18 months.
- Children who have received 1 dose of HepA vaccine before age 24 months, should receive a second dose 6 to 18 months after the first dose.
- For any person aged 2 years and older who has not already received the HepA vaccine series, 2 doses of HepA vaccine separated by 6 to 18 months may be administered if immunity against hepatitis A virus infection is desired.

Catch-up vaccination:
- The minimum interval between the two doses is 6 months.

Special populations:
- Administer 2 doses of Hep A vaccine at least 6 months apart to previously unvaccinated persons who live in areas where vaccination programs target older children, or who are at increased risk for infection.

12. Human papillomavirus (HPV) vaccines. (HPV4 [Gardasil] and HPV2 [Cervarix]). (Minimum age: 9 years)

Routine vaccination:
- Administer a 3-dose series of HPV vaccine on a schedule of 0, 1-2, and 6 months to all adolescents aged 11-12 years. Either HPV4 or HPV2 may be used for females, and only HPV4 may be used for males.
- The vaccine series can be started beginning at age 9 years.
- Administer the second dose 1 to 2 months after the **first** dose and the third dose 6 months after the **first** dose (at least 24 weeks after the first dose).

Catch-up vaccination:
- Administer the vaccine series to females (either HPV2 or HPV4) and males (HPV4) at age 13 through 18 years if not previously vaccinated.
- Use recommended routine dosing intervals (see above) for vaccine series catch-up.

13. Meningococcal conjugate vaccines (MCV). (Minimum age: 6 weeks for Hib-MenCY, 9 months for Menactra [MCV4-D], 2 years for Menveo [MCV4-CRM]).

Routine vaccination:
- Administer MCV4 vaccine at age 11–12 years, with a booster dose at age 16 years.
- Adolescents aged 11 through 18 years with human immunodeficiency virus (HIV) infection should receive a 2-dose primary series of MCV4, with at least 8 weeks between doses. See MMWR 2011; 60:1018–1019 available at: http://www.cdc.gov/mmwr/pdf/wk/mm6030.pdf.
- For children aged 2 months through 10 years with high-risk conditions, see below.

Catch-up vaccination:
- Administer MCV4 vaccine at age 13 through 18 years if not previously vaccinated.
- If the first dose is administered at age 13 through 15 years, a booster dose should be administered at age 16 through 18 years with a minimum interval of at least 8 weeks between doses.
- If the first dose is administered at age 16 years or older, a booster dose is not needed.
- For other catch-up issues, see Figure 2.

Vaccination of persons with high-risk conditions:
- For children younger than 19 months of age with anatomic or functional asplenia (including sickle cell disease), administer an infant series of Hib-MenCY at 2, 4, 6, and 12-15 months.
- For children aged 2 through 18 months with persistent complement component deficiency, administer either an infant series of Hib-MenCY at 2, 4, 6, and 12 through 15 months or a 2-dose primary series of MCV4-D starting at 9 months, with at least 8 weeks between doses. For children aged 19 through 23 months with persistent complement component deficiency who have not received a complete series of Hib-MenCY or MCV4-D, administer 2 primary doses of MCV4-D at least 8 weeks apart.
- For children aged 24 months and older with persistent complement component deficiency or anatomic or functional asplenia (including sickle cell disease), who have not received a complete series of Hib-MenCY or MCV4-D, administer 2 primary doses of either MCV4-D or MCV4-CRM. If MCV4-D (Menactra) is administered to a child with asplenia (including sickle cell disease), do not administer MCV4-D until 2 years of age and at least 4 weeks after the completion of all PCV13 doses. See MMWR 2011;60:1391–2, available at http://www.cdc.gov/mmwr/pdf/wk/mm6040.pdf.
- For children aged 9 months and older who are residents of or travelers to countries in the African meningitis belt or to the Hajj, administer an age appropriate formulation and series of MCV4 for protection against serogroups A and W-135. Prior receipt of Hib-MenCY is not sufficient for children traveling to the meningitis belt or the Hajj. See MMWR 2011;60:1391–2, available at http://www.cdc.gov/mmwr/pdf/wk/mm6040.pdf.
- For children who are present during outbreaks caused by a vaccine serogroup, administer or complete an age and formulation-appropriate series of Hib-MenCY or MCV4.
- For booster doses among persons with high-risk conditions refer to http://www.cdc.gov/vaccines/pubs/acip-list.htm#mening.

Additional information
- For contraindications and precautions to use of a vaccine and for additional information regarding that vaccine, vaccination providers should consult the relevant ACIP statement available online at http://www.cdc.gov/vaccines/pubs/acip-list.htm.
- For the purposes of calculating intervals between doses, 4 weeks = 28 days. Intervals of 4 months or greater are determined by calendar months.
- Information on travel vaccine requirements and recommendations is available at http://wwwnc.cdc.gov/travel/page/vaccinations.htm.

U.S. Department of Health and Human Services
Centers for Disease Control and Prevention

FIG 31-11, cont'd

The figure below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. Always use this table in conjunction with Figure 1 and the footnotes that follow.

Vaccine	Minimum Age for Dose 1	Minimum Interval Between Doses			
		Dose 1 to dose 2	Dose 2 to dose 3	Dose 3 to dose 4	Dose 4 to dose 5
Persons aged 4 months through 6 years					
Hepatitis B[1]	Birth	4 weeks	8 weeks and at least 16 weeks after first dose; minimum age for the final dose is 24 weeks		
Rotavirus[2]	6 weeks	4 weeks	4 weeks[2]		
Diphtheria, tetanus, pertussis[3]	6 weeks	4 weeks	4 weeks	6 months	6 months[3]
Haemophilus influenzae type b[5]	6 weeks	4 weeks if first dose administered at younger than age 12 months 8 weeks (as final dose) if first dose administered at age 12–14 months No further doses needed if first dose administered at age 15 months or older	4 weeks[5] if current age is younger than 12 months 8 weeks (as final dose)[5] if current age is 12 months or older and first dose administered at younger than age 12 months and second dose administered at younger than 15 months No further doses needed if previous dose administered at age 15 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 through 59 months who received 3 doses before age 12 months	
Pneumococcal[6]	6 weeks	4 weeks if first dose administered at younger than age 12 months 8 weeks (as final dose for healthy children) if first dose administered at age 12 months or older or current age 24 through 59 months No further doses needed for healthy children if first dose administered at age 24 months or older	4 weeks if current age is younger than 12 months 8 weeks (as final dose for healthy children) if current age is 12 months or older No further doses needed for healthy children if previous dose administered at age 24 months or older	8 weeks (as final dose) This dose only necessary for children aged 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age	
Inactivated poliovirus[7]	6 weeks	4 weeks	4 weeks	6 months[7] minimum age 4 years for final dose	
Meningococcal[13]	6 weeks	8 weeks[13]	see footnote 13	see footnote 13	
Measles, mumps, rubella[9]	12 months	4 weeks			
Varicella[10]	12 months	3 months			
Hepatitis A[11]	12 months	6 months			
Persons aged 7 through 18 years					
Tetanus, diphtheria; tetanus, diphtheria, pertussis[4]	7 years[4]	4 weeks	4 weeks if first dose administered at younger than age 12 months 6 months if first dose administered at 12 months or older	6 months if first dose administered at younger than age 12 months	
Human papillomavirus[12]	9 years	Routine dosing intervals are recommended[12]			
Hepatitis A[11]	12 months	6 months			
Hepatitis B[1]	Birth	4 weeks	8 weeks (and at least 16 weeks after first dose)		
Inactivated poliovirus[7]	6 weeks	4 weeks	4 weeks[7]	6 months[7]	
Meningococcal[13]	6 weeks	8 weeks[13]			
Measles, mumps, rubella[9]	12 months	4 weeks			
Varicella[10]	12 months	3 months if person is younger than age 13 years 4 weeks if person is aged 13 years or older			

NOTE: The above recommendations must be read along with the footnotes of this schedule.

FIG 31-12 Catch-up immunization schedule for persons ages 4 months through 18 years who start late or are more than 1 month behind. (From Centers for Disease Control and Prevention: *Catch-up immunization schedule for persons aged 4 months through 18 years—United States,* 2013.)

HepA vaccine is now recommended for all children beginning at age 1 year (i.e., 12 months to 23 months). The second dose in the two-dose series may be administered no sooner than 6 months after the first dose. For further information, see Fig. 31-11.

Hepatitis B Virus. Hepatitis B is a significant pediatric disease because HBV infections that occur during childhood and adolescence can lead to fatal consequences from cirrhosis or liver cancer during adulthood. Up to 90% of infants infected perinatally and 25% to 50% of children infected before age 5 years become HBV carriers. In addition, the incidence of HBV infection increases rapidly during adolescence. It is recommended that newborns receive the HepB vaccine before hospital discharge if the mother is hepatitis B surface antigen (HBsAg) negative. Monovalent HepB vaccine should be given as the birth dose, whereas a combination vaccine containing HepB may be given for subsequent doses in the series (see also Fig. 31-11). Both full-term and preterm infants born to mothers whose HBsAg status is positive or unknown should receive the HepB vaccine and hepatitis B immune globulin (HBIG) within 12 hours of birth at two different injection sites. Because the immune response to the HepB vaccine is not optimal in newborns weighing less than 2000 g (4 lb 7 oz), the first HepB vaccine dose should be given to such infants at 1 month, as long as the mother's HBsAg status is negative (AAP Committee on Infectious Diseases, 2012). In the event that the preterm infant is given a dose at birth, the current recommendation is that the infant be given the full series (three additional doses) at 1, 2, and 6 months of age. The AAP

Committee on Infectious Diseases (2012) also encourages immunization of all children by age 11 years.

In the late 1990s, the HepB vaccine contained small amounts of mercury (thimerosal) as a preservative, which generated concern regarding possible mercury poisoning in infants and led to a subsequent decrease in HepB immunization rates in newborns. However, a preservative-free HepB vaccine (Recombivax HB, pediatric-adolescent formulation) is available, and the Centers for Disease Control and Prevention (CDC) (2011a) strongly recommends that HepB immunization occur in newborns before discharge from the birth hospital. Studies have not found any association between thimerosal in vaccines and neurologic developmental disorders such as autism spectrum disorder (Miller and Reynolds, 2009; Price, Thompson, Goodson, et al., 2010) (see Critical Thinking Case Study).

The vaccine is given intramuscularly in the vastus lateralis in newborns or in the deltoid for older infants and children. One study found that needle length affected the immune response of obese adolescents receiving the HBV vaccine; according to this study, obese adolescents immunized with a 1.5-inch (38-mm) needle achieved significantly higher antibody titers to hepatitis B than those immunized with a standard 1-inch needle (Middleman, Anding, and Tung, 2010). Regardless of age, avoid the dorsogluteal site because it has been associated with low antibody seroconversion rates, indicating a reduced immune response. No data exist regarding the seroconversion when the ventrogluteal site is used. The vaccine can be safely administered simultaneously at a separate site with DTaP, MMR, and Hib vaccines.

Diphtheria. Although cases of diphtheria are rare in the United States, the disease can result in significant morbidity. Respiratory manifestations include respiratory nasopharyngitis or obstructive laryngotracheitis with upper airway obstruction. The cutaneous manifestations of the disease include vaginal, otic, conjunctival, or cutaneous lesions, which are seen primarily in urban homeless persons and in the tropics. Administer a single dose of equine antitoxin (currently not available in the United States) intravenously to the child with clinical symptoms because of the often fulminant progression of the disease (AAP Committee on Infectious Diseases, 2012). Diphtheria vaccine is commonly administered:

1. In combination with tetanus and pertussis vaccines (DTaP) or DTaP and Hib vaccines for children younger than 7 years
2. In combination with a conjugate *H. influenzae* type B vaccine (see Fig. 31-11)
3. In a combined vaccine with tetanus (DT) for children younger than 7 years who have some contraindication to receiving pertussis vaccine
4. In combination with tetanus and acellular pertussis (Tdap) for children 11 years and older
   OR
5. As a single antigen when combined antigen preparations are not indicated

Although the diphtheria vaccine does not produce absolute immunity, protective antitoxin persists for 10 years or more when given according to the recommended schedule, and boosters are given every 10 years for life (see discussion below for adolescent diphtheria and acellular pertussis and tetanus toxoid recommendation). Several vaccines contain diphtheria toxoid (Hib, meningococcal, pneumococcal), but this does not confer immunity to the disease.

Tetanus. Three forms of tetanus vaccine—tetanus toxoid, tetanus immunoglobulin (TIG) (human), and tetanus antitoxin (equine antitoxin)—are available; however, tetanus antitoxin is no longer available in the United States. Tetanus toxoid is used for routine primary immunization, usually in one of the combinations listed for diphtheria, and provides protective antitoxin levels for approximately 10 years.

Tetanus and diphtheria toxoids along with acellular pertussis vaccine (Tdap, adolescent formulation) are now recommended for children ages 11 to 12 years who have completed the recommended DTaP/DTP vaccine series but have not received the tetanus (Td) booster dose. Children ages 7 through 10 years who are not fully vaccinated for pertussis (did not receive 5 doses of DTaP or 4 doses of DTaP with the fourth dose being administered on or after the fourth birthday) should receive a dose of Tdap (CDC, 2011b). Boostrix (Tdap) is currently licensed for children 10 to 18 years of age, whereas Adacel (Tdap) is licensed for individuals 11 to 64 years of age. For more information see Fig. 31-11.

For wound management, passive immunity is available with TIG. Persons with a history of two previous doses of tetanus toxoid can receive a booster dose of the toxoid. Separate syringes and different sites are used when tetanus toxoid and TIG are given concurrently.

For children older than 7 years who require wound prophylaxis, tetanus immunization may be accomplished by administering Td (adult-type diphtheria and tetanus toxoids). If TIG is not available, the equine antitoxin (not available in the United States) may be administered after appropriate testing for sensitivity. The antitoxin is administered in a separate syringe and at a separate intramuscular site if given concurrently with tetanus toxoid. For further

CRITICAL THINKING CASE STUDY

Childhood Immunizations and Autism

Monica, a 26-year-old mother of 2 children, ages 8 months and 2 years, brings them to the clinic for a well-child check. When asked if the children are up to date on their immunization schedule, Monica replies that she and her partner have decided not to have the children immunized. She states that a neighbor has a 9-year-old with autism and her Internet research and talks with various neighbors have convinced them that autism may possibly be caused by all of the immunizations children are receiving. Monica also points out that her children do not go to day care and that she plans to home school them; therefore she believes the risk for communicable disease contraction is low. "Besides, none of our neighborhood kids have ever had any of those diseases like measles or chickenpox because their parents get them immunized," she states. Upon physical examination, the two children appear to be in excellent health and their previous health history and family health history do not reveal any major health risk factors.

1. Evidence—Is there sufficient evidence to draw any conclusions about Monica's concerns about childhood immunizations?
2. Assumptions—Describe any underlying assumptions about the following:
   a. Childhood immunizations and autism
   b. Monica's reasons for not immunizing her children
   c. The concept of herd immunity
3. What approach would be the best to address Monica's concerns about not immunizing her children?
4. Is there objective evidence to support your conclusions?

information on wound prophylaxis, see the *2012 Red Book* (AAP Committee on Infectious Diseases, 2012).

Pertussis. Pertussis vaccine is recommended for all children 6 weeks through 6 years of age (up to the seventh birthday) who have no neurologic contraindications to its use. Concerns over outbreaks of the disease in the past decade have prompted discussion about vaccinating infants and adults. Many cases of pertussis have occurred in children younger than 6 months or persons older than 7 years, both groups falling in the category for which pertussis immunization previously was not recommended (CDC, 2005b). The tetanus and diphtheria toxoids and acellular pertussis vaccine (Tdap) is now recommended at ages 11 to 12 years for children who have completed the DTaP/DTP childhood series. The Tdap is also recommended for adolescents 13 to 18 years old who have not received a tetanus booster (Td) or Tdap dose and have completed the childhood DTaP/DTP series. In June 2013 the Advisory Committee on Immunization Practices (ACIP) recommended against universal revaccination with Tdap for adolescents and adults who have previously been vaccinated for pertussis; this recommendation was based on data indicating a low burden of pertussis illness in this age-group and an increased cost of universal revaccination (Long, 2013). Children ages 7 through 10 years who are not fully vaccinated for pertussis (did not receive 5 doses of DTaP or 4 doses of DTaP with the fourth dose being administered on or after the fourth birthday), should receive a dose of Tdap (CDC, 2011b) (see discussion in the Tetanus section).

Currently, two forms of pertussis vaccine are available in the United States. The whole-cell pertussis vaccine is prepared from inactivated cells of *Bordetella pertussis* and contains multiple antigens. In contrast, the acellular pertussis vaccine contains one or more immunogens derived from the *B. pertussis* organism. The highly purified acellular vaccine is associated with fewer local and systemic reactions than those occurring with the whole-cell vaccine in children of similar age. The acellular pertussis vaccine is recommended for the first three immunizations and is usually given at 2, 4, 6 months, 15 to 18 months, and 4 to 6 years of age with diphtheria and tetanus (DTaP). Several forms of acellular pertussis vaccine are currently licensed for use in infants: Daptacel, Pediarix, Kinrix (DTaP and IPV), and Infanrix (diphtheria, tetanus toxoid, and acellular pertussis conjugate). Pentacel is licensed for use in infants 4 weeks old and older; in addition to acellular pertussis, diphtheria, and tetanus, this vaccine also contains inactivated poliovirus (IPV) and Hib conjugate. Either the acellular or whole-cell vaccine may be given for the fourth and fifth doses, but the acellular is preferred. It is also recommended that the first three DTaP vaccinations be from the same manufacturer. The fourth dose may be from a different manufacturer. The child who has received one or more whole-cell vaccines may complete the series of five with the acellular vaccine.

Health care workers who may be susceptible to pertussis as a result of waning immunity and who have potential exposure to children or adults with pertussis should receive a single dose of Tdap (if not previously vaccinated with same) and take the necessary protective precautions against droplet contamination (wear procedural or surgical masks and practice hand washing). The diagnosis of pertussis may be missed or delayed in unvaccinated infants, who often are seen with respiratory distress and apnea without the typical cough. Additional guidelines for prevention and treatment of pertussis among health care workers and close contacts are available from the Centers for Disease Control and Prevention (CDC) website: www.cdc.gov/vaccines/.

The ACIP and American College of Obstetricians and Gynecologists recently recommended that pregnant women who are not protected against pertussis receive the Tdap vaccine anytime after 20 weeks of gestation or after birth before discharge from the hospital; breastfeeding is not a contraindication to Tdap vaccination (CDC, 2012).

Polio. An all-IPV (inactivated poliovirus) vaccine schedule for routine childhood polio vaccination is now recommended for children in the United States. All children should receive a dose of IPV at 2 months, 4 months, 6 to 18 months, and 4 to 6 years of age, for a total of four doses (AAP Committee on Infectious Diseases, 2012).

The change from the exclusive use of oral polio vaccine (OPV) to the exclusive use of the IPV vaccine is related to the rare risk for vaccine-associated polio paralysis (VAPP) from OPV. The exclusive use of the IPV vaccine eliminates the risk for VAPP but is associated with an increased number of injections and increased cost. Since IPV vaccine usage was instituted in the United States in 2000, no new cases of VAPP have occurred. PEDIARIX is a combination vaccine containing DTaP, hepatitis B, and IPV; this may be used as the primary immunization beginning at 2 months of age (AAP Committee on Infectious Diseases, 2012). KINRIX contains DTaP and IPV, and it may be used as the 5th dose in the DTaP series and the 4th dose in the IPV series in children ages 4 to 6 years whose previous vaccine doses have been with INFANRIX and/or PEDIARIX for the first three doses and INFANRIX for the 4th dose. As just noted, Pentacel is also licensed for use in infants 4 weeks old and older and contains DTaP, Hib, and inactivated poliovirus. PEDIARIX has been licensed for use in children as young as 6 weeks and contains DTaP, Hep B, and inactivated poliovirus.

Measles. The measles (rubeola) vaccine is given at 12 to 15 months of age. During the course of measles outbreaks, the vaccine can be given any time after 6 months of age, followed by a second inoculation after age 12 months. The second measles immunization is recommended at 4 to 6 years of age (at school entry) but may be given earlier provided that 4 weeks have elapsed since the administration of the previous dose. Revaccination should occur by 11 to 12 years of age if the measles vaccine was not administered at school entry (4 to 6 years). Any child who is vaccinated before 12 months of age should receive two additional doses beginning at 12 to 15 months and separated by at least 4 weeks (AAP Committee on Infectious Diseases, 2012). Revaccination should include all individuals born after 1956 who have not received two doses of measles vaccine after 12 months of age. Individuals born before this date are thought to be immune from exposure to natural measles virus. Because of the continuing occurrence of measles in older children and young adults, identify potentially susceptible adolescents and young adults and immunize them if two doses of measles vaccine have not been administered previously or the person had a confirmed case of the illness. The National Institute of Allergy and Infectious Diseases (NIAID), in collaboration with 34 other professional organizations, published new evidence-based guidelines for the diagnosis and management of food allergy; the NIAID recommends that children receive the MMR or MMRV (measles, mumps, rubella, and varicella) vaccine despite a history of severe egg allergy reaction (Boyce, Assa'ad, Burks, et al., 2010).

The MMRV vaccine (ProQuad) is an attenuated live virus vaccine and may be given to children 12 months to 12 years of age concurrent with other vaccines. Concerns for increased risk for febrile

seizures in children 12 months to 23 months of age after administration of MMRV vaccine initially prompted the ACIP (CDC, 2008) to remove its recommendation for MMRV being the preferred vaccine (vs. separate injections of MMR and varicella vaccines). However, after further review, the ACIP amended that recommendation and now recommends either administering MMR and varicella vaccines (two separate vaccines) or the MMRV vaccine as the first vaccination in children ages 12 to 47 months. For children 48 months and older, the first dose with MMRV is recommended to decrease the number of injections. For the same reason, MMRV is also recommended for the second dose at any age (15 months through 12 years).

The risks and benefits of administering the MMRV vaccine should be fully explained to the parent or caregiver; the risk for a febrile seizure at 5 to 12 days in children 12 to 23 months old remains relatively low and should be weighed with the benefit of one less intramuscular injection (AAP, 2012).

Mumps. Mumps virus vaccine is recommended for children at 12 to 15 months of age and is typically given in combination with measles and rubella. It should not be administered to infants younger than 12 months because persisting maternal antibodies can interfere with the immune response.

Because of recent outbreaks of the disease, especially in children 10 to 19 years of age, mumps immunization is recommended for all individuals born after 1957 who may be susceptible to mumps (i.e., those who have no history of having had the disease or vaccine and who have no laboratory evidence of immunity).

Rubella. Rubella is a relatively mild infection in children, but in a pregnant woman the actual infection presents serious risks to the developing fetus. Therefore the aim of rubella immunization is actually protection of the unborn child rather than the recipient of the immunization.

Rubella immunization is recommended for all children at 12 to 15 months of age and is administered in a combined form with measles and mumps vaccine. Increased emphasis should also be placed on vaccinating all unimmunized prepubertal children and susceptible adolescents and adult women in the childbearing age-group. Because the live attenuated virus may cross the placenta and theoretically present a risk to the developing fetus, rubella vaccine is currently not given to any pregnant woman. Although this is standard practice, current evidence from women who received the vaccine while pregnant and delivered unaffected offspring indicates that the risk to the fetus is negligible. In addition, there is no reported danger of administering rubella vaccine to a child if the mother is pregnant. Postpubertal females without evidence of rubella immunity should be immunized unless they are pregnant; they should be counseled not to become pregnant for 28 days after receiving the rubella-containing vaccine (AAP, 2012).

Pneumococcal Infections. Streptococcal pneumococci are responsible for a number of bacterial infections in children younger than 2 years, which may cause serious morbidity and mortality. Among these are generalized infections such as septicemia and meningitis or localized infections such as otitis media, sinusitis, and pneumonia. These illnesses are particularly problematic in children who attend day care facilities (the incidence in day care children is 2 or 3 times higher than in children not attending out-of-home day care) and in those who are immunocompromised. In 2010, a 13-valent pneumococcal conjugate vaccine (PCV 13 [Prevnar 13]) was licensed for use and is currently recommended as the standard pneumococcal vaccine for children ages 6 weeks to 24 months. Children who have started the PCV series with PCV 7 may complete the vaccine series with PCV 13 (CDC, 2010).

The PCV 13 vaccine is administered at 2, 4, and 6 months, with a fourth dose at 12 to 15 months of age. A single supplemental dose of PCV 13 is recommended for children 14 through 59 months who have received an age-appropriate series of PCV 7, and a single supplemental dose of PCV 13 is also recommended for children ages 60 through 71 months who received a series of PCV 7. PCV 13 is also recommended for all children younger than 24 months and for older children (24 to 71 months) with sickle cell disease; functional or anatomic asplenia; nephrotic syndrome or chronic renal failure; conditions associated with immunosuppression, such as solid organ transplantation, drug therapy, or cytoreduction therapy (including long-term systemic corticosteroid therapy); diabetes mellitus; cochlear implants; congenital immunodeficiency; human immunodeficiency virus (HIV) infection; cerebrospinal fluid leaks; chronic cardiovascular disease (e.g., congestive heart failure or cardiomyopathy); chronic pulmonary disease (e.g., emphysema or cystic fibrosis, but not asthma); chronic liver disease (e.g., cirrhosis); or exposure to living environments or social settings in which the risk for invasive pneumococcal disease or its complications is very high (e.g., Alaskan Native, African-American, and certain Native-American populations) The PCV 13 vaccine may be administered in conjunction with all other immunizations in a separate syringe and at a separate intramuscular site. For further information, see Fig. 31-11.

The PPV (pneumococcal polysaccharide [23-valent] vaccine) is not recommended for children younger than 24 months who do not have one of the high risk conditions described previously. One dose of PPV is recommended in children older than 23 months who have one of the high risk conditions after primary immunization with PCV 13 (see Fig. 31-11).

Haemophilus influenzae Type B. Hib conjugate vaccines protect against a number of serious infections caused by Hib, especially bacterial meningitis, epiglottitis, bacterial pneumonia, septic arthritis, and sepsis (Hib is not associated with the viruses that cause influenza, or "flu"). Hib vaccines that are currently available include PedvaxHIB, Pentacel, and Comvax, which are combination vaccines; Hiberix; and ActHIB. Pentacel is described in the previous section on Pertussis. MenHibrix has been licensed for administration to children ages 6 weeks to 18 months and provides protection against meningococcal (groups A, C, Y, and W-135) as well as *Haemophilus influenzae* type b (Hib) infections. MenHibrix is administered in a four-dose series at 2, 4, 6, and 12 to 15 months of age. These conjugate vaccines connect Hib to a nontoxic form of another organism, such as meningococcal protein, tetanus toxoid, or diphtheria protein. There is no antibody response to these nontoxic proteins, but they significantly improve the antibody response to Hib, especially in infants. The use of combination vaccines provides equivalent immunogenicity and decreases the number of injections an infant receives. However, it is important that they be given to the appropriate-age child. Hiberix is a conjugate vaccine licensed for use as the booster (final) dose of the Hib vaccine series for children ages 15 months to 4 years (CDC, 2009). In 2013 the AAP Committee on Infectious Diseases clarified that only one dose of Hib vaccine should be given to children 15 months of age or older who have not been previously vaccinated (AAP Committee on Infectious Diseases, 2013).

When possible, the Hib conjugate vaccine used at the first vaccination should be used for all subsequent vaccinations in the primary series. All Hib vaccines are administered by intramuscular injection using a separate syringe and at a site separate from any concurrent vaccinations. For more information, see Fig. 31-11.

! NURSING ALERT

The use of meningococcal and diphtheria proteins in combination vaccines does not mean the child has received adequate immunization for meningococcal or diphtheria illnesses; the child must be given the appropriate vaccine for that specific disease.

Varicella. Administration of the cell-free live-attenuated varicella vaccine is recommended for any susceptible child (one who lacks proof of varicella vaccination or has a reliable history of varicella infection). A single dose of 0.5 mL should be given by subcutaneous injection. The first dose of varicella vaccine is recommended for children ages 12 to 15 months, and to ensure adequate protection, a second varicella vaccine is recommended for children at 4 to 6 years of age. The second varicella vaccine may be administered before 4 years of age as long as a period of 3 months occurs between the first and second dose. Children 13 years of age or older who are susceptible should receive two doses administered at least 4 weeks apart. Children in the same age-group (13 to 18 years) who have received only one previous varicella vaccine should receive a second varicella vaccine. The two-dose regimen was adopted to protect children who did not have adequate protection with one dose, not because of waning immunity to the vaccine (AAP Committee on Infectious Diseases, 2012). The combination vaccine MMRV (ProQuad) is licensed for use in children ages 12 months to 12 years (see discussion in the Measles section).

According to the AAP Committee on Infectious Diseases (2012), children who have received two doses of the varicella vaccine are one-third less likely to have breakthrough illness in the first 10 years of immunization in comparison with those who have received one dose. Children who do contract varicella after immunization reportedly have milder cases with fewer vesicles, lower degree of fever, and faster recovery. Antibodies persist for at least 8 years.

Keep the vaccine frozen in the lyophilic form (stable particles that readily go into solution) and use it within 30 minutes of being reconstituted to ensure viral potency.

Varicella vaccine may be administered simultaneously with MMR. However, separate syringes and injection sites should be used. If they are not administered simultaneously, the interval between administration of varicella vaccine and MMR should be at least 1 month. Varicella vaccine may also be given simultaneously with DTaP, IPV, HepB, or Hib vaccine (AAP Committee on Infectious Diseases, 2012). The vaccine is administered subcutaneously. For more information, see Fig. 31-11.

Influenza. The influenza vaccine is recommended annually for children ages 6 months to 18 years. Influenza vaccine (inactivated influenza vaccine [IIV*]) may be given to any healthy children 6 months old and older. The vaccine is administered in early fall before the flu season begins and is repeated yearly for ongoing protection. The intramuscular vaccine is administered as two separate doses 4 weeks apart in first-time recipients younger than 9 years. The dose is 0.25 mL for children ages 6 to 35 months and 0.5 mL for children 3 years and older. An intradermal form of IIV has been licensed for persons 18 to 64 years of age. The vaccine may be given simultaneously with other vaccines but in a separate syringe and at a separate site. The vaccine is administered yearly because different strains of influenza are used each year in the manufacture of the vaccine. The NIAID 2010 guidelines (Boyce, Assa'ad, Burks, et al., 2010) state that there is insufficient evidence to recommend administering either one of the available influenza vaccines to patients with a history of severe reactions to egg proteins; however the guidelines also point out that egg protein allergy is relatively common in individuals who would benefit from the influenza vaccine (e.g., children with asthma). The AAP Committee on Infectious Diseases (2012) recommends an assessment of the egg allergenic reaction, mild versus severe, before making a decision about the vaccine administration to children who have a history of egg allergy. Several options for administering the influenza vaccine are described in the literature, and individuals should discuss the risks and benefits with a knowledgeable health care practitioner.

The live attenuated influenza vaccine (LAIV) is an acceptable alternative to the intramuscular vaccine in specific age-groups. The vaccine is given nasally as two doses at least 28 days apart in healthy persons ages 2 to 49 years. The LAIV form is not recommended for children 2 to 4 years of age with wheezing in the previous 12 months or diagnosed asthma (AAP Committee on Infectious Diseases, 2012). Although it is an alternative to the injection, it costs more and may not be covered by insurance companies. Either IIV or LAIV may be given to healthy, nonpregnant persons ages 2 to 49 years (AAP Committee on Infectious Diseases, 2012). Yearly influenza vaccine should be administered to health care workers and to children ages 6 to 59 months with medical conditions (including asthma, cardiac disease, HIV, diabetes, and sickle cell disease) that place them at risk for influenza-related complications.

The H1N1 virus (swine flu) is a subtype of influenza type A. Previous outbreaks of H1N1 influenza occurred in 1918, and the mortality rates were significant both in the United States and worldwide. The 2009 pandemic of H1N1 caused significant morbidity and mortality worldwide, but particularly in Mexico and the United States. Antigenic shift occurs when influenza A viruses undergo significant changes that result in new infection subtypes; such is the case in the pandemic of 2009.

Meningococcal Infections. Invasive meningococcal disease continues to be the cause of high morbidity in children in the United States. Infants younger than 1 year are particularly susceptible, yet the highest fatalities occur in adolescents (approximately 20%). There is also evidence that the risk for meningococcal infections is high in college freshmen living in dormitories. Meningococcal infections are also responsible for significant morbidities, including limb or digit amputation, skin scarring, hearing loss, and neurologic disabilities.

Neisseria meningitidis is the leading cause of bacterial meningitis in the United States. It is not recommended that children 9 months to 10 years old routinely receive the meningococcal conjugate vaccines because the infection rate is low in this age-group. Children at increased risk for meningococcal infection should receive a two-dose series of a meningococcal conjugate vaccine (MCV4) given at least 2 months apart. These include children with terminal complement component deficiency, anatomic or functional asplenia, or HIV. In such cases, these children should receive two doses of either MenACWY-D (Menactra) or MenACWY-CRM (Menveo), both of

*The trivalent inactivated influenza vaccine (TIV) was changed to Inactivated Influenza Vaccine (IIV) because of the anticipated quadrivalent influenza vaccine in the 2013-2014 season (AAP Committee on Infectious Diseases, 2013).

which are MCV4 vaccines (AAP Committee on Infectious Diseases, 2012). A meningococcal and Hib vaccine, MenHibrix (Hib-MenCY-TT), has been licensed for administration to children ages 6 weeks to 18 months and provides protection against meningococcal infections (groups A, C, Y, and W-135) and *Haemophilus influenzae* type b (Hib) infections. MenHibrix is administered in a four-dose series at 2, 4, 6, and 12 to 15 months of age and is recommended for infants at increased risk for meningococcal disease rather than as a routinely recommended vaccine (CDC, 2013). Children ages 2 to 18 years who travel to or reside in countries where *N. meningitidis* is hyperendemic or epidemic or who are at risk during a community outbreak should receive one dose of MCV4 (either Menveo or Menactra). Menactra is licensed for administration in children as young as 9 months, whereas Menveo is licensed only for children 2 years of age and older.

Children and adolescents 11 to 12 years of age should receive a single immunization of MCV4 (either Menactra or Menveo) and a booster of the same at age 16 to 18 years. Others at high risk who should receive MCV4 include college freshmen living in dormitories and military recruits. For more information see Fig. 31-11.

Persons who are at high risk for the disease and previously received MPSV4 (meningococcal polysaccharide vaccine) 3 or more years previously should be reimmunized with MCV4. MCV4 (Menveo or Menactra) is administered as an intramuscular injection (0.5 mL) and may be administered in conjunction with other vaccines in a separate syringe and at a separate site. Immunization with MCV4 is contraindicated in persons with hypersensitivity to any components of the vaccine, including diphtheria toxoid, and to rubber latex (part of vial stopper).

Recommendations for Selected Immunizations

Two additional vaccines are recommended for children and adolescents at high risk for particular diseases. Two rotavirus vaccines, RotaTeq and Rotarix, have received a license from the U.S. Food and Drug Administration for distribution in the United States. Rotavirus is one of the leading causes of severe diarrhea in infants and young children. RotaTeq is licensed for administration to infants at 6 to 12 weeks of age, with two additional doses administered at 4- to 10-week intervals but not after 32 weeks of age; the dose is 2 mL, and the product must be protected from light until administration (AAP Committee on Infectious Diseases, 2012). Rotarix (1 mL) may be administered beginning at 6 weeks of age with a second dose at least 4 weeks after the first dose but before 24 weeks of age. Both vaccines are administered orally.

Two human papillomavirus (HPV) vaccines have been licensed for use in adolescents; a quadrivalent HPV4 vaccine, Gardasil, has been approved and is recommended for female children and adolescents to prevent HPV-related cervical cancer. The vaccine is administered intramuscularly in three separate doses; the first dose in the series may be given at 11 to 12 years of age (minimum age, 9 years), and the second dose is administered 2 months after the first, with the third dose being given 6 months after the first dose. The HPV4 vaccine may also be administered to boys and men ages 9 to 26 years in a three-dose series to reduce the likelihood of genital warts (AAP Committee on Infectious Diseases, 2012). The bivalent vaccine (HPV2), Cervarix, is licensed for use in girls and women ages 10 to 25 years for the prevention of HPV-related cervical cancer; this vaccine is given in a three-dose series.

Immunizations that may be used in older children and adolescents in the future and that are being evaluated include vaccines for preventing diseases such as herpes simplex virus, human cytomegalovirus, and Epstein-Barr virus. Others, such as the rabies vaccine, are discussed elsewhere in this text.

Reactions

Vaccines for routine immunizations are among the safest and most reliable drugs available. However, minor side effects do occur after many of the immunizations, and, rarely, a serious reaction may result from the vaccine.

With inactivated antigens, such as DTaP, side effects are most likely to occur within a few hours or days of administration and are usually limited to local tenderness, erythema, and swelling at the injection site; low-grade fever; and behavioral changes (drowsiness, fretfulness, eating less, prolonged or unusual cry). Rarely, more severe reactions may occur, especially with pertussis. Reactions to DTaP tend to be more severe if they occurred with a previous immunization; fever, swelling, irritability, and pain are more common after the fourth DTaP vaccination in the series. Acetaminophen may help reduce this discomfort and should be given in an age-appropriate dose and time interval.

Hib vaccine is one of the safest vaccines available but may be associated with low-grade fever and mild local reactions at the site of injection, which resolve rapidly. Fever (temperature >38.5°C [101.3°F]) may rarely occur.

A number of inactive components are incorporated in vaccines to enhance their effectiveness and safety. Some of these components include preservatives, stabilizers, adjuvants, antibiotics, and purified culture medium proteins to enhance effectiveness. A child may react to the preservative in the vaccine rather than the vaccine component; an example of this is the HepB vaccine, which is prepared from yeast cultures. Yeast hypersensitivity might preclude one from receiving that particular vaccine. Trace amounts of neomycin are used to decrease bacterial growth within certain vaccine preparations, and persons with documented anaphylactic reactions to neomycin should avoid those vaccines. Most vaccine preparations now contain vial stoppers with a synthetic rubber to prevent latex allergy reactions; however, health care personnel administering vaccines should make sure that the package insert specifies there is no latex in the stopper. In the event that an individual has had a severe reaction to a vaccine and subsequent immunizations are required, an allergist should be consulted to determine the best course of action. The influenza vaccine contains small amounts of egg protein; thus children who have severe allergy to egg should seek the advice of an allergist regarding this vaccine. Most children with egg allergy are reported to be likely to develop a tolerance to small amounts over time (Settipane, Siri, and Bellanti, 2009).

Some vaccines contain a preservative, thimerosal, which contains ethylmercury. Concerns regarding possible mercury poisoning in the 1990s prompted many to put off vaccination of infants and small children for fear of childhood developmental problems such as autism. A number of manufacturers have since stopped producing vaccines containing thimerosal. No local hypersensitivity reactions to thimerosal have been recorded, and studies on thimerosal and the potential link to autism or any other pervasive developmental disorder failed to establish a causal relationship between the two (Hviid, Stellfeld, Wohlfahrt, et al., 2003; Parker, Schwartz, Todd, et al., 2004; Price, Thompson, Goodson, et al., 2010; Schultz, 2010). The Institute of Medicine (2004), following an in-depth 3-year study, concluded that there was no link between autism and the MMR vaccine or vaccines containing the preservative *thimerosal.*

A commonly observed reaction includes localized erythema and induration, which may occur when the vaccine is not administered deeply enough into the muscle. This reaction can be prevented by

ATRAUMATIC CARE

Immunizations

Needle length is an important factor and must be considered for each individual child; fewer reactions to immunizations are observed when the vaccine is given deep into the muscle rather than into subcutaneous tissue. Contrary to previous belief, deep intramuscular tissue has a better blood supply and fewer pain receptors than adipose tissue, thus providing an optimal site for immunizations with fewer side effects (Zuckerman, 2000).

To minimize local reactions from vaccines:

- Recommended needle length for newborn to 2 months is 16 mm (⅝ inch).
- Select a needle of adequate length (25 mm [1 in] in infants) to deposit the antigen deep in the muscle mass.
- Toddlers and older children require a needle length of 16 to 25 mm (⅝ to 1 inch) for deltoid, or 25 to 32 mm (1 to 1¼ in) for vastus lateralis (Schechter, Zempsky, Cohen, et al., 2007).
- Adolescents require a needle length of 25 to 51 mm (1 to 2 in) in deltoid or vastus lateralis (Schechter, Zempsky, Cohen, et al., 2007) depending on size of muscle mass.
- Inject into the vastus lateralis or ventrogluteal muscle; the deltoid may be used in children 18 months of age or older.

Use one or more of the following techniques to minimize pain:

- Apply the topical anesthetic *EMLA* (lidocaine-prilocaine) to the injection site and cover with an occlusive dressing for at least 1 hour before the injection.
- Apply the topical anesthetic *LMX4* (4% lidocaine) to the injection site 30 minutes before the injection; there is no evidence that an occlusive dressing is required except to prevent ingestion or accidental application to the eyes in infants (Wong, 2003).
- Apply a vapocoolant spray (e.g., ethyl chloride or Fluori-Methane) directly to the skin or to a cotton ball, which is placed on the skin for 15 seconds immediately before the injection (Reis and Holubkov, 1997).
- There is evidence that a concentrated oral sucrose solution (24%) and nonnutritive sucking (NNS) (pacifier) decrease the pain related to minor invasive procedures in neonates (Stevens, Johnston, Franck, et al., 1999; Stevens, Yamada, and Ohlsson, 2001). Most studies have focused on heel lance, venipuncture, and circumcision (neonatal period), but one institution has incorporated a neonatal oral sucrose pain protocol for painful procedures, including intramuscular injections (Thompson, 2005). Hatfield (2008) found that 2- and 4-month-old infants who received a 0.6 mL/kg dose of 24% sucrose and NNS 2 minutes before immunization administration had decreased pain behavioral responses compared with a control group of infants who received only sterile water and NNS 2 minutes before the injection. Liaw, Zeng, Yang, et al., (2011) found that NNS and oral sucrose provided analgesia to newborns receiving the hepatitis B vaccine. Therefore it is recommended that a concentrated oral sucrose solution (1 to 2 mL) be administered orally 2 minutes before the injection, during the injection, and up to 3 minutes after the procedure to decrease neonatal pain with immunizations.
- In preschool children, use distraction, such as telling the child to "take a deep breath and blow and blow and blow until I tell you to stop."
- A combination of pharmacologic and nonpharmacologic interventions including breastfeeding, oral sucrose, and NNS has been found to decrease the pain sensation in infants receiving their childhood immunizations (Shah, Taddio, Rieder, et al., 2009).

NOTE: Changing the needle on the syringe after drawing up the vaccine and before injecting it has not been shown to decrease local reactions. In children 4 to 6 years of age, the administration of sequential injections or simultaneous injections of vaccines did not alter their perceptions of distress, but parents preferred the simultaneous method (Horn and McCarthy, 1999).

ensuring that needle length is appropriate for the child's muscle size. Although many vaccine preparations are commercially available in prepackaged form, the enclosed needle may not be of adequate length to penetrate the muscle in certain children (see Atraumatic Care box above and Administration, p. 896).

Unlike the inactivated antigens, live attenuated virus vaccines such as MMR multiply for days or weeks, and unfavorable reactions and vaccine-associated disorders can occur for 30 to 60 days. These reactions are usually mild, although reactions to rubella tend to be more troublesome in older children and adults.

Contraindications and Precautions

Nurses need to be aware of the reasons for withholding immunizations—both for the child's safety in terms of avoiding reactions and for the child's maximum benefit from receiving the vaccine. Unfounded fears and lack of knowledge regarding contraindications can needlessly prevent a child from having protection from life-threatening diseases. Issues that have surfaced regarding vaccines include the misconception that administering combination vaccines may overload the child's immune system; the combined vaccines have undergone rigorous study in relation to side effects and immunogenicity rates following administration. Others may express concern that vaccines are not a part of the individual's natural immunity and that administering too many vaccines may decrease the child's immunity to such diseases. Parents may also voice concerns that vaccines may cause diseases such as asthma, multiple sclerosis, or diabetes mellitus (Kimmel, Burns, Wolfe, et al., 2007). Another concern of parents is the number of vaccines or "shots" given to infants at any given time and the pain and discomfort this may cause.

A *contraindication* is considered as a condition in an individual that increases the risk for a serious adverse reaction (e.g., not administering a live virus vaccine to a severely compromised child). A *precaution* is a condition in a recipient that might increase the risk for a serious adverse reaction or that might compromise the ability of the vaccine to produce immunity (CDC, 2011c).

The general contraindication for all immunizations is a severe febrile illness. This precaution avoids adding the risk for adverse side effects from the vaccine to an already ill child or mistakenly identifying a symptom of the disease as having been caused by the vaccine. The presence of minor illnesses such as the common cold is not a contraindication. Live virus vaccines are generally not administered to anyone with an altered immune system, since multiplication of the virus may be enhanced, causing a severe vaccine-induced illness.

In general, live virus vaccines such as varicella and MMR should not be administered to persons who are severely immunocompromised (National Center for Immunization and Respiratory Diseases, 2011). Another contraindication to live virus vaccines (e.g., MMR and varicella) is the presence of recently acquired passive immunity through blood transfusions, immunoglobulin, or maternal antibodies. Administration of MMR and varicella vaccines should be postponed for a minimum of 3 months after passive immunization with

immunoglobulins and blood transfusions (except washed red blood cells (RBCs), which do not interfere with the immune response). Suggested intervals between administration of immunoglobulin preparations and MMR and varicella vaccines depend on the type of immune product and dosage. If the vaccine and immunoglobulin are given simultaneously because of imminent exposure to disease, the two preparations are injected at sites far from each other. Vaccination should be repeated after the suggested intervals unless there is serologic evidence of antibody production.

A family history of seizures or any other adverse events following vaccination, penicillin allergy, allergies to duck meat or duck feathers, and a family history of SIDS are not considered contraindications to receiving childhood vaccines (AAP Committee on Infectious Diseases, 2012).

A final contraindication is a known allergic response to a previously administered vaccine or a substance in the vaccine. MMR vaccines contain minute amounts of neomycin; measles and mumps vaccines, which are grown on chick embryo tissue cultures, are not believed to contain significant amounts of egg cross-reacting proteins. Therefore only a history of anaphylactic reaction to neomycin, gelatin, or the vaccine itself is considered a contraindication to their use.

Pregnancy is a contraindication to MMR vaccines, although the risk for fetal damage is primarily theoretical. Breastfeeding is not a contraindication for any vaccine. The only vaccine virus that has been isolated in human milk is rubella, and there is no indication this is harmful to infants. Rubella infection in an infant as a result of exposure to the rubella virus in human milk would likely be well tolerated since the vaccine is attenuated (AAP Committee on Infectious Diseasaes, 2012). See also Family-Centered Care box.

Administration

The principal precautions in administering immunizations include proper storage of the vaccine to protect its potency and institution of recommended procedures for injection. The nurse must be familiar with the manufacturer's directions for storage and reconstitution of the vaccine. For example, if the vaccine is to be refrigerated, it should be stored on a center shelf, not in the door, where frequent temperature increases from opening the refrigerator can alter the vaccine's potency. For protection against light, the vial can be wrapped in aluminum foil. Periodic checks are established to ensure that no vaccine is used after its expiration date.

The DTaP vaccines contain the adjuvant *alum* to retain the antigen at the injection site and prolong the stimulatory effect. Because subcutaneous or intracutaneous injection of the adjuvant can cause local irritation, inflammation, or abscess formation, attention to excellent intramuscular injection technique must be used (see Atraumatic Care box, p. 895). Ipp, Parkin, Lear, et al. (2009) evaluated the administration order of the vaccines diphtheria-tetanus–acellular pertussis–*Haemophilus influenzae* type b (DTaP-Hib) and pneumococcal conjugate vaccine (PCV) and pain perception in 120 infants 2 to 6 months of age. The infants who were given the primary DTaP-Hib vaccine before the PCV vaccine had significantly lower pain scores as measured by the Modified Behavioral Pain Scale than those who received the PCV vaccine first. Both groups of infants were given both vaccines. Additional pain measures included crying as measured by video recording and parent perception of child pain using the Visual Analog Scale. The researchers recommend giving the primary DTaP-Hib vaccine before the PCV to reduce pain in infants receiving routine immunizations.

One of the most important features of injecting vaccines is adequate penetration of the muscle for deposition of the drug

FAMILY-CENTERED CARE

Communicating with Parents About Immunizations

- Provide accurate and user-friendly information on vaccines (the necessity for each one, the disease each prevents, potential adverse effects).
- Realize that the parent is expressing concern for the child's health.
- Acknowledge the parent's concerns in a genuine, empathetic manner.
- Tailor the discussion to the needs of the parent.
- Avoid judgmental or threatening language.
- Be knowledgeable about the benefits of individual vaccines, the common adverse effects, and how to minimize those effects.
- Give the parent the vaccine information statement (VIS) beforehand and be prepared to answer any questions that may arise.
- Help the parent make an informed decision regarding the administration of each vaccine.
- Be flexible and provide parents options regarding the administration of multiple vaccines, especially in infants, who must receive multiple injections at 2, 4, and 6 months (i.e., allow parents to space the vaccinations at different visits to decrease the total number of injections at each visit; make provisions for office visits for immunization purposes only [does not incur a practitioner fee except for administration of vaccine], provided the child is healthy).
- Involve the parent in minimizing the potential adverse effects of the vaccine (e.g., administering an appropriate dose of acetaminophen 45 minutes before administering the vaccine [as warranted]; applying EMLA [lidocaine-prilocaine] or LMX4 [4% lidocaine] to the injection sites before administration; following up to check on the child if untoward reactions have occurred in the past or parent is especially anxious about the child's well-being).
- Respect the parent's ultimate wishes.

Data from Coyer SM: Understanding parental concerns about immunizations, *J Pediatr Health Care* 16(4):193–196, 2002; Fredrickson DD, Davis TC, Bocchini JA: Explaining the risks and benefits of vaccines to parents, *Pediatr Ann* 30(7):400–406, 2001; Rosenthal P: Overcoming skepticism toward vaccines: a look at the real benefits and risks, *Consult Pediatr* 4(Suppl):S3–S7, 2004.

intramuscularly and not subcutaneously (depending on the manufacturer's recommendation for administration). The use of appropriate needle length is an essential component of administering vaccines. In two studies, the use of longer needles significantly decreased the incidence of localized edema and tenderness when vaccines were administered to a group of infants (Diggle and Deeks, 2000; Diggle, Deeks, and Pollard, 2006) (see Evidence-Based Practice box). Similar findings have been recorded for children 4 to 6 years of age receiving the 5th DTaP vaccine (Jackson, Yu, Nelson, et al., 2011). In some studies the site of administration influenced pain perception and localized reactions. Cook and Murtagh (2006) found that administration of the pertussis vaccine in the ventrogluteal muscle in children ages 2 months to 18 months was safe and had few localized reactions compared with anterolateral thigh administration. Junqueira, Tavares, Martins, et al. (2010) found that administration of the hepatitis B vaccine in the ventrogluteal muscle (vs. anterolateral thigh) of 580 infants resulted in a lower incidence of fever and localized reactions (see Intramuscular Administration, Chapter 39).

The total series requires several injections, and every attempt is made to rotate the sites and administer the injections as painlessly as possible (see Intramuscular Administration, Chapter 39). When two or more injections are given at separate sites, the order of

EVIDENCE-BASED PRACTICE

Appropriate Site, Technique, Needle Size, and Dose for Intramuscular Injections in Infants, Toddlers, and Small Children

Ask the Question

In infants, toddlers, and small children, what is the best site, technique, needle size and gauge, and dosage for intramuscular (IM) injections?

Search the Evidence

Search Strategies

Literature from 1990 to 2009 was reviewed to obtain clinical research studies related to this issue.

Databases Used

CINAHL, PubMed

Critically Analyze the Evidence

Searches reviewed were small studies. There were no randomized trials, double-blind trials, or large clinical studies addressing the subject of IM injections in children.

Infants and Toddlers

- A 16-mm needle was sufficient to penetrate the anterolateral thigh muscle if the needle is inserted at a 90° angle without pinching the muscle in children ages 2, 4, 6, and 18 months (Cook and Murtagh, 2002).
- A 25-mm needle is necessary to penetrate the thigh muscle when a 45° injection technique was employed. Longer needle length is needed to fully deposit the medication into the muscle in children ages 2, 4, 6, and 18 months (Cook and Murtagh, 2002).
- When diphtheria-tetanus-pertussis (DTP) immunizations were administered to infants ≤7 months of age, 84.6% of injections were administered at the correct site (anterior thigh). Incorrect sites of administration included 5.1% dorsogluteal and 2.6% deltoid muscles (Daly, Johnston, and Chung, 1992).
- Vaccines containing adjuvant such as alum (e.g., DTaP, hepatitis A and hepatitis B, diphtheria-tetanus [DT or Td]) should be given deep into the muscle to prevent local reactions (American Academy of Pediatrics [AAP], 2012; Centers for Disease Control and Prevention [CDC], 2002; Petousis-Harris, 2008; Taddio, Ilersich, Ipp, et al., 2009).
- Injecting adjuvant-containing vaccines into subcutaneous tissue increases the incidence of local reactions (Taddio, Ilersich, Ipp, et al., 2009; Zuckerman, 2000).
- 4-month-old infants experienced fewer local side effects (redness, tenderness, and swelling) when immunizations were administered into the anterior aspect of the thigh with a 25-mm (1-inch) needle versus shorter 16-mm (⅝-inch) needle (Diggle and Deeks, 2000).
- Localized vaccine reactions were significantly reduced when long needles (25 mm) were used for infant immunizations (Diggle, Deeks, and Pollard, 2006; Petousis-Harris, 2008).
- A 16-mm needle may be adequate for injections in small infants, and a 22- to 25-mm (⅞- to 1-inch) needle can be used in infants 2 months and older (AAP, 2012).
- A 22- to 32-mm (⅞- to 1¼-inch) needle is recommended for injections in toddlers if deltoid muscle size is adequate (CDC, 2002).
- A minimum of a 25-mm long needle is recommended for anterolateral thigh injection in toddlers (CDC, 2002).
- Dorsogluteal muscle should be avoided in infants and toddlers, and in smaller preschoolers with smaller muscle mass, because of the possibility of damaging the sciatic nerve (AAP, 2012).
- In children >1 year old, deltoid muscle is recommended for IM injections. When multiple vaccines are given, two may be given in the thigh (anterior and lateral) because of its larger size (Diggle, 2003).
- Injections in the anterolateral thigh should be given at least 2.5 cm (1 inch) apart so local reactions are less likely to overlap (AAP, 2012).
- No research or supportive data were found regarding the amount of medication to be given at the different sites in infants and toddlers.

Children and Adolescents

- A 22- to 25-gauge needle for all IM childhood immunizations is recommended (AAP, 2012; CDC, 2002).
- Deltoid muscle may be used for immunizations in toddlers, older children, and adolescents (AAP, 2012; CDC, 2002).
- 16-mm needle for children <60 kg and 25-mm needle for children 60-70 kg are appropriate for IM injections in the deltoid injection site (Koster, Stellato, Kohn, et al., 2009).
- Ventrogluteal site is relatively free of important nerves and vascular structures and is the site of choice for pediatric IM injections in children of all ages; no complications at this site were reported (Beecroft and Kongelbeck, 1994).
- Longer needle (25 mm) was preferred for injection when bunching the skin and injecting; shorter needle (16 mm) was perceived as causing fewer localized reactions when the injection was administered with the skin being held taut (Groswasser, Kahn, Bouche, et al., 1997).
- Needle length found to be the most significant variable for local reactions in children after injection: 25-mm needle was associated with fewer localized reactions versus 16-mm needle (Davenport, 2004).
- In children older than 1 year, deltoid muscle is recommended for IM injections. When multiple vaccines are given, two may be given in the thigh (anterior and lateral) because of its larger size (Diggle, 2003).
- Injections in the anterolateral thigh should be given at least 2.5 cm (1 inch) apart so local reactions are less likely to overlap (AAP, 2012).
- IM injections in the buttocks with longer needles and 90° angle are associated with less reactogenicity (Petousis-Harris, 2008).

Apply the Evidence: Nursing Implications

There is **low quality evidence** with **strong recommendation** to continue administering IM injections to children in the anterolateral thigh (up to 12 months old), deltoid (12 months and older), and ventrogluteal site (Guyatt, Oxman, Vist, et al., 2008). Needle length is an important factor in decreasing local reactions; the length should be adequate to deposit the medication into the muscle for IM injections. Recommendations are for a 25-mm (1-inch) needle in infants, a 25- to 32-mm (1- to 1¼-inch) needle for toddlers, and a 38- to 51-mm (1½- to 2-inch) needle for older children; preterm and small emaciated infants may require a shorter needle (16 to 25 mm [⅝ to 1 inch]) based on weight and muscle mass size.

injections is arbitrary. Because allergic reactions can occur after injection of vaccines, appropriate precautions are taken (see Anaphylaxis, Chapter 42).

Nurses administer vaccines and thus have the responsibility for adequately informing parents of the nature, prevalence, and risks of the disease; the type of immunization product to be used; the expected benefits and the risk for side effects of the vaccine; and the need for accurate immunization records. Referring to immunizations as "baby shots" and limiting the discussion to vague statements about the vaccines are unacceptable practices.

Another important nursing responsibility is accurate documentation. Each child should have an immunization record for parents to keep, especially for families who move frequently. Although immunization rates have increased significantly, health care professionals should use every opportunity to encourage complete immunization of all children (see Family-Centered Care box on p. 896). Blank immunization records may be downloaded from a number of websites, including the Immunization Action Coalition,* which has vaccine information and records in a number of languages.

The following information is documented on the medical record: day, month, and year of administration; manufacturer and lot number of vaccine; and the name, address, and title of the person administering the vaccine. Additional data to record are the site and route of administration and evidence that the parent or legal guardian gave informed consent before the immunization was administered. Any adverse reactions after the administration of any vaccine are reported to the Vaccine Adverse Event Reporting System.*

An additional source of vaccine information that must be given to parents (by law; National Childhood Vaccine Injury Act of 1986) before the administration of vaccines is the vaccine information statement (VIS) for the particular vaccine being administered. Health care practitioners are required to fully inform families of the risks and benefits of the vaccines. VISs are designed to provide updated information to the adult vaccinee or parents or legal guardians of children being vaccinated regarding the risks and benefits of each vaccine. Questions regarding the information in the VISs should be answered by the practitioner. VISs are available for the following vaccines: anthrax, tetanus, diphtheria, pertussis, MMR, MMRV, IPV, varicella, Hib, influenza, meningococcal, pneumococcal, rabies, shingles, smallpox, yellow fever, Japanese encephalitis, rotavirus, human papillomavirus, typhoid, HPV, HepA, and HepB. An updated VIS should be provided, and

*www.immunize.org.

documentation in the patient's chart should state that the VIS was given and include the publication date of the VIS; this represents informed consent once the parent or caregiver gives permission to administer the vaccines. VISs are available from state or local health departments or from the Immunization Action Coalition* and Centers for Disease Control and Prevention (CDC) in various languages.†

In response to the concerns of manufacturers, practitioners, and parents of children with serious vaccine-associated injuries, the National Childhood Vaccine Injury Act of 1986 and the Vaccine Compensation Amendments of 1987 were passed. These laws are designed to provide fair compensation for children who are inadvertently injured and provide greater protection from liability for vaccine manufacturers and providers. For further information, contact the National Vaccine Injury Compensation Program: 800 338-2382; www.hrsa.gov/vaccinecompensation/.

Safety Promotion and Injury Prevention

Injuries are a major cause of death during infancy, especially for children 6 to 12 months old. According to a Canadian survey (Flavin, Dostaler, Simpson, et al., 2006), the top leading causes of injury to infants were falls, ingestion injuries, and burns. The three leading causes of accidental death injury in infants were suffocation, motor vehicle–related injuries, and drowning (CDC, 2007). Mack, Gilchrist, and Ballesteros (2008) report that fall-related injuries in the home were the most common reason for emergency department visits in infants ages 0 to 12 months; according to these authors, one infant is injured every 1½ minutes. In a similar study of infants treated for accidents, the bed was commonly listed as being involved, whereas car seat at 2 months of age and stairs at 12 months were reported to be the cause of the accidental injury (Mack, Gilchrist, and Ballesteros, 2008). According to a recent Cochrane study, one third of all injuries occur in the home, yet there is insufficient evidence to demonstrate that modification of the home environment has an impact on the rate of injuries (Turner, Arthur, Lyons, et al., 2011). Constant vigilance, awareness, and supervision are essential as the child gains increased locomotor and manipulative skills that are coupled with an insatiable curiosity about the environment. Box 31-1 lists the major developmental achievements of each period during infancy and the appropriate injury prevention plan. Table 31-2 lists common types of injuries and associated objects that predispose to such injuries. Suggestions for promoting safety in the home environment are given for specific types of injuries. The acronym *S-A-F-E P-A-D* shown in Table 31-2 may be used to identify common types of injuries to infants and older children.

Motor Vehicle Safety

Automobile injuries are the leading cause of accidental death in children between the ages of 1 and 9 years (Bernard, Paulozzi, and Wallace, 2007). A significant number of nonfatal vehicle-related injuries in children between 1 and 4 years of age occur as a result of back-over while children are playing in a driveway (CDC, 2005a). In addition, a significant number of infants are injured or die from improper restraint within the vehicle, most often from riding on the lap of another occupant. Desapriya, Joshi, Subwarzi, et al. (2008) found that falls accounted for a significant proportion of injuries (98%) in infants from birth to 4 months of age as a result of inappropriate use of a car restraint system. Reports indicate that child restraint use decreases with increasing age of children and increasing number of occupants. Lack of proper child restraint continues to be a major factor in fatal accidents involving children. All infants must be secured in a federally approved restraint rather than held or placed on the seat of the car. There is no safe alternative.

FIG 31-13 Rear-facing infant seat in rear seat of car. The infant is placed in the seat when going home from the hospital. (Courtesy Brian and Mayannyn Sallee, Anchorage, AK.)

Infant restraints are designed either as an infant-only model or as a convertible infant-toddler model. Either restraint is a semireclined seat that faces the rear of the car. A rear-facing car seat provides the best protection for the disproportionately heavy head and weak neck of an infant (Fig. 31-13). This position minimizes the stress on the neck by spreading the forces of a frontal crash over the entire back, neck, and head; the spine is supported by the back of the car seat. If the seat were faced forward, the head would whip forward because of the force of the crash, creating enormous stress on the neck. It is now recommended that all infants and toddlers ride in rear-facing car safety seats until they reach the age of 2 years or the height recommended by the car seat manufacturer (AAP, 2011).* Some infant-only rear-facing infant car safety seats can accommodate children weighing up to a maximum of 35 pounds. Studies indicate that toddlers up to 24 months of age are safer riding in convertible seats in the rear-facing position (Bull and Durbin, 2008; Henary, Sherwood, Crandall, et al., 2007).

The restraint is anchored to the vehicle with the vehicle's seat belt, and the restraint has a harness system for securing the infant. Some harness systems require a clip to keep the shoulder straps correctly positioned. Newer vehicles (manufactured after 1999) have tether straps that attach to anchors in the car seat to better secure the seat and minimize forward movement of the forward-facing convertible seats in the event of an accident. The LATCH (lower anchor and tether for children) system provides car seat anchors between the front cushion and backrest so that the seat belt does not have to be used. However, the National Highway Traffic Safety Administration (NHTSA) recommends (as of February 2014) that the seat belt be used to anchor the car seat instead of the LATCH system if the combined weight of the child and car seat exceeds 65 pounds. Some automobiles have tether straps for

*Car seat information is available from the AAP at www.aap.org/healthtopics/carseatsafety.cfm; and from the Insurance Institute for Highway Safety, 1005 N. Glebe Road, Suite 800, Arlington, VA 22201; 703-247-1500; fax: 703-247-1588; www.iihs.org. The National Highway Traffic Safety Administration, www.nhtsa.gov, also provides child passenger safety and air bag safety information for parents.

BOX 31-1 SAFETY PROMOTION AND INJURY PREVENTION DURING INFANCY

Birth to 4 Months

Major Developmental Accomplishments

- Exhibits involuntary reflexes (e.g., crawling reflex may propel infant forward or backward; startle reflex may cause the body to jerk)
- May roll over
- Has increasing eye-hand coordination and voluntary grasp reflex

Injury Prevention

Aspiration

- Aspiration is not as great a danger to this age-group, but parents should begin practicing safeguarding early (see under Age 4 to 7 Months).
- Never shake baby powder directly on infant; place powder in hand and then on infant's skin; store container closed and out of infant's reach.
- Hold infant for feeding; do not prop bottle.
- Know emergency procedures for choking.
- Use pacifier with one-piece construction and loop handle.

Burns

- Install smoke detectors in home.
- Do not microwave infant formula or breast milk because this can cause burns because of uneven warming.
- Check bathwater temperature.
- Do not pour hot liquids when infant is close by, such as sitting on lap.
- Beware of cigarette ashes that may fall on infant.
- Do not leave infant in sun for more than a few minutes; keep skin covered.
- Wash flame-retardant clothes according to label directions.
- Use cool-mist vaporizers.
- Do not leave child in parked car.
- Check surface heat of car restraint before placing child in seat.

Suffocation and Drowning

- Keep all plastic bags stored out of infant's reach; discard large plastic garment bags after tying in a knot.
- Do not cover mattress with plastic.
- Use firm mattress and loose blankets, with no pillows.
- Make certain crib design follows federal regulations and mattress fits snugly—crib slats 2.375 inches (6 cm) apart.*
- Position crib away from other furniture and away from heat radiators.
- Do not tie pacifier on a string around infant's neck.
- Remove bibs at bedtime.
- Never leave infant alone in bath.
- Do not leave infant younger than 12 months alone on adult or youth mattress or "beanbag" type seats.
- Install carbon monoxide monitor.

Motor Vehicles

- Transport infant in federally approved, rear-facing car seat, preferably in back seat.†
- Do not place infant on seat (of car) or in lap.
- Do not place child in a carriage or stroller behind a parked car.
- Do not place infant or child in front passenger seat with an air bag.
- Do not leave infant unattended in car, especially in environmental temperatures above 70° F.

Falls

- Crib rails are fixed and firmly latched. As of 2011, only beds with fixed rails are recommended, but some older models may be in use (suggest purchasing a rail-latching mechanism for older models).
- Never leave infant alone on a raised, unguarded surface.
- When in doubt as to where to place child, use floor.
- Restrain child in infant seat, and never leave child unattended while the seat is resting on a raised surface.
- Avoid using a high chair until child can sit well with support.

Poisoning

- Poisoning is not as great a danger to this age-group, but parents should begin practicing safeguards early (see under Age 4 to 7 Months).

Bodily Damage

- Keep sharp or jagged objects such as knives and broken glass out of child's reach.
- Keep diaper pins closed and away from infant.

Age 4 to 7 Months

Major Developmental Accomplishments

- Rolls over
- Sits momentarily
- Grasps and manipulates small objects
- Resecures a dropped object
- Has well-developed eye-hand coordination
- Can focus on and locate very small objects
- Has prominent mouthing (oral fixation)
- Can push up on hands and knees
- Crawls backward

Injury Prevention

Aspiration

- Keep buttons, beads, syringe caps, and other small objects out of infant's reach.
- Keep floor free of any small objects.
- Do not feed infant hard candy, nuts, food with pits or seeds, or whole or circular pieces of hot dog.
- Exercise caution when giving teething biscuits, since large chunks may be broken off and aspirated.
- Do not feed infant while he or she is lying down.
- Inspect toys for removable parts.
- Keep baby powder, if used, out of reach.
- Avoid storing large quantities of cleaning fluid, paints, pesticides, and other toxic substances.
- Discard used containers of poisonous substances.
- Do not store toxic substances in food or drink containers.
- Discard used button-size batteries; store new batteries in safe area.
- Know telephone number of local poison control center ([800] 222-1222) (usually listed in front of telephone directory).

Suffocation

- Keep all latex balloons out of reach.
- Remove all crib toys that are strung across crib or play yard when child begins to push up on hands or knees or is 5 months old.

Burns

- Keep water faucets out of reach.
- Place hot objects (cigarettes, candles, incense) on high surface out of child's reach.
- Limit exposure to sun; apply sunscreen.

BOX 31-1 SAFETY PROMOTION AND INJURY PREVENTION DURING INFANCY—cont'd

Falls
- Restrain in a high chair.
- Crib rails are fixed and firmly latched. As of 2011, only beds with fixed rails are recommended.

Motor Vehicles
- See under Birth to 4 Months.

Poisoning
- Make certain that paint for furniture or toys does not contain lead.
- Place toxic substances on a high shelf or in locked cabinet.
- Hang plants or place on high surface rather than on floor.
- Know telephone number of local poison control center ([800] 222-1222) (usually listed in front of telephone directory).

Bodily Damage
- Give toys that are smooth and rounded, preferably made of wood or plastic.
- Avoid long, pointed objects as toys.
- Avoid toys that are excessively loud.
- Keep sharp objects out of infant's reach.

Age 8 to 12 Months

Major Developmental Accomplishments
- Crawls or creeps
- Stands, holding onto furniture
- Stands alone
- Cruises around furniture
- Walks
- Climbs
- Pulls on objects
- Throws objects
- Is able to pick up small objects; has pincer grasp
- Explores by putting objects in mouth
- Dislikes being restrained
- Explores away from parent
- Increasingly understands simple commands and phrases

Injury Prevention

Aspiration
- Keep small objects off floor, off furniture, and out of reach of children.
- Take care in feeding solid table food to give very small pieces.
- Do not use beanbag toys or allow child to play with dried beans.
- See also under Age 4 to 7 Months.

Bodily Damage
- See under Age 4 to 7 Months.
- Avoid placing televisions or other large objects on top of furniture, which may be overturned when infant pulls self to standing position.

Falls
- Avoid walkers, especially near stairs.*
- Ensure that furniture is sturdy enough for child to pull self to standing position and cruise.
- Fence stairways at top and bottom if child has access to either end.*
- Dress infant in safe shoes and clothing (soles that do not "catch" on floor, tied shoelaces, pant legs that do not touch floor).

Suffocation and Drowning
- Keep doors of ovens, dishwashers, refrigerators, coolers, and front-loading clothes washers and dryers closed at all times.
- If storing an unused large appliance, such as a refrigerator, remove the door.
- Supervise contact with inflated balloons; immediately discard popped balloons, and keep uninflated balloons out of reach.
- Fence swimming pools and other bodies of standing water such as decorative fountains; lock gate to swimming pools so only adult can access.
- Always supervise when near any source of water, such as cleaning buckets, drainage areas, ponds, toilets.
- Keep bathroom doors closed.
- Eliminate unnecessary pools of water.
- Keep one hand on child at all times when in bathtub.

Poisoning
- Administer medications as a drug, not as a candy.
- Do not administer medications unless prescribed by a practitioner.
- Return medications and poisons to safe storage area immediately after use; replace caps properly if a child-protector cap is used.
- Have poison control center number ([800] 222-1222) on telephone and refrigerator.

Burns
- Place guards in front of or around any heating appliance, fireplace, or furnace.
- Keep electrical wires hidden or out of reach.
- Place plastic guards over electrical outlets; place furniture in front of outlets.
- Keep hanging tablecloths out of reach (child may pull down hot liquids or heavy or sharp objects).

*Information on many items such as cribs or walkers is available from U.S. Consumer Product Safety Commission, (800) 638-2772; www.cpsc.gov/.

†See footnote on p. 899.

rear-facing infant-only seats as well. Although many infant restraints can be recliners, they are used in the car only in the position specified by the manufacturer.

Severe injuries and deaths in children have occurred from air bags deploying on impact in the front passenger seat. The back seat is the safest area of the car for children. For restraints to be effective, they must be used properly. Dressing the infant in an outfit with sleeves and legs allows the harness to hold the child securely in the seat. A small blanket or towel rolled tightly can be placed on either side of the head to minimize movement and keep the infant's hips against the back of the seat. Padding between the infant's legs and crotch is added to prevent slouching. Thick, soft padding is not placed under the infant or behind the back because during the impact, the padding will compress, leaving the harness straps loose. Preterm infants being discharged home from the hospital should be placed in an appropriate car seat restraint as it would be placed in the car, and the infant's heart rate and oxygen saturation are monitored for a minimum of 1 hour and maximum of 3 hours (depending on the length of the trip to the home) to detect any potential problems with airway occlusion. (See Community Focus, p. 708, for preterm infant restraint; for further discussion of car seat restraints, see Chapter 25.)

TABLE 31-2 COMMON INFANT INJURIES, ASSOCIATED RISK FACTORS, AND SAFETY PROMOTION

SAFE PAD	RISK FACTORS	SUGGESTED SAFETY INTERVENTIONS
S—Suffocation, Sleep position	Latex balloons	Avoid latex balloons except with close adult supervision.
	Plastic bags	Tie unused plastic bags in a knot and dispose of in a safe container.
	Bed surface (noninfant) such as sofa or adult bed	Avoid placing infants to sleep on sofas, soft bedding, or adult bed.
	Pillows	Avoid use of pillows for sleep.
	Soft cushions and blankets	Clear bedding of soft cushions and blankets.
	Prone sleeping	Place infant to sleep on back at all times.
A—Asphyxia, animal bites	Food items: cylindric items such as hot dogs, hard candy, peanuts, almonds	Cut hot dogs lengthwise; avoid hard candy in infants and toddlers. Infants should completely chew up each food item in mouth; do not feed more until item is swallowed.
	Toys: small toys such as Legos	As a general rule of thumb, if the toy fits into a toilet paper cardboard roll, it can be swallowed by a small child.
	Small objects: batteries, buttons, beads, dried beans, syringe caps, safety pins	Keep out of reach of infants, who are naturally inquisitive.
	Pacifiers	Pacifiers should be one piece.
	Baby (talc) powder	Avoid shaking powder over infant; if used, place on adult's hand and then place on infant's skin.
	Domestic dogs, cats	Supervise child around domestic animals; teach not to approach dog that is eating, has puppies, or is not feeling well. Animals that are "tame" can be unpredictable. Small children are the right size for most domesticated animals to come face to face. Closely supervise child around visiting pets. (See Pet and Wild Animal Bites, Chapter 47.)
F—Falls	Stairs	Infants like to climb; place childproof gate at top and bottom of stairs.
	Diaper changing table	Infants do not have depth perception and cannot perceive a dangerous height from one that is safe. Never leave infants unattended on a flat surface, even if not rolling over.
	Crib, bed-crib sides can fall when infant leans on them	In 2011, a mandate was made to stop selling drop-side infant cribs.*
	Infant carriers	Never leave infant unattended in a carrier on top of a surface such as a shopping cart, clothes dryer, washer, kitchen cabinet; place carrier on floor.
	Car seat restraints	Secure infant in car seat restraint and never leave unattended if unrestrained.
	High chair	Restrain infant in high chair; avoid using high chair except for feeding and only if adult supervision is adequate; even restrained infants can squirm out of some restraints and fall.
	Infant walkers	Use only stationary walkers. There is no evidence that walkers help infants "walk" any sooner. Wheeled walkers can easily be propelled off stairs and other platforms such as porches or decks, causing significant injury.
	Windows, screens	Avoid placing furniture next to a window. Infants learn to climb and can fall out of open windows, even with screens.
	Television, stereos, sound systems	These must be secured to the stand; infants can pull the stand over, causing the TV or sound system to land on their heads, causing significant injury.
E—Electrical burns or burns	Electrical outlets	Place safety cap over electrical outlets; infants may be burned by placing conductive object into outlet.
	Hot hair combs, curlers	Keep out of reach of infant and keep turned off when not in use.
	Water	Infants may turn on tap or faucet in bathtub and burn self. Lower the water heater to a safe temperature of 49° C (120° F). Before placing infant in tub, check temperature of water and completely turn off faucet so child cannot alter temperature of water. NEVER leave infant unattended in tub or sink of water.
	Fireplace	Place a childproof screen in front of fireplace.
	Stove, hot liquids	Keep top front burners off and keep pot handles turned toward back to avoid infant pulling hot pot onto self and causing burn injuries.
	Cigarettes	Avoid smoking and holding infant on lap while smoking cigar or cigarette.

TABLE 31-2 COMMON INFANT INJURIES, ASSOCIATED RISK FACTORS, AND SAFETY PROMOTION—cont'd

SAFE PAD	RISK FACTORS	SUGGESTED SAFETY INTERVENTIONS
P—Poisoning, ingestions	Medication, ointments, cream, lotions	Medications left in purses or handbags or on a table top can often be ingested by the curious infant. Keep Poison Control Center number readily available ([800]-222-1222).
	Plants: household plants may be a source of accidental poisoning	Keep plants out of child's reach.
	Cleaning solutions	Store in locked cabinet or in top cabinet where there are no drawers or shelves for infant to climb on. Avoid storing cleaning and caustic solutions in containers such as a soda bottle or jar—infants and toddlers cannot differentiate a soda from a caustic drain cleaner.
	Inhalation or oral or nasal ingestion of poisonous or harmful chemicals such as methamphetamine, gasoline, turpentine	Keep gasoline and turpentine stored in a locked cabinet or closet out of child's reach. Avoid storing in containers that are also used to keep drinks or food.
A—Automobile safety	Car or truck and hot weather	An automobile-related hazard for infants is overheating (hyperthermia) and subsequent death when left in a vehicle in hot weather (>26.4° C [80° F]). Infants dissipate heat poorly, and an increase in body temperature may cause death in a few hours. Caution parents against leaving infants in a vehicle alone for *any reason*.
	Air bags	Avoid placing infant in a car restraint behind an air bag. Deactivate the air bag (available in certain models) or place the infant in the back seat in a proper car seat restraint.
	Car seat restraint	See discussion on p. 899.
D—Drowning	Bath tub	NEVER leave infant unattended in tub or sink of water.
	Swimming pools, bird baths, decorative ponds of water, splash pads	Place fence around pools with gate lock that is out of child's reach. Supervise infants in water at ALL times; an infant may drown in as little as 2 inches of water. Swimming lessons are encouraged but are not foolproof for drowning if infant or child hits head on hard object and becomes unconscious as falling into the water.
	5-gal buckets	Keep 5-gal buckets empty of water or elevated out of child's reach.

*A number of parent education pamphlets—such as Crib Safety Tips and Is Your Used Crib Safe?—are available in English and Spanish from the U.S. Consumer Product Safety Commission, 4330 East West Highway, Bethesda, MD 20814; (800) 638-2772; www.cpsc.gov/.

! NURSING ALERT

Rear-facing infant safety seats must not be placed in the front seats of cars equipped with an air bag on the passenger side. If an infant safety seat is placed in the passenger seat with an air bag, the child could be seriously injured if the air bag is released, since rear-facing infant seats extend closer to the dashboard.

Another automobile-related hazard for infants is *overheating* (hyperthermia) and subsequent death when left in a vehicle in hot weather (over 26.4° C [80° F]). Infants dissipate heat poorly, and an increase in body temperature may cause death in a few hours. Parents are cautioned against leaving infants in a vehicle alone for *any reason*. A small sign or placard has been designed to hang in the rear-view mirror to remind the parent that there is a child in the back seat. Busy parents may forget the child in the back when preoccupied with errands, children's school and extracurricular activities, and busy work schedules.

Nurse's Role in Injury Prevention

The task of injury prevention begins to be appreciated only when the potential environmental dangers to which infants are vulnerable are considered. Injury prevention and parent education should be handled on a growth and developmental basis. It is simply impossible to completely protect infants and small children from all potential dangers without placing them in a sterile, impractical environment. However, a large percentage of childhood deaths continue to occur as a result of *preventable* injuries (Martin, Kochanek, Strobino, et al., 2005; Schnitzer, 2006). Nurses must be aware of the possible causes of injury in each age-group to provide anticipatory, preventive teaching. For example, the nurse should discuss guidelines for injury prevention during infancy (see Box 31-1) before the child reaches the susceptible age-group. Preventive teaching ideally begins during pregnancy.

One third of all injuries to children occur in the home, and therefore the importance of safety cannot be overemphasized. The Patient Teaching box summarizes a home safety checklist that can be presented to parents to increase their awareness of danger areas in the home and assist them in implementing safety devices and practices *before* their absence can inflict injury on infants. Hands-on displays such as cabinet latches or toilet seat locks can familiarize parents with inexpensive, commercial devices that can be used in the home to prevent injuries.

Injury prevention requires protection of the child and education of the caregiver. Nurses in ambulatory care settings, health maintenance centers, and visiting nurse agencies are in a most favorable position for injury education. This does not exclude nurses in inpatient facilities, who could use visiting times as an excellent opportunity for discussing this topic. Although early discharge after birth may be restrictive for parent teaching, this is an excellent opportunity to introduce the family to infant safety and safety for other

PATIENT TEACHING

Child Home Safety Checklist

Safety: Fire, Electrical, Burns

- Guards in front of or around any heating appliance, fireplace, or furnace (including floor furnace)*
- Electrical wires hidden or out of reach*
- No frayed or broken wires; no overloaded sockets
- Plastic guards or caps over electrical outlets; furniture in front of outlets*
- Hanging tablecloths out of reach, away from open fires*
- Smoke detectors tested and operating properly
- Kitchen matches stored out of child's reach*
- Large, deep ashtrays throughout house (if used)
- Small stoves, heaters, and other hot objects (cigarettes, candles, coffee pots, slow cookers) placed where they cannot be tipped over or reached by children
- Hot water heater set at 49° C (120° F) or lower
- Pot handles turned toward back of stove, center of table
- No loose clothing worn near stove
- No cooking or eating hot foods or liquids with child standing nearby or sitting in lap
- All small appliances, such as iron, turned off, disconnected, and placed out of reach when not in use
- Cool, not hot, mist vaporizer if used
- Fire extinguisher available on each floor and checked periodically
- Electrical fuse box and gas shutoff accessible
- Family escape plan in case of a fire practiced periodically; fire escape ladder available on upper-level floors
- Telephone number of fire or rescue squad and address of home with nearest cross street posted near phone

Safety: Suffocation and Aspiration

- Small objects stored out of reach*
- Toys inspected for small removable parts or long strings*
- Hanging crib toys and mobiles placed out of reach
- Plastic bags stored away from young child's reach; large plastic garment bags discarded after tying in knots*
- Mattress or pillow not covered with plastic or in manner accessible to child*
- Crib design according to federal regulations (crib slats less than 2.375 inches [6 cm] apart) with snug-fitting mattress*†
- Crib positioned away from other furniture or windows*
- Portable play yard gates up at all times while in use*
- Accordion-style gates not used*
- Bathroom doors kept closed and toilet lids down*
- Faucets turned off firmly*
- Pool fenced with locked gate
- Proper safety equipment at poolside
- Electronic garage door openers stored safely and garage door adjusted to rise when door strikes object
- Doors of ovens, trunks, dishwashers, refrigerators, and front-loading clothes washers and dryers kept closed*
- Unused appliance, such as a refrigerator, securely closed with lock or doors removed*
- Food served in small, non-cylindric pieces*
- Toy chests without lids or with lids that securely lock in open position*
- Buckets and wading pools kept empty when not in use*
- Clothesline above head level
- At least one member of household trained in basic life support (cardiopulmonary resuscitation), including first aid for choking

Safety: Poisoning

- Toxic substances, including batteries, placed on a high shelf, preferably in locked cabinet
- Toxic plants hung or placed out of reach*
- Excess quantities of cleaning fluid, paints, pesticides, drugs, and other toxic substances not stored in home
- Used containers of poisonous substances discarded where child cannot obtain access
- Telephone number of local poison control center ([800] 222-1222) and home address with nearest cross street posted near phone
- Medicines clearly labeled in childproof containers and stored out of reach
- Household cleaners, disinfectants, and insecticides kept in their original containers, separate from food and out of reach
- Smoking in areas away from children

Safety: Falls

- Nonskid mats, strips, or surfaces in tubs and showers
- Exits, halls, and passageways in rooms kept clear of toys, furniture, boxes, or other items that could be obstructive
- Stairs and halls well lighted, with switches at both top and bottom
- Sturdy handrails for all steps and stairways
- Nothing stored on stairways
- Treads, risers, and carpeting in good repair
- Glass doors and walls marked with decals
- Safety glass used in doors, windows, and on walls
- Gates on top and bottom of staircases and elevated areas, such as porch, fire escape*
- Guardrails on upstairs windows with locks that limit height of window opening and access to areas such as fire escape*
- Crib side rails raised to full height; mattress lowered as child grows*
- Restraints used in high chairs, walkers, or other baby furniture; preferably walkers not used*
- Scatter rugs secured in place or used with nonskid backing
- Walks, patios, and driveways in good repair

Safety: Bodily Injury

- Knives, power tools, and unloaded firearms stored safely or placed in locked cabinet
- Garden tools returned to storage racks after use
- Pets properly restrained and immunized for rabies
- Swings, slides, and other outdoor play equipment kept in safe condition
- Yard free of broken glass, nail-studded boards, other litter
- Cement birdbaths placed where young child cannot tip them over*
- Furniture anchored so child cannot pull down on top of self when climbing or pulling to stand

*Safety measures are specific for homes with young children. All safety measures should be implemented in homes where children reside and visit frequently, such as those of grandparents or baby-sitters.

†Federal regulations are available from U.S. Consumer Product Safety Commission, (800) 638–2772; www.cpsc.gov.

children as well. Parents should be encouraged to take an infant cardiopulmonary resuscitation (CPR) class to deal effectively with potential problems. This tool further empowers the parents to raise their new infant in the best environment possible.

One approach to teaching injury prevention is to relate why children in various age-groups are prone to specific types of injuries. Stressing prevention is just as important as emphasizing the *why* of the injury. However, injury prevention must also be practical. Asking parents for their ideas leads to realistic suggestions that can be followed. For instance, bathroom cleaning agents, cosmetics, and personal care items can be placed on a top shelf in the linen closet and towels or sheets can be stored on the lower shelves and floor.

If an injury has occurred, the nurse should not be too quick to admonish the parent. Injuries do not always indicate neglect. It is a difficult task to watch children carefully without overprotecting or unnecessarily confining them. Allowing children to explore while maintaining consistent, age-appropriate limits is sound advice.

Parents need to remember that infants and young children cannot anticipate danger or understand when it is or is not present. Also, infants have no cognitive concept of cause and effect and therefore cannot relate meaning to experiences or potential dangers. A dead electrical wire may present no actual harm, but if the child is allowed to play with it, a poor behavior is enforced and will be practiced when the child encounters a live wire. Although it is always wise to explain why something is dangerous, it must be remembered that small children need to be physically removed from the situation.

It is not easy to teach safety, supervise closely, and refrain from saying "no" a hundred times a day. Parents become acutely aware of this dilemma as soon as the infant learns to crawl. Preventing injuries to children is usually the first reason for limit setting and discipline, but limits are also set to prevent damage to valuable household objects. When small children are in the home, dangerous objects must be removed or guarded and valuable articles placed out of reach.

When children are taught the meaning of "no," they should also be taught what "yes" means. Children should be praised for playing with suitable toys, their efforts at behaving or listening should be reinforced, and innovative and creative recreational toys should be provided for them. Infants love to tear paper and avidly pursue books, magazines, or newspapers left on the floor. Instead of always scolding them for destroying a valued book, parents should provide child-safe books (e.g., those constructed of fabric) for them to play with. If they enjoy pots and pans, a cabinet can be arranged with safe utensils for them to explore.

One additional factor must be stressed concerning injury prevention and education. Children are imitators; they copy what they see and hear. *Practicing safety teaches safety,* which applies to parents and their children and to nurses and their patients. Saying one thing but doing another confuses children and can lead to difficulties as the child grows older.

Anticipatory Guidance—Care of Families

Childrearing is no easy task; it presents challenges to both new and "seasoned" parents. Society's changing roles and mores, combined with a highly mobile population, leave little stability for traditional role models and time-honored methods of raising children. As a result, parents look to health care professionals for guidance. Nurses are in an advantageous position to render assistance and offer suggestions. Every phase of a child's life has its particular traumas—toilet training for toddlers, unexplained fears for preschoolers, and identity crises for adolescents. For parents of an infant, some challenges center around dependency, discipline, increased mobility, and safety. Major areas for parental guidance during the first year are listed in the Patient Teaching box.

PATIENT TEACHING

Guidance During Infant's First Year

First 6 Months

- Teach car safety with use of federally approved restraint, facing rearward, in the middle of the back seat—not in a front seat with an air bag.
- Understand each parent's adjustment to the newborn, especially mother's emotional needs after birth.
- Teach care of infant and help parents understand his or her individual needs and temperament and that the infant expresses wants through crying.
- Reassure parents that infant cannot be spoiled by too much attention during the first 4 to 6 months.
- Encourage parents to establish a schedule that meets needs of child and themselves.
- Help parents understand infant's need for stimulation in environment.
- Support parents' pleasure in seeing child's growing friendliness and social response, especially smiling.
- Plan anticipatory guidance for safety.
- Stress need for routine childhood immunizations.
- Prepare for introduction of solid foods.

Second 6 Months

- Prepare parents for child's "stranger anxiety."
- Encourage parents to allow child to cling to them and avoid long separation from either.
- Guide parents concerning discipline because of infant's increasing mobility.
- Encourage use of negative voice and eye contact rather than physical punishment as a means of discipline.
- Encourage showing most attention when infant is behaving well, rather than when infant is crying.
- Teach injury prevention because of child's advancing motor skills and curiosity.
- Encourage parents to leave child with suitable caregiver to allow some free time.
- Discuss readiness for weaning (as desired).
- Explore parents' feelings regarding infant's sleep patterns.

SPECIAL HEALTH PROBLEMS

Colic (Paroxysmal Abdominal Pain)

Colic is reported to occur in 15% to 40% of all infants (Morin, 2009b), yet it has no particular affinity in regard to the sex, race, or socioeconomic status (Ellett, 2003). An organic cause may be identified in fewer than 5% of infants seen by physicians because of excessive crying (Roberts, Ostapchuk, and O'Brien, 2004). The condition is generally described as abdominal pain or cramping that is manifested by loud crying and drawing the legs up to the abdomen. Other definitions include variables such as duration of cry greater than 3 hours a day occurring more than 3 days per week and for more than 3 weeks and parental dissatisfaction with the child's behavior. Some studies report an increase in symptoms (fussiness and crying) in the late afternoon or evening (Morin, 2009b); however, in some infants, the onset of symptoms occurs at another time. Colic is more

common in infants younger than 3 months than in older infants, and infants with difficult temperaments are more likely to be colicky.

Despite the obvious behavioral indications of pain, the infant with colic gains weight and usually thrives. There is no evidence of a residual effect of colic on older children except perhaps a strained parent-child relationship in some cases. In other words, infants who are colicky grow up to be normal children and adults. Colic is self-limiting and in most cases resolves as infants mature, generally around 12 to 16 weeks of age (Lobo, Kotzer, Keefe, et al., 2004; O'Connor, 2009).

Among the theories investigated as potential causes are too rapid feeding, overeating, swallowing excessive air, improper feeding technique (especially in positioning and burping), and emotional stress or tension between the parent and child. Although all of these may occur, there is no evidence that one factor is consistently present. Infants with cow's milk allergy (CMA) symptoms have a high rate of colic (44%), and eliminating cow's milk products from the infant's diet can reduce the symptoms. However, there is considerable controversy about the role of allergy and colic because there does not appear to be an increased incidence of atopy in infants with colic (Sicherer, 2003).

Keefe, Lobo, Froese-Fretz, et al. (2006) propose that colic has origins in the infant's inability to self-regulate the sleep-wake cycles based on central nervous system (CNS) immaturity rather than gastrointestinal (GI) system dysfunction. These researchers implemented a home-based intervention program aimed at promoting infant state regulation (sleep-wake cycles), promoting synchrony between parent and child, providing parental support, and decreasing infant irritability. The results of the study found that infants in the treatment group cried 1.7 hours less per day than infants in the control group. In addition, families in both the treatment and control group reported benefitting from a nurse visiting in the home and listening to parents' concerns about the infant's and the family's well-being.

Parental smoking, strained parent-infant interaction, lactase deficiency, difficult infant temperament, difficulty regulating emotions, overstimulation, CNS immaturity, and neurochemical dysregulation in the brain have also been proposed as potential causes of colic (Ellett, 2003; Neu and Robinson, 2003). A positive association between consumption of fruit juices (carbohydrate malabsorption) and colic has been demonstrated in some cases (Duro, Rising, Cedillo, et al., 2002). Some experts have suggested that gastroesophageal reflux is a cause of colic, but studies have not supported this theory (St. James-Roberts, 2008). The consensus of many experts who study colic is that it is multifactorial and that no single treatment for every colicky infant will be effective in alleviating the symptoms. Some researchers have found an association between colic in infancy and later childhood physical conditions such as abdominal pain and allergic disorders; however, causality was not confirmed in this group of children (Savino, Castagno, Bretto, et al., 2005).

Therapeutic Management

Management of colic should begin with an investigation of possible organic causes, such as CMA, intussusception, or other GI problem. If a sensitivity to cow's milk is strongly suspected, a trial substitution of another formula such as an extensively hydrolyzed (Nutramigen, Alimentum, Pregestimil), whey hydrolysate, or amino acid (Neocate, EleCare) formula is warranted. Soy formulas are usually avoided because of the possibility of sensitivity to soy protein as well (AAP, 2009). Oral administration of *Lactobacillus reuteri* to colicky exclusively breastfed infants decreased crying symptoms to less than 3 hours per day within 21 days of initiation in a randomized, double-blind, placebo-controlled trial of 50 colicky infants (Savino, Cordisco, Tarasco, et al., 2010). Savino, Palumeri, Castagno, et al. (2006) found that infants fed a partially hydrolyzed whey protein formula supplemented with oligosaccharides had decreased crying time after 7 days when compared with infants fed a standard formula and simethicone.

When no specific inciting agent can be found, the supportive measures discussed under Care Management are used.

The use of drugs, including sedatives, antispasmodics, antihistamines, and antiflatulents, is sometimes recommended. The most commonly used sedatives are phenobarbital, hydroxyzine hydrochloride (Atarax), and chloral hydrate. Simethicone (Mylicon) may also help allay the symptoms of colic. However, in most controlled studies, none of these drugs completely reduced the symptoms of colic. Behavioral interventions have not proved effective at reducing the symptoms of colic but have helped parents deal with their crying infants in a more positive manner. The addition of lactase to infant formula has produced mixed results as far as abatement of overall symptoms.

An extensive review of a wide variety of interventions for colic indicates no specific safe remedies are available to alleviate symptoms of colic in every infant. Dietary changes, such as eliminating cow's milk protein from the lactating mother's diet, and behavioral interventions were shown to be effective in helping parents reduce stimulation and respond to the infant's crying, yet these interventions are perceived only as moderately effective (Joanna Briggs Institute, 2008). Administering sucrose was effective at reducing crying in colicky infants for a short period (3-30 minutes) (Joanna Briggs Institute, 2008). A recent position statement by the Canadian Paediatric Society, Nutrition and Gastroenterology Committee (Critch, 2011) concluded that dietary modifications are beneficial in some cases but not all; the use of lactate, probiotics, prebiotics, or soy formula independently to decrease symptoms of colic had insufficient evidence to support their use. The use of complementary medicines for infantile colic, namely fennel extract, herbal tea, and sugar solutions, reportedly lack sufficient evidence to recommend their use (Perry, Hunt, and Ernst, 2011).

Another study found that a combination of interventions—massage, herbal tea, sucrose solution, and hydrolyzed formula—decreased crying in reported colicky infants; the administration of the hydrolyzed formula achieved best results, whereas massage was least effective at reducing crying (Arikan, Alp, Gozum, et al., 2008).

CARE MANAGEMENT

The initial step in managing colic is to take a thorough, detailed history of the usual daily events. Areas that should be stressed include (1) the infant's diet; (2) the diet of the breastfeeding mother; (3) the time of day when crying occurs; (4) the relationship of crying to feeding time; (5) the presence of specific family members during crying and habits of family members, such as smoking; (6) activity of the mother or usual caregiver before, during, and after crying; (7) characteristics of the cry (duration, intensity); (8) measures used to relieve crying and their effectiveness; and (9) the infant's stooling, voiding, and sleeping patterns. Of special emphasis is a careful assessment of the feeding process via demonstration by the parent.

If cow's milk sensitivity is suspected, breastfeeding mothers should follow a milk-free diet for a minimum of 3 to 5 days in an attempt to reduce the infant's symptoms. Caution mothers that some nondairy creamers may contain calcium caseinate, a cow's

FIG 31-14 The "colic carry" may be comforting to an infant with colic. (Photo by Paul Vincent Kuntz, Texas Children's Hospital, Houston, TX.)

milk protein. If a milk-free diet is helpful, lactating mothers may need calcium supplements to meet the body's requirement. Bottle-fed infants may improve with the same dietary modifications as for infants with CMA. Additional approaches for managing colic are listed in the Patient Teaching box (see also Fig. 31-14).

One important nursing intervention (before or after an organic cause has been eliminated) is reassuring both parents that they are not doing anything wrong and that the infant is not experiencing any physical or emotional harm. Parents, especially mothers, become easily frustrated with their infant's crying and perceive this as a sign that something is horribly wrong. In addition, colicky infants may be at increased risk for being shaken or otherwise abused by their caregivers and experiencing traumatic brain injury. A survey of fathers of colicky infants revealed that professional assistance was limited. The fathers described the experience of having a colicky infant as similar to falling into an abyss from which they had to climb with the assistance of family and friends, thus reinforcing the importance of empathetic nurses (Ellett, Appleton, and Sloan, 2009). An empathetic, gentle, and reassuring attitude, in addition to suggestions for treatment, will help allay parents' anxieties, which are usually exacerbated by loss of sleep and preoccupation over the infant's welfare. Colic disappears spontaneously, usually by 3 to 4 months of age, although guarantees should never be given since it may continue for much longer. Other support persons and extended family members may be enlisted to support the parents during this difficult time.

Failure to Thrive (Growth Failure)

Failure to thrive (FTT), or growth failure, is a sign of inadequate growth resulting from an inability to obtain or use calories required for growth. FTT has no universal definition, although one of the more common criteria is a weight (and sometimes height) that falls below the 5th percentile for the child's age. Another definition of FTT includes a weight for age (height) *z* value of less than −2.0 (a *z* value is a standard deviation value that represents anthropometric data normalizing for sex and age with greater precision than growth percentile curves [Markowitz, Watkins, and Duggan, 2008]). A third way to define FTT is a weight curve that crosses more than 2 percentile lines on a standardized growth chart after previous achievement of a stable growth pattern. Weight for length is reported to be a better indicator of acute undernutrition (Cole and Lanham, 2011). Growth measurements alone are not used to diagnose children with FTT. Rather, the finding of a pattern of persistent deviation from established growth parameters is cause for concern. In addition to lack of consensus on the precise definition of FTT, some advocate for a change in terminology; thus terms such as *growth failure, growth faltering,* and *pediatric undernutrition* are used in the literature for FTT (Locklin, 2005). The term *FTT* will be used in the following discussion. According to Cole and Lanham (2011), approximately 5% to 10% of children in primary care in the United States have FTT, with the majority presenting before the age of 18 months.

Some experts suggest that the previously used classifications of *organic FTT* and *nonorganic FTT* are too simplistic because most cases of growth failure have mixed causes; they suggest that FTT be classified according to pathophysiology in the categories in Box 31-2.

The cause of FTT is often multifactorial and involves a combination of infant organic disease, dysfunctional parenting behaviors, subtle neurologic or behavioral problems, and disturbed parent-child interactions (Block, Krebs, and AAP Committee on Child Abuse and Neglect and Committee on Nutrition, 2005). However, the primary etiology is inadequate caloric intake, regardless of the cause.

PATIENT TEACHING

Managing the Colicky Infant

- Place infant prone over a covered hot-water bottle, heated towel, or covered heating pad.
- Massage infant's abdomen.
- Respond immediately to the crying.
- Change infant's position frequently; walk with child's face down and with body across parent's arm, with parent's hand under infant's abdomen, applying gentle pressure.
- Use a front carrier for transporting infant.
- Swaddle infant tightly with a soft, stretchy blanket.
- Place infant in an electric (or wind-up) infant swing for short periods.
- Take infant for car rides or outside for a change in environment.
- Use bottles that minimize air swallowing (curved bottle or inner collapsible bag).
- Use a commercial device in the crib that stimulates the vibration and sound of a car ride or plays soothing "noise," in utero sounds, or music.
- Provide smaller, frequent feedings; burp infant during and after feedings using the shoulder position or sitting upright, and place infant in an upright seat after feedings.
- Introduce a pacifier for added sucking.
- In breastfed infants, mother should avoid all milk products for a trial period.
- If household members smoke, avoid smoking near infant; preferably confine smoking activity to outside of home.
- Give appropriate dose of acetaminophen elixir or suppository if suggested by health care professional; not recommended for daily use.
- If nothing reduces the crying, place infant in crib and allow to cry; periodically hold and comfort child and put down again.
- Maintain a brief diary of the time of day the crying starts; events going on in household; time, amount, and type of last feeding; length of crying; and characteristics of cry. Although this will not stop the crying, it may help the practitioner identify a possible cause.

BOX 31-2 PATHOPHYSIOLOGIC CAUSES OF FAILURE TO THRIVE

- **Inadequate caloric intake**—Incorrect formula preparation, neglect, food fads, excessive juice consumption, poverty, breastfeeding problems, behavioral problems affecting eating, or central nervous system problems affecting intake
- **Inadequate absorption**—Cystic fibrosis, celiac disease, vitamin or mineral deficiencies, HIV infection, biliary atresia, or hepatic disease
- **Increased metabolism**—Hyperthyroidism, congenital heart disease, or chronic immunodeficiency
- **Defective utilization**—Genetic anomaly such as trisomy 21 or 18, chronic infection, or metabolic storage diseases

Adapted from Krugman SD, Dubowitz H: Failure to thrive, *Am Fam Physician* 68(5):879–886, 2003.

Infants who are born preterm and with very low birth weight (VLBW) or extremely low birth weight (ELBW), as well as those with intrauterine growth restriction (IUGR), are often referred for FTT within the first 2 years of life because they typically do not grow physically at the same rate as term cohorts even after discharge from the acute care facility. Catch-up growth has been shown to be much more difficult to achieve in ELBW and VLBW infants. As children, former VLBW and ELBW infants are more likely to have small stature and demonstrate lower cognitive and academic achievement scores than term cohorts (Casey, Whiteside-Mansell, Barrett, et al., 2006). Children with congenital heart disease are also more likely to develop FTT in infancy as a result of inadequate caloric intake, malabsorption, increased energy expenditure that superseded caloric intake, and pulmonary hypertension (Cook and Higgins, 2010).

Other factors that can lead to inadequate caloric intake in infancy include poverty, health or childrearing beliefs such as fad diets, child neglect, inadequate nutritional knowledge, family stress, feeding resistance, and insufficient breast milk intake. In infants younger than 8 weeks, breastfeeding problems as a result of inadequate latch or uncoordinated sucking and swallowing may occur (Cole and Lanham, 2011). One account reports a 6-month-old term infant with FTT as a result of severe ankyloglossia (tongue tie) (Forlenza, Paradise Black, McNamara, et al., 2010).

Diagnostic Evaluation

Diagnosis is initially made from evidence of FTT. If FTT is recent, the weight but not the height is below accepted standards (usually the 5th percentile); if FTT is longstanding, both weight and height are low, indicating chronic malnutrition. The use of weight velocities (according to the World Health Organization growth charts at http://www.who.int/childgrowth/standards/en/ may be a better indicator of short-term growth failure while considering age-dependent changes in growth (Cole and Lanham, 2011). Perhaps as important as anthropometric measurements are a complete health and dietary history (including perinatal history), physical examination for evidence of organic causes, developmental assessment, and family assessment. A dietary intake history, either a 24-hour food intake or a history of food consumed over a 3- to 5-day period, is also essential. In addition, explore the child's activity level, parental height, perceived food allergies, and dietary restrictions. An assessment of household organization and mealtime behaviors and rituals is important in the collection of pertinent data. It is often helpful to obtain the growth patterns of the affected child's parents and siblings; these can be compared with norm-referenced standards to evaluate the child's growth (Markowitz, Watkins, and Duggan, 2008). An assessment of the home environment and child-parent interaction may be helpful as well. Other tests (lead toxicity, anemia, stool-reducing substances, occult blood, ova and parasites, alkaline phosphatase, and zinc levels) are selected only as indicated to rule out organic problems. In most cases, laboratory studies are of little diagnostic value (AAP, 2009; Cole and Lanham, 2011). To prevent the overuse of diagnostic procedures, consider FTT early in the differential diagnosis. To avoid the social stigma of FTT during the early investigative phase, some health care workers use the term *growth delay* (or *failure*) until the actual cause is established.

Therapeutic Management

The primary management of FTT is aimed at reversing the cause of the growth failure. If malnutrition is severe, the initial treatment is directed at reversing the malnutrition while avoiding the refeeding syndrome. The goal is to provide sufficient calories to support "catch-up" growth—a rate of growth greater than the expected rate for age.

In addition to adding caloric density to feedings, the child may require multivitamin supplements and dietary supplementation with high-calorie foods and drinks. Any coexisting medical problems are treated.

In most cases of FTT, an interdisciplinary team of physician, nurse, dietitian, child life specialist, occupational therapist, pediatric feeding specialist, and social worker or mental health professional is needed to deal with the multiple problems. Make efforts to relieve any additional stresses on the family by offering referrals to welfare agencies or supplemental food programs. In some cases, family therapy may be required. Temporary placement in a foster home may relieve the family's stress, protect the child, and allow the child some stability if insurmountable obstacles are preventing appropriate family function. Behavior modification aimed at mealtime rituals (or lack thereof) and family social time may be required. Hospitalization admission is indicated for (1) evidence (anthropometric) of severe acute malnutrition, (2) child abuse or neglect, (3) significant dehydration, (4) caregiver substance abuse or psychosis, (5) outpatient management that does not result in weight gain, and (6) serious intercurrent infection (AAP, 2009; Block, Krebs, and AAP Committee on Child Abuse and Neglect and Committee on Nutrition, 2005).

Prognosis. The prognosis for children with FTT is related to the cause. If the parents have simply not understood the infant's needs, teaching may remedy the child's limited caloric intake and permanently reverse the growth failure. Inadequate or infrequent feeding periods by the infant's primary caregiver, in conjunction with family disorganization, are often observed to be the cause of FTT.

Few long-term studies provide data on the prognosis for children with FTT; however, some studies indicate that children who had FTT as infants had shorter heights, lower weights, and lower scores on measures of psychomotor development than peers (Black, Dubowitz, Krishnakumar, et al., 2007; Rudolf and Logan, 2005). Low-birth-weight preterm infants are also at high risk for faltering growth and cognitive delays as a result of poor growth (Cole and Lanham, 2011). Factors related to poor prognosis are severe feeding resistance, lack of awareness in and cooperation from the parent(s), low family income, low maternal educational level, adolescent mother, preterm birth, IUGR, and early age of onset of FTT. Because later cognitive and motor function are affected by malnourishment

BOX 31-3 CLINICAL MANIFESTATIONS OF FAILURE TO THRIVE

- Growth failure (see p. 907 for definitions)
- Developmental delays—social, motor, adaptive, language
- Undernutrition
- Apathy
- Withdrawn behavior
- Feeding or eating disorders, such as vomiting, feeding resistance, anorexia, pica, rumination
- No fear of strangers (at age when stranger anxiety is normal)
- Avoidance of eye contact
- Wide-eyed gaze and continual scan of the environment ("radar gaze")
- Stiff and unyielding or flaccid and unresponsive
- Minimal smiling

in infancy, many of these children are below normal in intellectual development, have poorer language development and less well-developed reading skills, attain lower social maturity, and have a higher incidence of behavioral disturbances (Markowitz, Watkins, and Duggan, 2008). Such findings indicate that a long-term plan and follow-up care are needed for the optimal development of these children.

CARE MANAGEMENT

Nurses play a critical role as part of the interdisciplinary team in the diagnosis of FTT through their assessment of the child, parents, and family interactions. Knowledge of the characteristics of children with FTT and their families is essential in helping identify these children and hastening the confirmation of a diagnosis (Box 31-3). Accurate assessment of initial weight and height and daily weight, as well as recording of all food intake, is imperative. The nurse documents the child's feeding behavior and the parent-child interaction during feeding, other caregiving activities, and play.

Besides showing signs of malnutrition and delayed social development, children with FTT may exhibit altered behavioral interactions. They may display intense interest in inanimate objects, such as toys, but much less interest in social interactions. They are often watchful of people at a distance but become increasingly distressed as others come closer. They may dislike being touched or held and avoid face-to-face contact. However, when held, they protest briefly on being put down and are apathetic when left alone.

Children with FTT may have a history of difficult feeding, vomiting, sleep disturbance, and excessive irritability. Patterns such as crying during feedings; vomiting; hoarding food in the mouth; ruminating after feeding; refusing to switch from liquids to solids; and displaying aversion behavior, such as turning from food or spitting food, become attention-seeking mechanisms to prolong the attention received at mealtime. In some cases, the child may use feeding as a control mechanism in a poorly organized or chaotic family situation; parents may allow the child to dictate the norms for behavior and feeding because of inexperience with parenting or poor parenting role models. Thus refusing to eat or eating only sweets and snacks with nonnutritive value may be the child's norm based on food availability and family tradition. In such cases, family therapy is essential to reverse the trend and assist the parents and child in understanding each others' roles.

Some parents are at increased risk for attachment problems because of (1) isolation and social crisis; (2) inadequate support systems, such as teenage and single mothers; and (3) poor parenting role models as a child. Other factors that should be considered are lack of education; physical and mental health problems such as physical and sexual abuse, depression, or drug dependence; immaturity, especially in adolescent parents; and lack of commitment to parenting, such as giving priority to entertainment or employment. Often these parents and their families are under stress and in multiple chronic emotional, social, and financial crises.

FIG 31-15 Consistent nursing contact is important in developing trust in infants with failure to thrive.

Because part of the difficulty between parent and child is dissatisfaction and frustration, the child should have a primary core of nurses (Fig. 31-15). The nurses caring for the child can learn to perceive the child's cues and reverse the cycle of dissatisfaction, especially in the area of feeding.

Because many of these children are responding to stimuli that have led to the negative feeding patterns, an important primary intervention is to structure the feeding environment to encourage healthful eating. Initially, staff members and a feeding specialist may need to feed these children to thoroughly assess the difficulties encountered during the feeding process and to devise strategies that eliminate or minimize such problems. General guidelines for the feeding process are outlined in the Guidelines box.

Four primary goals in the nutritional management of children with FTT are to (1) correct nutritional deficiencies and achieve ideal weight for height, (2) provided adequate calories for catch-up growth, (3) restore optimal body composition, and (4) educate the parents or primary caregivers regarding the child's nutritional requirements and appropriate feeding methods (Corrales and Utter, 2005; Maggioni and Lifshitz, 1995). For infants, 24 kcal/oz formulas may be provided to increase caloric intake; older children (1 to 6 years) may benefit from a 30-kcal/oz formula (AAP, 2009). Other carbohydrate additives include fortified rice cereal and vegetable oil. Because vitamin and mineral deficiencies may occur, multivitamin supplementation, including zinc and iron, is recommended. For toddlers, a high-calorie milk drink such as PediaSure may be used to increase caloric intake. Carefully monitor for signs of intolerance to the formula.

Because maladaptive feeding practices often contribute to growth failure, give parents specific step-by-step directions for formula preparation, as well as a written schedule of feeding times. Restrict

GUIDELINES

Feeding the Child with Failure to Thrive

Provide a primary core of staff to feed the child. The same nurses are able to learn the child's cues and respond consistently.

Provide a quiet, unstimulating atmosphere. A number of children with failure to thrive (FTT) are very distractible and their attention is diverted with minimal stimuli. Older children do well at a feeding table; bottle-fed infants and children should always be held.

Maintain a calm, even temperament throughout the meal. Negative outbursts may be commonplace in this child's habit formation. Limits on eating behavior definitely need to be provided, but they should be stated in a firm, calm tone. If the nurse is hurried or anxious, the feeding process will not be optimized.

Talk to the child by giving directions about eating. "Take a bite, Lisa" is appropriate and directive. The more distractible the child, the more directive the nurse should be to refocus attention on feeding. Positive comments about feeding are actively given.

Be persistent. This is perhaps one of the most important guidelines. Parents often give up when the child begins negative feeding behavior. Calm perseverance through 10 to 15 minutes of food refusal will eventually diminish negative behavior. Although forced feeding is avoided, "strictly encouraged" feeding is essential.

Maintain a face-to-face posture with the child when possible. Encourage eye contact and remain with the child throughout the meal.

Introduce new foods slowly. Often these children have been exclusively bottle-fed. If acceptance of solids is a problem, begin with pureed food and, after it is accepted, advance to junior and regular solid foods.

Follow the child's rhythm of feeding. The child will set a rhythm when the previous conditions are met.

Develop a structured routine. Disruption in other activities of daily living has great impact on feeding responses, so bathing, sleeping, dressing, playing, and feeding are structured. The nurse should feed the child in the same way and place as often as possible. The length of the feeding should also be established (usually 30 minutes).

juice intake in children with FTT until adequate weight gain has been achieved with appropriate milk sources; thereafter give no more than 4 oz/day of juice.

Behavior modification techniques may be used with older infants and toddlers to interrupt poor feeding patterns. Feeding times may actually involve "struggles of will" in cases of maladaptive feedings that result in FTT. These behaviors are different from the occasional toddler behavior of food refusal, which is primarily developmental, not pathologic. The association of appropriate food with good or bad behaviors and consequent rewards may be part of the complex problem. In severe cases of malnourishment, tube feedings or intravenous therapy may be required.

In addition to attending to the child's physical needs, the interdisciplinary team must plan care for appropriate developmental stimulation. After an approximate developmental age is established, a planned program of play is begun. Ideally, a child life specialist is involved to implement and supervise the stimulation program. Every effort is made to teach the parent how to play and interact with the child.

Nursing care of children with FTT involves a "family systems" approach. In other words, for the entire family to become healthy, each member must be helped to change. Care of the parents is aimed at helping them improve their self-esteem by acquiring positive, successful parenting skills. Initially, this necessitates providing an environment in which they feel welcomed and accepted. Depending on the cause of FTT, many children are treated on an outpatient basis.

Sudden Infant Death Syndrome

Sudden infant death syndrome (SIDS) is defined as the sudden death of an infant younger than 1 year that remains unexplained after a complete postmortem examination, including an investigation of the death scene and a review of the case history. Since 1992, the incidence of SIDS in the United States has decreased by 53% to an all-time low of 0.57 per 1000 live births in 2002 (AAP Task Force on Sudden Infant Death Syndrome, 2005). The dramatic decrease is attributed to the Back to Sleep campaign.* SIDS is the third leading cause of infant deaths (birth to 12 months) and the leading cause of postneonatal deaths (between 1 and 12 months). SIDS claimed the lives of 2145 infants in the United States in 2006; preliminary data from 2011 indicate there were 1711 deaths from SIDS (Hoyert and Xu, 2012). For the years 2010 to 2011 infant mortality rates decreased by 16.1% for SIDS, whereas other causes of infant mortality remained static (Hoyert and Xu, 2012). Despite dramatic decreases in SIDS rates, rates for African-American, Native-American, and American-Alaskan infants remains disproportionately higher than for the rest of the population. In 2007, SIDS rates were 2.4 times higher for Native-American mothers and 1.9 times higher for African-American mothers compared with non-Hispanic Caucasian mothers (Mathews and MacDorman, 2011; Mathews and MacDorman, 2012). It is also important to note that overall infant death rates for 2006 and 2007 were significantly higher for African-American infants (13.59 per 1000 live births) than for Hispanic (5.59 per 1000 live births) and Caucasian (5.70 per 1000 live births) infants. Likewise, the percentage of infants born preterm (<37 weeks) was significantly higher (18.5%) in African-American women than Caucasian women (11.7%) (MacDorman and Mathews, 2011). Preterm births rank second as cause of infant death; this trend has been constant since the mid-1990s when the rates of SIDS deaths significantly decreased in the United States.

The SIDS rate remained fairly static between 1999 and 2001. This has been attributed to improved death scene investigation and determination of non-SIDS causes of postneonatal mortality. In addition, there is speculation that deaths attributed to SIDS during the period of 1992 to 2001 may have been a result of other causes (AAP Task Force on Sudden Infant Death Syndrome, 2005). Table 31-3 summarizes the major epidemiologic characteristics of SIDS.

There has been considerable debate over the term *SIDS,* yet the definition noted above remains for the time being. Other terms have been developed to explain sudden deaths in infants. *Sudden unexpected early neonatal death* (SUEND) and *sudden unexpected infant death* (SUID) share similar features but differ in regard to the timing of death: whereas SUID is considered a death in the postneonatal period, SUEND occurs in the first week of life. The AAP Task Force on Sudden Infant Death Syndrome (2011) policy statement considers SIDS to be a component of SUID.

Etiology

There are numerous theories regarding the etiology of SIDS; however, the cause remains unknown. One hypothesis is that SIDS is related to a brainstem abnormality in the neurologic regulation

TABLE 31-3 EPIDEMIOLOGY OF SUDDEN INFANT DEATH SYNDROME

FACTOR	OCCURRENCE
Incidence	55.4 per 100,000 live births (2008)*
Peak age	2–3 mo; 95% occur by 6 mo; preterm infants die from sudden infant death syndrome (SIDS) at mean age of 6 wk later than mean age of death from SIDS for term infants
Sex	Higher percentage of boys affected
Time of death	During sleep
Time of year	Increased incidence in winter
Racial	Greater incidence in African Americans and Native Americans. (See Sudden Infant Death Syndrome, p. 910.)
Socioeconomic	Increased occurrence in lower socioeconomic class
Birth	Higher incidence in: • Preterm infants, especially infants of extremely and very low birth weight • Multiple births† • Neonates with low Apgar scores • Infants with central nervous system disturbances and respiratory disorders such as bronchopulmonary dysplasia • Increasing birth order (subsequent siblings as opposed to firstborn child)
Health status	Infants with a recent history of illness; lower incidence in immunized infants
Sleep habits	Highest risk associated with prone position; use of soft bedding; overheating (thermal stress); cosleeping with adult, especially on sofa or noninfant bed; higher incidence in cosleeping with adult smoker Infants cosleeping with adult at higher risk if younger than 11 weeks
Feeding habits	Lower incidence in breastfed infants
Pacifier	Lower incidence in infants put to sleep with pacifier
Siblings	May have greater incidence in siblings of SIDS victims
Maternal	Young age; cigarette smoking, especially during pregnancy; poor prenatal care; substance abuse (heroin, methadone, cocaine). A few studies have shown an increased risk in infants exposed to second-hand environmental tobacco smoke.

†Although a rare event, simultaneous death of twins from SIDS can occur.

of cardiorespiratory control. This maldevelopment affects arousal and physiologic responses to a life-threatening challenge during sleep (AAP Task Force on Sudden Infant Death Syndrome, 2005). Abnormalities include prolonged sleep apnea, increased frequency of brief inspiratory pauses, excessive periodic breathing, and impaired arousal responsiveness to increased carbon dioxide or decreased oxygen. However, *sleep apnea is not the cause of SIDS.* The vast majority of infants with apnea do not die, and only a minority of SIDS victims have documented apparent life-threatening events (ALTEs) (see Apparent Life-Threatening Event, p. 915). Numerous studies indicate that no association exists between SIDS and any childhood vaccine.

A genetic predisposition to SIDS has been postulated as a cause. In one study, a genetic mutation on chromosome 6q 22.1-22.31 was positively linked to a syndrome of SIDS and dysgenesis of the testis (Puffenberger, Hu-Lince, Parod, et al., 2004). Three triple-risk hypotheses have been proposed to explain the etiology of SIDS. Proposed factors include an underlying infant vulnerability factor (e.g., brain abnormality), a critical incident in the fetal developmental period or in early neonatal life, and an environmental stressor such as prone sleep positioning (Filiano and Kinney, 1994; Guntheroth and Spiers, 2002; Matthews and Moore, 2013). However, the triple-risk theories have not been fully accepted by all experts as a cause for SIDS, and further data are needed to identify a single cause or combination of causes for SIDS deaths (Guntheroth and Spiers, 2002).

Risk Factors for SIDS

Maternal smoking during pregnancy has emerged in numerous epidemiologic studies as a major factor in SIDS, and tobacco smoke in the infant's environment after birth has also been shown to have a possible relationship to the incidence of SIDS (AAP Task Force on Sudden Infant Death Syndrome, 2005, 2011). Data show that exposure to tobacco smoke increased an infant's risk for SIDS 1.9 times over infants not exposed; 59% of SIDS deaths in smoke-exposed infants were attributed to maternal smoking (Anderson, Johnson, and Batal, 2005). It has been postulated that 12% of all SIDS deaths could be prevented with prenatal maternal smoking cessation (Pollack, 2001). Increased nicotine concentrations in lung tissue were found in children who died from SIDS compared with a group of control children (McMartin, Platt, Hackman, et al., 2002).

Cosleeping, or an infant sharing a bed with an adult or older child on a noninfant bed, has been reported to have a positive

association with SIDS. One survey found a high association between infant deaths, nonstandard beds (sofa, day bed), and bed sharing; a large percentage of infants were found dead on their backs when bed sharing, suggesting suffocation (Unger, Kemp, Wilkins, et al., 2003). A study from Scotland indicates that the risk for SIDS when bed sharing is significantly increased for infants younger than 11 weeks (Tappin, Ecob, and Brooke, 2005). Vennemann, Bajanowski, Brinkmann, et al. (2009) identified infant sleeping in the house of a friend or relative and sleeping in the family living room as significant risk factors for SIDS. Other studies correlated higher incidences of SIDS and infant cosleeping with maternal smoking, cosleeping with multiple family members, sleeping on a couch, use of a pillow in the infant's bed, maternal overweight, soft bedding, and unintentional asphyxiation resulting from adult intoxication (overlaying) (AAP Task Force on Infant Sleep Position and Sudden Infant Death Syndrome, 2000; AAP Task Force on Sudden Infant Death Syndrome, 2005, 2011; Blair, Sidebotham, Evason-Coombe, et al., 2009; Carroll-Pankhurst and Mortimer, 2001; Hauck, Herman, Donovan, et al., 2003; Li, Zhang, Zielke, et al., 2009; McGarvey, McDonnell, Chong, et al., 2003; Person, Lavezzi, and Wolf, 2002).

Studies from countries other than the United States link sleep habits with an increased risk for SIDS. Prone sleeping may cause oropharyngeal obstruction or affect thermal balance or arousal state. One study found that healthy full-term infants had significantly impaired arousal from active and quiet sleep states when sleeping prone (Horne, Ferens, Watts, et al., 2001). Rebreathing of carbon dioxide by infants in the prone position is also a possible cause of SIDS. Infants sleeping prone and on soft bedding may not be able to move their heads to the side, thus increasing the risk for suffocation and lethal rebreathing. Evidence from other countries and the United States shows an increased incidence of SIDS in infants placed in a side-lying position; thus *the side-lying position is no longer recommended* for infants sleeping at home, day care, or hospitals (unless medically indicated). Most preterm infants being discharged from the hospital should be placed in a supine sleeping position unless special factors predispose them to airway obstruction.

One postulated cause of SIDS has been a prolonged Q-T interval; however, there has been no strong evidence to support this as a cause of SIDS or universal testing of newborns for prolonged Q-T interval (AAP Task Force on Sudden Infant Death Syndrome, 2005).

Soft bedding such as waterbeds, sheepskins, beanbags, pillows, and quilts should be avoided for infant sleeping surfaces. Bedding items such as stuffed animals and toys should be removed from the crib while the infant is asleep. Head covering by a blanket has also been found to be a risk factor for SIDS, thus supporting the recommendation to avoid extra bed linens and other items (Mitchell, Thompson, Becroft, et al., 2008). Crib bumper pads have not been shown to reduce infant injury and should therefore be avoided (AAP Task Force on Sudden Infant Death Syndrome, 2011).

In a recent retrospective study of SIDS deaths, Ostfield, Esposito, Perl, et al. (2010) found that at least one modifiable risk factor such as those previously listed was present in 96% of the deaths; a total of 78% of the deaths had anywhere from two to seven risk factors.

Protective Factors for SIDS

One study indicated that breastfeeding during the first 16 weeks of life decreased the likelihood of SIDS (Alm, Wennergren, Norvenius, et al., 2002). A subsequent meta-analysis confirmed that exclusive breastfeeding for any period of time decreased the overall risk for SIDS (Hauck, Thompson, Tanabe, et al., 2011). Some studies have found pacifier use in infants to be a protective factor against the occurrence of SIDS; the data for pacifier use in infants in the first year of life are said to be more compelling than data linking pacifier use to the development of dental complications and the inhibition of breastfeeding (AAP Task Force on Sudden Infant Death Syndrome, 2005, 2011). Therefore the AAP recommends using a pacifier at naptime and bedtime, using a pacifier only if the infant is breastfeeding successfully, not using a sweetened coating on the pacifier, and avoiding forcing the infant to use the pacifier.

The AAP Task Force on Sudden Infant Death Syndrome (2005, 2011) recommends that all infants be placed to sleep in the supine (on the back) position. The AAP Task Force on Sudden Infant Death Syndrome (2011) emphasizes that medically stable preterm infants and infants diagnosed with gastroesophageal reflux (GER) be placed in a supine sleep position unless there is a specific upper airway disorder wherein the risk for death from the condition is greater than the risk for SIDS. The supine sleep position has not demonstrated an increased risk for choking and aspiration in infants, including those with GER (AAP Task Force on Sudden Infant Death Syndrome, 2011).

Since the Back to Sleep campaign in 1992 advocating nonprone sleeping for infants, an increased incidence of positional plagiocephaly has been observed (see p. 914). It is recommended that an infant's head position be alternated during sleep time to prevent plagiocephaly. Infants may be placed prone during awake periods to prevent positional plagiocephaly and to encourage development of upper shoulder girdle strength (AAP Task Force on Sudden Infant Death Syndrome, 2005, 2011). Updated childhood immunization status has also been shown to be protective against SIDS.

Although the cause of SIDS is unknown, autopsies reveal consistent pathologic findings, such as pulmonary edema and intrathoracic hemorrhages, that confirm the diagnosis. Consequently, autopsies should be performed on all infants suspected of dying of SIDS, and findings should be shared with the parents as soon as possible after the death. Postmortem findings in SIDS and accidental suffocation or intentional suffocation such as in Munchausen syndrome by proxy (see Child Maltreatment, Chapter 33) are practically the same. Individuals with less experience and training in performing autopsies, such as coroners instead of medical examiners, may not correctly identify some deaths as SIDS. Therefore mortality statistics can vary in different regions.

Infant Risk Factors

Certain groups of infants are at increased risk for SIDS:

- Low birth weight
- Low Apgar scores
- Recent viral illness
- Siblings of two or more SIDS victims
- Male sex
- Infants of Native-American or African-American ethnicity

No diagnostic tests exist to predict which infants, including those in the above groups, will survive, and home apnea monitoring is no guarantee of survival. Whether subsequent siblings of one SIDS infant are at increased risk for SIDS is unclear. Even if the risk is increased, families have a 99% chance that their subsequent child will *not* die of SIDS. A review of sibling deaths attributed to SIDS in England failed to ascertain a precise risk for recurrence; previous studies suggested a recurrence risk range of 1.7 to 10.1, yet the researchers concluded the studies had too many methodologic flaws to draw any firm conclusions (Bacon, Hall, Stephenson, et al., 2008). Others report that recurrence risks for a SIDS death in a family with a previous infant SIDS death range from 2% to 6% (AAP Task Force

on Sudden Infant Death Syndrome, 2005). ***Home apnea monitoring is not recommended*** for this group of children, but it is often used by health care practitioners and may even be requested by parents (AAP Task Force on Sudden Infant Death Syndrome, 2005, 2011). There is no evidence that home apnea monitoring prevents SIDS (Strehle, Gray, Gopisetti, et al., 2012). Monitoring is best initiated on an individual basis.

CARE MANAGEMENT

Nurses have a vital role in preventing SIDS by educating families about the risk of prone sleeping position in infants from birth to 6 months of age, the use of appropriate bedding surfaces, the association with maternal smoking, and the dangers of cosleeping on noninfant surfaces with adults or other children. Also, nurses have an important role in modeling behaviors for parents to foster practices that decrease the risk for SIDS, including placing infants in a supine sleeping position in the hospital. Data indicate that a small percentage of nurses still place healthy infants in a side-lying position in the hospital (Bullock, Mickey, Green, et al., 2004; Thompson, 2005). Statistics for infants being placed in a prone sleeping position in the United States decreased from 70% in 1992 to 13% in 2004 (AAP Task Force on Sudden Infant Death Syndrome, 2005). One study of neonatal intensive care unit (NICU) nurses indicated that 52% routinely provided discharge instructions that promote supine sleep positions at home; common nonsupine positions recommended by the nurses included either supine or side or exclusive side-lying sleep position (Aris, Stevens, Lemura, et al., 2006). A survey of levels II and III NICU nurses found that nurses still positioned infants in a side-lying position for fear of aspiration (29%), for comfort reasons (28%), and for infant safety (20%) (Grazel, Phalen, and Palomano, 2010). Nurses ***must*** be proactive in further decreasing the incidence of SIDS; after-birth discharge planning, newborn discharges, follow-up home visits, well-baby clinic visits, and immunization visits provide excellent opportunities to educate parents in these matters.

Many health care workers are concerned that infants placed on the back to sleep will aspirate emesis or mucus, yet studies fail to show an increase in infant deaths, spitting up during sleep, aspiration, asphyxia, or respiratory failure as a result of supine sleep positioning (AAP Task Force on Sudden Infant Death Syndrome, 2011; Malloy, 2002; Tablizo, Jacinto, Parsley, et al., 2007).

Research findings have important implications for practices that may reduce the risk for SIDS, such as avoiding smoking during pregnancy and near the infant; using the supine sleeping position; avoiding soft, moldable mattresses, blankets, and pillows; avoiding bed sharing; breastfeeding; and avoiding overheating during sleep. Nurses must continue to take every opportunity to advocate for infants by providing information for parents and caregivers about the modifiable risk factors for SIDS that can be implemented to prevent its occurrence across all sectors of the population.

Loss of a child from SIDS presents several crises with which the parents must cope. In addition to grief and mourning the death of their child, the parents must face a tragedy that was sudden, unexpected, and unexplained. The psychologic intervention for the family must deal with these additional variables. This discussion focuses primarily on the objectives of care for families experiencing SIDS rather than on the process of grief and mourning, which is explored in Chapter 36.

Care of the Family of a SIDS Infant. The first persons to arrive at the scene may be the police and emergency medical service personnel. They should handle the situation by asking few questions; giving no indication of wrongdoing, abuse, or neglect; making sensitive judgments concerning any resuscitation efforts for the child; and comforting the family members as much as possible. A compassionate, sensitive approach to the family during the first few minutes can help spare them some of the overwhelming guilt and anguish that commonly follow this type of death.

The medical examiner or coroner may go to the home or place of death and make the death pronouncement; until then, the sleep environment should remain as it was when the infant was initially found (Koehler, 2008). If the infant is not pronounced dead at the scene, he or she may be transported to the emergency department to be pronounced by a physician. Usually there is no attempt at resuscitation in the emergency department. While they are in the emergency department, the parents should be asked only factual questions, such as when they found the infant, how he or she looked, and whom they called for help. The nurse should avoid any remarks that may suggest responsibility, such as "Why didn't you go in earlier?" "Didn't you hear the infant cry out?" "Was the head buried in a blanket?" or "Were the siblings jealous of this child?" It is the coroner's responsibility to document these findings at the scene rather than have parents recount the experience in the emergency department (Koehler, 2008). Parents may also express feelings of guilt about administering cardiopulmonary resuscitation (CPR) correctly or the timing of CPR in relation to finding the infant.

At this time, the physician should initiate the discussion of an autopsy, often with the nurse being present to support the family. The physician or medical examiner, depending on the circumstances, should emphasize that a diagnosis cannot be confirmed until the postmortem examination is completed. Nurses may balk at the idea of requesting an autopsy because of the parents' emotional state; however, an autopsy may clear up possible misconceptions regarding the death. Instructions about the autopsy and funeral arrangements may need to be repeated or put in writing. If the mother was breastfeeding, she needs information about abrupt discontinuation of lactation. The nurse or physician should contact the primary care practitioner for the infant and the mother to avoid any miscommunications or telephone calls at a later date inquiring about the child's health status.

A review of 60 studies shows that parents experiencing perinatal death perceive health care workers' responses as having a significant impact on the parents' grieving process; parents perceived the behavior of many health care workers as thoughtless or insensitive. The findings suggest that nurses and physicians would benefit from more bereavement training (Gold, 2007).

An important aspect of compassionate care for these parents is allowing them to say good-bye to their child. These are the parents' last moments with their child, and they should be as quiet, meaningful, peaceful, and undisturbed as possible. Encourage parents to hold their infant before leaving the emergency department. Because the parents leave the hospital without their infant, it is helpful to accompany them to the car or arrange for someone else to take them home. A debriefing session may help health care workers who dealt with the family and deceased infant to cope with emotions that are often engendered when a SIDS victim is brought into the acute care facility. Comprehensive guidelines have been published for health care professionals involved in SIDS investigations to assist the family and at the same time to determine that the infant's death was not the result of other factors such as child maltreatment (AAP Committee on Child Abuse and Neglect, 2001).

When the parents return home, a competent, qualified professional should visit them as soon after the death as possible. They

should receive printed material that contains excellent information about SIDS (available from the national organizations*).

During the initial visit, help the parents gain an intellectual understanding of the condition. The nursing objectives are to assess what the parents have been told about SIDS; what they think happened; and how they explained this to the other siblings, family members, and friends. One question that the nurse will never be able to answer and therefore should not attempt to is, "Why did this happen to our baby?" or "Who is responsible for this tragedy?" These and other questions may linger in the parents' minds for months or even years.

When the unexpected death of a child occurs, it is common for one parent to blame the other for the child's death. Parents may also experience guilt over the child's death; if they had checked earlier, the child might still be alive. It is important that the nurse assist parents in working through these feelings to prevent marital disruption in addition to the loss of the loved child.

Some parents are able to discuss their feelings openly, and the nurse should be supportive of this coping skill. However, others may be reluctant to express their grief, and the nurse can encourage the expression of emotions by asking about crying and feeling sad, angry, or guilty. This is an attempt to provoke a display of emotion, not just an admission of a feeling. During this session, help the parents explore their usual coping mechanisms and, if these are ineffectual, to investigate new approaches. For example, one parent may refrain from discussing the death for fear of upsetting the other parent, but each may need to hear how the other feels.

Ideally, the number of visits and plans for subsequent intervention need to be flexible. Parents facing the question of having a subsequent child will need support. Both the birth of a subsequent child and the survival of that child, especially past the age of death of the previous child, are important transitional stages for parents.

Positional Plagiocephaly

Since the Back to Sleep campaign began in 1992 advocating nonprone sleeping for infants to prevent sudden infant death syndrome (SIDS), an increase in the incidence of positional plagiocephaly has been observed (AAP Task Force on Sudden Infant Death Syndrome, 2005; Littlefield, Saba, and Kelly, 2004). The prevalence of positional plagiocephaly at 4 months is reported to range from slightly less than 20% to as much as 48% (Robinson and Proctor, 2009). The term *plagiocephaly* connotes an oblique or asymmetric head; *positional plagiocephaly, deformational plagiocephaly*, or *nonsynostotic plagiocephaly* implies an acquired condition that occurs as a result of cranial molding during infancy (Hummel and Fortado, 2005). Because infants' sutures are not closed, the skull is pliable and, when infants are placed on their backs to sleep, the posterior occiput flattens over time (Fig. 31-16, *A*). A typical bald spot develops, which is usually transient. As a result of prolonged pressure on one side of the skull, that side becomes misshapen; mild facial asymmetry may develop. The sternocleidomastoid muscle may tighten on the preferential side, and torticollis may also develop. Congenital or acquired torticollis may cause plagiocephaly; other causes of deformational plagiocephaly include certain craniofacial syndromes. This discussion centers only on positional plagiocephaly caused by supine sleeping position.

FIG 31-16 A, Plagiocephaly. **B,** Helmet used to correct plagiocephaly. (Courtesy Dr. Gerardo Cabrera-Meza, Department of Neonatology, Baylor College of Medicine, Houston, TX.)

Diagnostic Evaluation

The diagnosis of positional plagiocephaly may be made on physical examination of the infant's head; the infant's head is viewed frontally and from above. The typical infant's head shape will resemble a parallelogram, with unilateral flattening of the occiput, frontal and parietal bossing, a prominent cheekbone, and an anterior ear displacement. An evaluation of neck movement and range of motion is also made to determine the presence of torticollis. In most cases, skull films and further radiologic studies (computed tomographic scan) are used only to rule out craniosynostosis or other cranial deformity that may affect brain growth.

Therapeutic Management

Prevention of positional plagiocephaly may begin shortly after birth by placing the infant to sleep supine and alternating the infant's head position nightly, avoiding prolonged placement in car safety seats and swings, and using prone positioning or "tummy time" for

*American SIDS Institute, 528 Ravens Way, Naples, FL 34110, (239) 431-5425, www.sids.org; First Candle, 1314 Bedford Ave., Suite 210, Baltimore, MD 21208, (800) 221-7437, www.firstcandle.org; National Sudden and Unexpected Infant/Child Death and Pregnancy Loss Resource Center, Georgetown University, Box 571272, Washington, DC 20057-1272, (866) 866-7437, 202-687-7466, www.sidscenter.org.

approximately 30 to 60 minutes per day when the infant is awake (Laughlin, Luerssen, Dias, et al., 2011).

Treatment of torticollis and plagiocephaly initially involves exercises to loosen the tight muscle and switching head position sides during feeding, carrying, and sleep. If the plagiocephaly is not resolved within 4 to 8 weeks of physical therapy, a customized helmet may be worn to decrease the pressure on the affected side of the skull (Fig. 31-16, *B*). If no improvement occurs with physical therapy or a molded helmet over a period of 2 to 3 months, the infant may be referred to a pediatric neurosurgeon or craniofacial surgeon; the referral should optimally occur by 4 to 6 months of age (Laughlin, Luerssen, Dias, et al., 2011).

The helmet is worn 23 hours a day for a prescribed period (usually 3 months). Repositioning and physical therapy are said to be more effective when used before the infant can roll over or move his or her head alone (i.e., before approximately 3 to 4 months of age) (Robinson and Proctor, 2009). Reports of developmental delay in infants with positional plagiocephaly (nonsynostotic) vary in regard to outcomes, but current studies do not conclusively prove that such infants are at higher risk for developmental delays (Robinson and Proctor, 2009).

CARE MANAGEMENT

Minor skull flattening is not considered significant, but parents should learn to prevent plagiocephaly by altering the infant's head position during sleep. Infants should be placed prone on a firm surface during awake time (tummy time) for at least 15 to 20 minutes, which prevents plagiocephaly and facilitates development of upper shoulder girdle strength; the latter helps in the progressive development of movements such as rolling over and starting to rise up on all fours, which are precursors to crawling and eventually walking. A total of thirty to sixty minutes of supervised tummy time per day in infants younger than 6 months is recommended (Laughlin, Luerssen, Dias, et al., 2011; Robinson and Proctor, 2009).

Despite the perceived increase in the incidence of positional plagiocephaly, the supine sleeping position is still recommended because it has led to a significant decrease in loss of infant lives from SIDS (AAP Task Force on Sudden Infant Death Syndrome, 2011). Additional measures to prevent positional plagiocephaly include avoiding excessive time spent in car restraint seats, infant seats, and bouncers. Alternating the infant's head position for sleep times can also prevent unilateral molding. When a nurse or parent notices plagiocephaly, a consultation with the primary health care practitioner is recommended to evaluate the head shape and ascertain the need for early intervention.

Nurses are in a unique position in well-child care settings to encourage parents to follow guidelines for preventing plagiocephaly, demonstrate alternating head placement for sleeping, demonstrate sternocleidomastoid muscle exercises (as appropriate to the condition), and encourage tummy time for infants during awake periods. Most important, nurses should continue to encourage parents to place the infant in a supine sleep position despite the development of plagiocephaly. Nurses can also assist parents in the proper use of a skull-molding helmet and reassure them of the high rate of success with the helmet. Allowing parents to verbalize concerns and feelings related to the health status of the child as well as provision of current best practice is an important nursing function. Parents should not become so alarmed by plagiocephaly that they abandon supine sleeping position for the infant but should consult with the health care practitioner for further advice.

Apparent Life-Threatening Event

An apparent life-threatening event (ALTE), formerly referred to as *aborted SIDS death* or *near-miss SIDS,* generally refers to an event that is sudden and frightening to the observer in which the infant exhibits a combination of apnea, change in color (pallor, cyanosis, redness), change in muscle tone (usually hypotonia), and choking, gagging, or coughing and that usually involves a significant intervention and even CPR by the caregiver who witnesses the event (National Institutes of Health, 1987). The definition of *ALTE* may include apnea, but ALTE may occur without apnea (Silvestri, 2012; Silvestri and Weese-Mayer, 2003). It is erroneous to characterize ALTE as a near-miss SIDS incident (Adams, Good, and Defranco, 2009). Infants with ALTE are at increased risk for SIDS; the risk for SIDS may be 3 to 5 times greater in infants who experienced an ALTE (Hunt and Hauck, 2011).

Results from the Collaborative Home Infant Monitoring Evaluation (CHIME) study found that apnea and bradycardia occurred at conventional and extreme alarm thresholds in all groups of infants studied—siblings of SIDS infants, infants with ALTEs, symptomatic (of apnea and bradycardia) and asymptomatic preterm infants weighing less than 1750 g (3 lb 13 oz) at birth, and healthy term infants. Approximately 30% of infants with ALTE were born at less than 37 weeks of gestation. The researchers concluded that many infants experience apnea and bradycardia in each of these groups yet do not die (Jobe, 2001; Ramanathan, Corwin, Hunt, et al., 2001). Furthermore, it was reported that apnea does not appear to be an immediate precursor to SIDS and that cardiorespiratory monitoring is not an effective tool for identifying infants at greater risk for SIDS (AAP Committee on Fetus and Newborn, 2003). CHIME data indicate that infants with ALTE did not have some of the typical characteristics associated with SIDS infants; these include fewer infants with low birth weight and who are small for gestational age at birth, fewer teenage pregnancies, and a younger infant age at the time of ALTE. The researchers concluded that despite some similar characteristics between ALTE and SIDS, the differences warrant a separate focus on ALTE events (Esani, Hodgman, Ehsani, et al., 2008).

Diagnostic Evaluation

An essential component of the diagnostic process includes a detailed description of the event, including who witnessed the event; where the infant was during the event; and what, if any, activities were involved (e.g., during or after a feeding, riding in a car seat restraint, presence of siblings or any minor children, what clothing the infant was wearing). In addition, a prenatal and postnatal history must be obtained. A short period of observation in the emergency department may be appropriate to observe the infant's respiratory pattern and response to feeding. A careful evaluation of late preterm and preterm infants in the car restraints currently in use is essential; upper airway occlusion and subsequent apnea and cyanosis may occur if the infant is not positioned properly. Reported diagnoses in infants with ALTE include a neurologic event such as a seizure (30% of cases seen); GI problem, including gastroesophageal reflux (50%); respiratory conditions (20%); and metabolic conditions, cardiac anomaly, or child abuse (each <5%). In some cases, multiple diagnoses may be made (Hall and Zalman, 2005).

In the event that an underlying diagnosis such as those mentioned previously is not established, home monitoring may be recommended. The most commonly used monitoring is continuous recording of cardiorespiratory patterns (cardiopneumogram or pneumocardiogram). Four-channel pneumocardiograms (or multichannel pneumogram) monitor heart rate, respirations (chest impedance), nasal airflow, and oxygen saturation. A more sophisticated test, polysomnography (sleep study), also records brain waves,

eye and body movements, esophageal manometry, and end-tidal carbon dioxide measurements. However, none of these tests can predict risk. Some children with normal results may still have subsequent apneic episodes.

Therapeutic Management

The treatment of an infant with an ALTE depends on the underlying condition (see p. 915). Treatment of recurrent apnea (without an underlying organic problem) usually involves continuous home monitoring of cardiorespiratory rhythms and, in some cases, the use of methylxanthines (respiratory stimulant drugs, such as caffeine). The decision to discontinue the monitoring is based on the infant's clinical condition. A general guideline for discontinuation is when infants with ALTEs have gone 2 or 3 months without significant numbers of episodes requiring intervention. Silvestri (2012) notes that the challenge in treating an infant with an ALTE is to determine if the infant is at further risk for a recurrent event and significant morbidity and death.

Newer home apnea monitors allow download of information that assists the health care practitioner in deciding when to discontinue home monitoring. It is imperative to remember, however, that the *home apnea monitor will not predict or prevent SIDS* (Strehle, Gray, Gopisetti, et al., 2012). Furthermore, impedance-based monitors detect chest wall movement and will not detect obstructive apnea unless the episode involves significant bradycardia. Monitors with respiratory impedance plethysmography (RIP) are capable of detecting obstruction as well as central apnea (Silvestri, 2012).

CARE MANAGEMENT

The diagnosis of an ALTE causes great anxiety and concern in parents, and the institution of home monitoring presents additional physical and emotional burdens. Parents of infants on home apnea monitors report experiencing emotional distress, especially depression and hostility, during the first few weeks after hospital discharge. For parents of a SIDS victim who have a new infant on home apnea monitoring, the anxiety is compounded by the uncertainty of the future of the living child and grief for the lost child. Home apnea monitoring may offer some predictability and control over the current child's survival through the period of uncertainty.

If home monitoring is required, the nurse can be a major source of support to the family in terms of education about the equipment; education regarding observation of the infant's status; and instructions regarding immediate intervention during apneic episodes, including CPR. Several reports indicate that the first week to month after discharge is the most stressful for parents, particularly when the rate of false alarms is high (Bennett, 2002). To help the family cope with the numerous procedures they must learn, adequate preparation before discharge and written instructions are essential. In the first few weeks after discharge, parents may benefit by having a practitioner readily available to answer questions regarding false alarms and for other technical assistance.

Several types of home monitors are available and are set up by either a home monitor equipment company or home health staff. Nurses, especially those involved in the care at home, must become familiar with the equipment, including its advantages and disadvantages. Safety is a major concern because monitors can cause electrical burns and electrocution. The following precautions are recommended:

- Remove leads from infant when not attached to the monitor.
- Unplug the power cord from the electrical outlet when the cord is not plugged into the monitor.
- Use safety covers on electrical outlets to discourage children from inserting objects into sockets.

Additional home use instructions should focus on troubleshooting the monitor alarms. *Encourage parents to first look at the infant if an alarm goes off to ensure the infant is breathing and then to determine the cause of the alarm.* Parents also need information about traveling or running necessary errands with an infant on an apnea monitor, what to do in case of power failure, and whom to contact if the monitor alarm goes off continuously but the infant appears well. Siblings should also be supervised when near the infant and taught that the monitor is not a toy. Other safety practices include informing local utility and rescue squads (fire and/or emergency services) of the home monitoring in case of an emergency, especially if the family lives in a remote rural area. Telephone numbers for these services should be posted in the home or set up as speed dial on certain phones in the event that a universal 911 system is not available. Post instructions for infant CPR in a central location of the house and encourage parents to tell visitors and other family members about the location of such instructions. If a cellular phone is the main house phone, make sure it stays in a central location for all family members to access in an emergency.

! NURSING ALERT

If the infant is apneic, gently stimulate the trunk by patting or rubbing it. Call loudly for help even if alone. If the infant is prone, turn to the back and flick the heels of the feet. If there is still no response, immediately begin CPR. After approximately 2 minutes of CPR, activate the emergency medical service—"Call 911!" and then resume CPR until emergency responders arrive or the infant starts breathing. Never vigorously shake the child. No more than 10 seconds are spent on stimulation before implementing CPR.

Caregivers need detailed information regarding proper attachment of the electrodes to the infant's chest with impedance monitors that detect chest movement. The electrodes are placed in the midaxillary line at a space one or two fingerbreadths below the nipple. For home use, electrodes attached to a belt that is placed around the child's trunk are preferred (Fig. 31-17). The belt is positioned so that

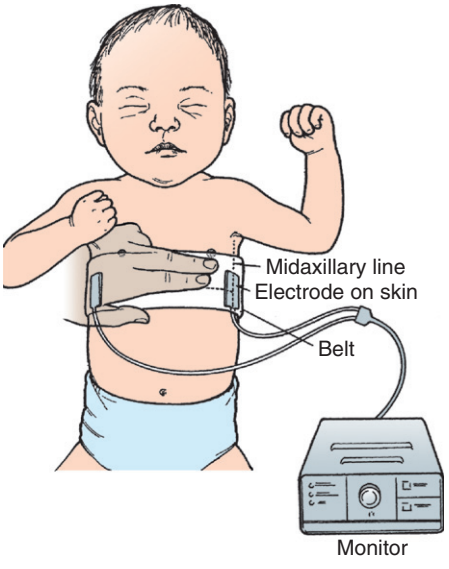

FIG 31-17 Placement of electrodes or belt for apnea monitoring. In small infants, one fingerbreadth below the nipple line may be used to determine correct placement of the monitor belt.

the electrodes contact the skin in the same area. Monitors may have memory chips that allow for event recording, which can be an effective tool in evaluating the use of the monitor, events immediately before and after the ALTE, and reported frequency of alarms.

Monitors are effective only if they are used. They do not prevent death but alert the caregiver to the ALTE in time to intervene. The need to use the monitor and to respond appropriately to alarms must be stressed. Noncompliance can result in the infant's death.

Family Support. Many of the stresses observed during the home monitoring period are characteristic of families with chronically ill children. The child with an apnea or cardiorespiratory monitor may have additional health care needs such as a gastrostomy, tracheostomy, and myriad medications or treatments that exacerbate the parents' stress. Parents report increased stress, including concern for the child's survival, fear of incompetence in assuming home responsibility, inadequate respite care, lack of time for other children and spouse, social isolation from friends and extended family, constant work, and fatigue. The monitored child is at risk for vulnerable child syndrome, which may lead to lack of parental separation and preferential treatment, causing further family disruption. To deal with these potential effects, nurses need to use the same interventions as those discussed for children with chronic illness and be aware of the need for referral when difficulties are suspected.

To lessen the continuous responsibility of monitoring, other family members, such as grandparents and other immediate family members should be taught how to manipulate the equipment, read and interpret the signals, and administer CPR. They are encouraged to stay with the infant for regular periods to allow the parents respite. Support groups of other families who have successfully completed monitoring can also be of benefit. Because reliable babysitters are difficult to locate, support group members and nursing students may be potential sources of qualified caregivers.

KEY POINTS

- Biologic development of the child encompasses proportional changes; sensory changes, including binocularity, depth perception, and visual preference; maturation of biologic systems; fine motor development; and gross motor development.
- Erikson's theory of psychosocial development (birth to 1 year) is concerned with acquiring a sense of trust while overcoming a sense of mistrust.
- Piaget's theory of cognitive development, as it applies to the infant, focuses on the sensorimotor phase, which includes the use of reflexes, primary circular reactions, secondary circular reactions, and coordination of secondary schemata and their application to new situations.
- Development of body image begins in infancy; by 1 year of age, infants recognize that they are distinct from their parents.
- Social development of the infant is guided by attachment, language development, personal-social behavior, and participation in play.
- Temperament influences the type of interaction that occurs between the child and parents and siblings.
- Parents are faced with many concerns, including selecting an appropriate day care, limit setting and discipline, thumb-sucking and pacifier use, and teething.
- Breast milk provides optimal nutrition for the infant during the first 6 months, followed by gradual introduction of solid food during the second 6 months. Commercial iron-fortified infant formula is a safe alternative to human milk. Whole milk is not recommended until after 12 months.
- Cleaning the teeth regularly in early childhood and appropriate dietary intake promote good dental health.
- Recommended routine immunizations in childhood include those for HBV, HAV, diphtheria, tetanus, pertussis, polio, measles, mumps, rubella, pneumococcus, meningococcus, chickenpox, influenza, and Hib.
- Recommended immunizations for selected groups of children and adolescents include the rotavirus and HPV vaccines.
- Because injuries are a major cause of death during infancy, parents should be alerted to aspiration of foreign objects, suffocation, falls, poisoning, burns, motor vehicle injuries, and bodily damage, as well as preventive actions needed to make the environment safe for infants.
- Treatment of colic may involve change in feeding practices, correction of a stressful environment, behavior modification, and support of the parent.
- FTT may occur in children who have a chronic illness, or it may occur in a family environment wherein healthy infant feeding practices are poorly managed or understood. The etiology of FTT is often multifactorial and not always associated with a pattern of disturbed maternal-infant relationship.
- SIDS is the third leading cause of infant death in the United States.
- Factors that place the infant at high risk for SIDS include prone sleeping position, soft bedding, sleeping in a noninfant bed with an adult or older child, and maternal prenatal smoking.
- Positional plagiocephaly can be easily prevented by allowing the awake infant to have periods of tummy time and by alternating the infant's head position during sleep.
- The primary nursing responsibility in care associated with sudden infant death is educating the family of newborns about the risks for SIDS, modeling appropriate behaviors in the hospital such as placing the infant in a supine sleep position, and providing emotional support of the family who have experienced a SIDS loss.
- Infants with an ALTE are carefully evaluated for clues to the underlying cause.
- Home apnea or cardiorespiratory monitors do not prevent SIDS.

CHAPTER

32

The Toddler and Family

David Wilson

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify the major biologic, psychosocial, cognitive, and social developments during the toddler years.
- Relate separation anxiety and negativism to developmental tasks.
- Recognize readiness for toilet training and offer parents guidelines.
- Prepare parents of toddlers for the birth of a sibling.
- Provide parents with guidelines for handling temper tantrums.
- Provide parents with feeding recommendations for the toddler.
- Outline a preventive dental hygiene plan for toddlers.
- Provide anticipatory guidance to parents regarding injury prevention based on the toddler's developmental achievements.

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

The term *terrible twos* has often been used to describe the toddler years, the period from 12 to 36 months of age. Although the term may be used often to describe the toddler's *behavior,* it is not meant to typify or label the child. It is a time of intense exploration of the environment as children attempt to find out how things work and how to control others through temper tantrums, negativism, and obstinacy. Although this can be a challenging time for parents and child as each learns to know the other better, it is an extremely important period for developmental achievement and intellectual growth. Toddlers are very lovable at times; however, because of their search for autonomy, they may test parents' and caregivers' patience.

Biologic Development

Proportional Changes

Growth slows considerably during toddlerhood. The average *weight* gain is 1.8 to 2.7 kg (4 to 6 lbs). The birth weight is quadrupled by 2½ years of age. The rate of increase in height also slows. The usual increment is an addition of 7.5 cm (3 inches) per year and occurs mainly in elongation of the legs rather than the trunk. The average *height* of a 2-year-old is 86.6 cm (34 inches). In general adult height is about twice the 2-year-old child's height. Accurate measurement of height and weight during the toddler years should reveal a steady growth curve that is *steplike* in nature rather than linear (straight), which is characteristic of the growth spurts during the early childhood years.

The rate of increase in *head circumference* slows somewhat by the end of infancy, and head circumference is usually equal to chest circumference by 1 to 2 years of age. The usual total increase in head circumference during the second year is 2.5 cm (1 inch). Then the rate of increase slows until at age 5 years the increase is less than 1.25 cm (0.5 inch) per year. The anterior fontanel closes between 12 and 18 months of age.

Chest circumference continues to increase in size and exceeds head circumference during the toddler years. Its shape also changes as the transverse, or lateral, diameter exceeds the anteroposterior diameter. After the second year the chest circumference exceeds the abdominal measurement; this, in addition to the growth of the lower extremities, gives the child a taller, leaner appearance. However, the toddler still appears relatively squat and "pot-bellied" because of the less well-developed abdominal musculature and short legs. The legs remain slightly bowed or curved during the second year from the weight of the relatively large trunk.

Sensory Changes

Visual acuity of 20/40 is considered acceptable during the toddler years. Full binocular vision is well developed, and any evidence of persistent strabismus requires professional attention as early as possible to prevent amblyopia. Depth perception continues to develop but, because of the child's lack of motor coordination, falls from heights are a persistent danger.

The senses of *hearing, smell, taste,* and *touch* become increasingly well developed, coordinated with one another, and associated with other experiences. All of the senses are used to explore the environment. Toddlers visually inspect an object by turning it over; they may taste it, smell it, and touch it several times before they are satisfied with their investigation. They shake it to see if it makes noise and vigorously test its durability.

Another example of the integrated function of the senses is the toddler's development of specific *taste preferences.* The toddler is much less likely than an infant to try a new food because of its appearance, texture, or smell, not just its taste.

Maturation of Systems

Most of the physiologic systems are relatively mature by the end of toddlerhood. Volume of the *respiratory tract* and growth of associated structures continue to increase during early childhood, lessening some of the factors that predisposed the child to frequent and serious infections during infancy. The internal structures of the ear and throat continue to be short and straight, and the lymphoid tissue of the tonsils and adenoids continues to be large. As a result otitis media, tonsillitis, and upper respiratory tract infections are common. The respiratory and heart rates slow, and the blood pressure increases (see Appendix C). Respirations continue to be abdominal.

Under conditions of moderate variation in temperature the toddler rarely has the difficulties of the young infant in maintaining *body temperature.* The mature functioning of the renal system serves to conserve fluid under times of stress, decreasing the risk of dehydration.

The *digestive processes* are fairly complete by the beginning of toddlerhood. The acidity of the gastric contents continues to increase and has a protective function because it is capable of destroying many types of bacteria. Stomach capacity increases to allow for the usual schedule of three meals a day.

One of the more prominent changes of the gastrointestinal system is the voluntary control of elimination. With complete myelination of the spinal cord, control of the anal and urethral sphincters is gradually achieved. The *physiologic* ability to control the sphincters probably occurs somewhere between ages 18 and 24 months. Bladder capacity also increases considerably, and by 14 to 18 months of age the child is able to retain urine for up to 2 hours or longer.

The *defense mechanisms* of the skin and blood, particularly phagocytosis, are much more efficient in toddlers than in infants. The production of antibodies is well established. However, many young children have a sudden increase in colds and minor infections when they enter preschool or other group situations such as day care because of their exposure to pathogens and the lack of understanding of general hygiene measures such as hand washing.

Gross and Fine Motor Development

The major *gross motor skill* during the toddler years is the development of locomotion. By 12 to 13 months of age toddlers walk alone using a wide stance for extra balance, and by 18 months they try to run but fall easily (Fig. 32-1). Between 2 and 3 years of age refinement of the upright, biped position is evident in improved coordination and equilibrium. At age 2 years toddlers can walk up and down stairs; by age 2½ years they can jump using both feet, stand on one foot for a second or two, and manage a few steps on tiptoe. By the end of the second year they can stand on one foot, walk on tiptoe, and climb stairs with alternate footing.

FIG 32-1 Typical toddling gait.

Fine motor development is demonstrated in increasingly skillful manual dexterity. For example, by age 12 months toddlers are able to grasp a very small object but are unable to release it at will. At 15 months they can drop a pellet into a narrow-necked bottle. Casting or throwing objects and retrieving them become almost obsessive activities at about 15 months. By 18 months of age toddlers can throw a ball overhand without losing their balance.

Mastery of gross and fine motor skills is evident in all phases of the child's activity such as play, dressing, language comprehension, response to discipline, social interaction, and propensity for injuries. Activities occur less in isolation and more in conjunction with other physical and mental abilities to produce a purposeful result. For example, the toddler walks to reach a new location, releases a toy to pick it up or to choose a new one, and scribbles to look at the image produced. The possibilities of the exploration, investigation, and manipulation of the environment—and its hazards—are endless.

Psychosocial Development

Toddlers are faced with the mastery of several important tasks. If the need for basic trust has been satisfied, they are ready to give up dependence for control, independence, and autonomy. Some of the specific tasks to be dealt with include:

- Differentiation of self from others, particularly the mother.
- Toleration of separation from parent.
- Ability to delay gratification.
- Control over bodily functions.
- Acquisition of socially acceptable behavior.
- Verbal means of communication.
- Ability to interact with others in a less egocentric manner.

Mastery of these goals is only begun during late infancy and the toddler years, and tasks such as developing interpersonal relationships with others may not be completed until adolescence. However, crucial foundations for successful completion of such developmental tasks are established during these early formative years.

Developing a Sense of Autonomy (Erikson)

According to Erikson (1963), the developmental task of toddlerhood is acquiring a sense of *autonomy* while overcoming a sense of *doubt*

and *shame.* As infants gain trust in the predictability and reliability of their parents, environment, and interaction with others, they begin to discover that their behavior is their own and that it has a predictable, reliable effect on others. However, although they realize their will and control over others, they are confronted with the conflict of exerting autonomy and relinquishing the much-enjoyed dependence on others. Exerting their will has definite negative consequences, whereas retaining dependent, submissive behavior is generally rewarded with affection and approval. At the same time continued dependency creates a sense of doubt regarding their potential capacity to control their actions. This doubt is compounded by a sense of shame for feeling this urge to revolt against others' will and a fear that they will exceed their own capacity for manipulating the environment.

Just as the infant has the social modalities of grasping and biting, the toddler has the newly gained modality of holding on and letting go. To hold on and let go is evident with the use of the hands, mouth, eyes, and eventually the sphincters when toilet training is begun. These social modalities are expressed constantly in the child's play activities such as casting or throwing objects; taking objects out of boxes, drawers, or cabinets; holding on tighter when someone says, "No, don't touch"; and spitting out food as taste preferences become strong.

Several characteristics, especially negativism and ritualism, are typical of toddlers in their quest for autonomy. As they attempt to express their will, they often act with **negativism,** the persistent negative response to requests. The words "no" or "me do" can be the sole vocabulary. Emotions are expressed strongly, usually in rapid mood swings. One minute toddlers can be engrossed in an activity, and the next minute they might be extremely frustrated because they are unable to manipulate a toy or open a door. If scolded for doing something wrong, they can have a temper tantrum and almost instantaneously pull at the parent's legs to be picked up and comforted. Understanding and coping with these swift changes in behavior is often difficult for parents. Many find the negativism exasperating and, instead of dealing constructively with it, give in to it, which further threatens children in their search for learning acceptable methods of interacting with others (see Temper Tantrums, p. 932; see Negativism, p. 933).

In contrast to negativism, which often disrupts the environment, **ritualism,** the need to maintain sameness and reliability, provides a sense of comfort. Toddlers can venture out with security when they know that familiar people, places, and routines still exist. One can easily understand why change such as hospitalization represents such a threat to these children. Without the comfortable rituals there is little opportunity to exert autonomy. Consequently dependency and regression occur (see Regression, p. 933).

Erikson focuses on the development of the *ego,* which may be thought of as reason or common sense, during this phase of psychosocial development. There is a struggle as the child deals with the impulses of the *id* and attempts to tolerate frustration and learn socially acceptable ways of interacting with the environment. The *ego* is evident as the child is able to tolerate delayed gratification.

There is also a rudimentary beginning of the *superego,* or conscience, which is the incorporation of the morals of society and the process of acculturation. With the development of the ego children further differentiate themselves from others and expand their sense of trust within themselves. However, as they begin to develop awareness of their own will and capacity to achieve, they also become aware of their ability to fail. This ever-present awareness of potential failure creates doubt and shame. Successful mastery of the task of autonomy necessitates opportunities for self-mastery while withstanding the frustration of necessary limit setting and delayed gratification. Opportunities for self-mastery are present in appropriate play activities, toilet training, the crisis of sibling rivalry, and successful interactions with significant others.

Cognitive Development

Sensorimotor and Preoperational Phase (Piaget)

The period from 12 to 24 months of age is a continuation of the final two stages of the sensorimotor phase. During this time the cognitive processes develop rapidly and at times seem similar to those of mature thinking. However, reasoning skills are still primitive and need to be understood to deal with the typical behaviors of a child of this age effectively.

Tertiary Circular Reactions

In the fifth stage of the sensorimotor phase (13 to 18 months of age), the child uses active experimentation to achieve previously unattainable goals. Newly acquired physical skills are increasingly important for the function they serve rather than for the acts themselves. The child incorporates the old learning of secondary circular reactions with new skills and applies the combined knowledge to new situations, with emphasis on the results of the experimentation. In this way there is the beginning of rational judgment and intellectual reasoning. During this stage there is further differentiation of one's self from objects. This is evident in the child's increasing ability to venture away from the parent and tolerate longer periods of separation.

Awareness of a causal relationship between two events is apparent. After flipping a light switch, toddlers are aware that a reciprocal response occurs. However, they are not able to transfer that knowledge to new situations. Therefore, every time they see what appears to be a light switch, they must reinvestigate its function. Such behavior demonstrates the beginning of *categorizing data into distinct classes and subclasses.* Examples of this type of behavior are innumerable as toddlers continuously explore the same object each time it appears in a new place.

Because classification of objects is still rudimentary, the *appearance* of an object denotes its function. For example, if the child's toys are stored in a paper bag or large container, that toy receptacle is no different from the garbage pail or laundry basket. If allowed to turn over the toy receptacle, the child will just as quickly do the same to other similar containers because in the child's mind there is no difference. Expecting the child to judge which receptacles are permissible to explore and which are not is inappropriate for this age-group. Instead the forbidden object such as the garbage pail should be placed out of reach. This has significance in relation to protecting the toddler from injury; the toddler is not able to differentiate between safe objects with which he or she can play and objects which are unsafe under similar circumstances. For example, if the child is allowed to throw a toy ball, he or she does not necessarily understand why a toy block that may harm someone cannot be thrown.

The discovery of objects as objects leads to the awareness of their spatial relationships. Children are able to recognize different shapes and their relationship to one another. For example, they can fit slightly smaller boxes into one another (nesting) and can place a round object into a hole, even if the board is turned around, upside down, or reversed. Children are also aware of space and the relationship of their body to dimensions such as height. They stretch, stand on a low stair or stool, and pull a string to reach an object.

Object permanence has also advanced. Although they still cannot find an object that has been invisibly displaced or moved from under one pillow to another without actually seeing the change, toddlers are increasingly aware of the existence of objects behind closed doors, in drawers, on countertops, and under tables. Parents are usually acutely aware of this developmental achievement and find high places and locked cabinets to be the only places inaccessible to toddlers.

Invention of New Means Through Mental Combinations

From ages 19 to 24 months the child is in the final sensorimotor stage. During this stage he or she completes the more primitive, autistic-like thought processes of infancy and is prepared for the more complex mental operations that occur during the phase of preoperational thought. One of the most dramatic achievements of this stage is in the area of object permanence. Children now actively search for an object in several potential hiding places. In addition, they can infer a cause when only experiencing the effect. They can infer that an object was hidden in any number of places even if they only saw the original hiding place.

Imitation displays deeper meaning and understanding. There is greater symbolization to imitation. The child is acutely aware of others' actions and attempts to copy them in gestures and words. Domestic **mimicry** (imitating household activities) and gender-role behavior become increasingly common during this stage, especially during the second year. Identification with the parent of the same gender becomes apparent by the second year and represents the child's intellectual ability to identify different models of behavior and imitate them appropriately (Fig. 32-2).

The concept of time is still embryonic; but children have some sense of timing in terms of anticipation, memory, and a limited ability to wait. They may listen to the command, "Just a minute," and behave appropriately. However, their sense of time is exaggerated; 1 minute can seem like an hour. Toddlers' limited attention spans also indicate their sense of immediacy and concern for the present.

FIG 32-2 Domestic mimicry and sex-role behavior are common during toddlerhood.

Preoperational Phase

At approximately 2 years of age the child enters the preconceptual phase of cognitive development, which lasts until about age 4 years. The preconceptual phase is a subdivision of the preoperational phase, which spans ages 2 to 7 years. It is primarily one of transition that bridges the purely self-satisfying behavior of infancy and the rudimentary socialized behavior of latency. *Preoperational thought* implies that children cannot think in terms of *operations* (i.e., the ability to manipulate objects in relation to one another in a logical fashion). Rather toddlers think primarily on the basis of their perception of an event. Problem solving is based on what they see or hear directly rather than on what they recall about objects and events. Several characteristics are unique to preoperational thought (Box 32-1).

Within the second year the child increasingly uses language symbolically and is concerned with the "why" and "how" of things. For example, a pencil is "something to write with," and food is "something to eat." However, such mental symbolization is closely associated with prelogical reasoning. For instance, a needle is "something that hurts." Such painful experiences take on new significance because memory is associated with the specific event, and fears are likely to develop such as resistance to people who wear a uniform or rooms that look like the practitioner's office. Because of the vulnerability of these early years, it is essential to prepare children for any new experience, whether it is a new baby-sitter or a visit to the practitioner or dentist.

Spiritual Development

Spiritual development in children is often discussed in terms of the child's developmental level because the evolution of spirituality often parallels cognitive development (Elkins and Cavendish, 2004). The child's family and environment strongly influence his or her perception of the world around him or her, and this often includes spirituality. Furthermore, family values, beliefs, customs, and expressions of these influence the child's perception of his or her spiritual self (Elkins and Cavendish, 2004). Neuman (2011) proposes that Fowler's stages of faith (Fowler, 1981) be used to better understand children and spirituality; she provides an excellent overview of the stages of faith in childhood. The relationship among spirituality, illness in childhood, and nursing has been studied in the context of suffering, terminal illness such as cancer, and end-of-life care. In the past decade there has been an increased interest in and focus on spiritual care in adults and children as further understanding of the influence of one's spirituality on health, illness, and well-being has progressed.

Toddlers learn about God through the words and actions of those closest to them. They have only a vague idea of God and religious teachings because of their immature cognitive processes; however, if God is spoken about with reverence, young children associate God with something special. During this period the assignment of powerful religious symbols and images is strongly influenced by the manner in which it is presented; therein lies the potential for the development of guilt and fear or conversely love and companionship with religious symbols (Roehlkepartain, King, Wagener, et al., 2006). Toddlers are said to be in the intuitive-projective phase of Fowler's faith construct (Fowler, 1981) wherein thinking is largely based on fantasy and rather fluid in relation to reality and fantasy. God may be described as being around like air by the toddler because of the fluidity in dividing fantasy and reality (Neuman, 2011).

BOX 32-1 CHARACTERISTICS OF PREOPERATIONAL THOUGHT

Egocentrism—Inability to envision situations from perspectives other than one's own

Example—If a person is positioned between the toddler and another child, the toddler, who is facing the person, will explain that both children can see the middle person's face. The young child is unable to realize that the other person views the middle person from a different perspective, the back.

Implication—Avoid moralizing about "why" something is wrong if it requires an understanding of someone else's feelings or opinion. Telling a child to stop hitting because hitting hurts the other person is often ineffective because to the aggressor it feels good to hit someone else. Instead emphasize that hitting is not allowed.

Transductive reasoning—Reasoning from the particular to the particular

Example—Child refuses to eat a food because something previously eaten did not taste good.

Implication—Accept child's reasoning; offer refused food at different time.

Global organization—Reasoning that changing any one part of the whole changes the entire whole

Example—Child refuses to sleep in room because location of bed is changed.

Implication—Accept child's reasoning; use same bed position or introduce change slowly.

Centration—Focusing on one aspect rather than considering all possible alternatives

Example—Child refuses to eat a food because of its color, even though its taste and smell are acceptable.

Implication—Accept child's reasoning.

Animism—Attributing lifelike qualities to inanimate objects

Example—Child scolds stairs for making child fall down.

Implication—Join child in the "scolding." Keep frightening objects out of view.

Irreversibility—Inability to undo or reverse actions initiated physically

Example—When told to stop doing something such as talking, child is unable to think of positive activity.

Implication—State requests or instructions *positively* (e.g., "Be quiet.")

Magical thinking—Believing that thoughts are all-powerful and can cause events

Examples—Child wishes someone died; then if the person dies, child feels at fault because of the "bad" thought that made the death happen.

- Calling children "bad" because they did something wrong makes them feel as if they are bad.

Implications—Clarify that thoughts do not make things happen and that child is not responsible.

- Use "I" rather than "you" messages to communicate thoughts, feelings, expectations, or beliefs without imposing blame or criticism. Emphasize that the act is bad, not the child.

Inability to conserve—Inability to understand the idea that a mass can be changed in size, shape, volume, or length without losing or adding to the original mass (instead children judge what they see by the immediate perceptual clues given to them)

Example—If two lines of equal length are presented in such a way that one appears longer than the other, child will state that one line is longer even if he or she measures both lines with a ruler or yardstick and finds that each has the same length.

Implications—Change the most obvious perceptual clue to reorient child's view of what is seen. For example, give medicine in a small medicine cup rather than a large cup because child will imagine that the large vessel contains more liquid. If child refuses the medicine in the small cup, pour it into a large cup, because the liquid will appear to be less in a tall, wide container.

- Give a large, flat cookie rather than a thick, small one or do the reverse with meat or cheese; child will usually eat larger size of favorite food and smaller size of less favorite food.

Toddlers begin to assimilate behaviors associated with the divine (folding hands in prayer). Routines such as saying prayers before meals or at bedtime can be important and comforting. Because toddlers tend to find solace in ritualistic behavior and routines, they incorporate routines associated with religious practices into their behavioral patterns without understanding all of the implications of the rituals until later. Near the end of toddlerhood, when children use preoperational thought, there is some advancement of their understanding of God. Religious teachings such as reward or fear of punishment (heaven or hell) and moral development (see Chapter 28), may influence their behavior (Fosarelli, 2003).

Development of Body Image

As in infancy the development of body image closely parallels cognitive development. Developing psychologic understanding provides greater self-awareness, and young children learn to answer the question, "Who am I?" During the second year children recognize themselves in a mirror and make verbal references to themselves ("Me big"). With increasing motor ability toddlers recognize the usefulness of body parts and gradually learn their names. They also learn that certain parts of the body have various meanings (e.g., during toilet training the genitalia become significant, and cleanliness is emphasized). By 2 years of age they recognize gender differences and refer to self by name and then by pronoun. Gender identity is developed by age 3 years. By this time the child also begins to remember events with reference to their personal significance, forming an autobiographic memory that helps establish a continuous identity throughout the events of life.

Once they begin preoperational thought, toddlers can use symbols to represent objects, but their thinking may lead to inaccuracies. For example, if someone who is pregnant is called "fat," they describe all "fat" women as having babies. There is a beginning recognition of words used to describe physical appearance such as "pretty," "handsome," or "big boy." Such expressions eventually influence how children view their own bodies.

Although little research has been done on body-image development in young children, it is evident that body integrity is poorly understood and intrusive experiences are threatening. For example, toddlers forcefully resist procedures such as examining the ear or mouth and taking an axillary temperature. The procedure itself (e.g., taking vital signs) is not hurting the child, but it represents an intrusion into the child's personal space, which elicits a strong protest. Toddlers also have unclear body boundaries and may associate nonviable parts such as feces with essential body parts. This can be seen in a toddler who is upset by flushing the toilet and watching the stool disappear.

Nurses can help parents foster a positive body image in their child by encouraging them to avoid negative labels such as "skinny arms" or "chubby legs," self-perceptions that can last a lifetime. Body parts, especially those related to elimination and reproduction, should be called by their correct names. Respect for the body should be practiced.

Development of Gender Identity

Just as toddlers explore their environment, they also explore their bodies and find that touching certain body parts is pleasurable. Genital fondling (masturbation) can occur and involves manual stimulation and posturing movements (especially in young girls) such as tightening the thighs or applying mechanical pressure to the pubic or suprapubic area. Other demonstrations of pleasurable activities include rocking, swinging, and hugging people and toys. Parental reactions to toddlers' sexual behavior influence the children's own attitudes and should be accepting rather than critical. If such acts are performed in public, parents should not condone or bring attention to the behavior but should teach the child that it is more acceptable to perform the behavior in private.

Children in this age-group are learning vocabulary associated with anatomy, elimination, and reproduction. Certain associations between words and functions become significant and can influence future sexual attitudes. For example, if parents refer to the genitalia as dirty, especially in the context of elimination, this association between "genitalia" and "dirty" may be transferred to sexual functions later in life. Sex-role differences become obvious to children and are evident in much of toddlers' imitative play. Although current research indicates that prenatal exposure to testosterone strongly influences the individual's gender identity, researchers also indicate that there are sensitive periods (e.g., puberty) that may influence the development of gender identity (Berenbaum and Beltz, 2011; Hines, 2011; Savic, Garcia-Falqueras, and Swaab, 2010). A sense of maleness or femaleness, or gender identity, is formed by age 3 years, and the child's feelings about being male or female begin to form (Fonseca and Greydanus, 2007). Early attitudes are formed about affectionate behaviors between adults from observing parental and other adult sexual or sensual activities. (See also Sex Education, Chapter 33.) The quality of relationships with parents is important to the child's capacity for sexual and emotional relationships later in life.

Social Development

A major task of the toddler period is differentiation of self from significant others, usually the mother. The differentiation process consists of two phases: *separation* (i.e., the child's emergence from a symbiotic fusion with the mother) and *individuation* (i.e., achievements that mark the child's expressions of his or her individual characteristics in the environment). Although the process begins during the latter half of infancy, the major achievements occur during the toddler years.

Toddlers have an increased understanding and awareness of object permanence and some ability to withstand delayed gratification and tolerate moderate frustration. As a result toddlers react differently to strangers than do infants. The appearance of unfamiliar people does not represent such a significant threat to their attachment to mother. They have learned from experience that parents still exist when physically absent. Repetition of events such as going to bed without the parents but waking to find them there again (in the household) reinforces the reliability of such brief separations. Consequently toddlers are able to venture away from their parents for brief periods.

According to Harpaz-Rotem and Bergman (2006), the separation-individuation phase encompasses the phenomenon of rapprochement; as the toddler separates from the mother and begins to make sense of experiences in the environment, he or she is drawn back to the mother for assistance in verbally articulating the meaning of the experiences. Developmentally the term *rapprochement* means the child moves away and returns for reassurance. If the mother's response to the toddler is inappropriate, the toddler may experience insecurity and confusion.

Transitional objects such as a favorite blanket or toy provide security for children, especially when they are separated from parents, dealing with a new stress, or just fatigued (Fig. 32-3). Security objects often become so important to toddlers that they refuse to have them taken away. Such behavior is normal; there is no need to discourage this tendency. During separations such as day care, hospitalization, or even overnight stays with relatives, transitional objects should be provided to minimize any feelings of fear or loneliness.

Learning to tolerate and master brief periods of separation is an important developmental task of children in this age-group. In addition, it is a necessary component of parenting because brief periods of separation allow parents to regain their energy and patience and minimize any tendency to direct their irritations and frustrations at the children.

Language

The most striking characteristic of language development during early childhood is the increasing level of comprehension. Although the number of words acquired (i.e., from about four at 1 year of age to approximately 300 at age 2 years is notable, *the ability to comprehend and understand speech is much greater than the number of words the child can say.* Bilingual children can also achieve their early linguistic milestones in each of the languages at the same time and produce a substantial number of semantically corresponding words in each of their two languages from the very first words or signs.

At age 1 year children use one-word sentences or holophrases. The word "up" can mean "pick me up" or "look up there." For children the one word conveys the meaning of a sentence, but to others it may mean many things or nothing. At this age about 25% of the vocalizations are intelligible. By the age of 2 years children use

FIG 32-3 Transitional objects such as a fuzzy stuffed animal are sources of security to a toddler. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

multiword sentences by stringing together two or three words such as the phrases "mama go bye-bye" or "all gone," and approximately 65% of their speech is understandable. By 3 years the children put words together into simple sentences, begin to master grammatical rules, acquire five or six new words daily, know their age and gender, and can count three objects correctly. Looking at books during this period provides an ideal setting for further language development (Feigelman, 2011). Authorities have evaluated the impact of television viewing on toddler language development and found that those who started watching television at younger than 12 months of age and who watched longer than 2 hours per day had significant language delays (Chonchaiva and Pruksananonda, 2008). Adult-child conversations with infants and toddlers have been shown to positively affect language development; the researchers recommend reading, storytelling, and interactive adult-child communication (Zimmerman, Gilkerson, Richards, et al., 2009). The American Academy of Pediatrics (AAP) Council on Communications and Media (2011) reaffirms that televised or recorded media usage in children younger than 2 years of age decreases language skills and the time parents interact with the child. Furthermore, educational programs have not been shown to increase cognitive skills in young children (AAP Council on Communications and Media, 2011).

Gestures precede or accompany each of the language milestones up to 30 months of age (putting phone to ear, pointing). After sufficient language development, gestures phase out, and the pace of word learning increases (Bates and Dick, 2002).

Personal-Social Behavior

Perhaps one of the most dramatic aspects of development in the toddler is personal-social interaction. Parents often wonder why their manageable, docile, lovable infant has turned into a determined, strong-willed, volatile little tyrant. In addition, the tyrant of the terrible twos can swiftly and unpredictably revert back to the adorable, cuddly child. All of this is part of growing up and is evident in such areas as dressing, feeding, playing, and establishing self-control.

Toddlers are developing skills of independence, and these are evident in all areas of behavior. By 15 months children feed themselves, drink well from a covered cup, and manage a spoon with considerable spilling. By 24 months they use a spoon well and by 36 months may be using a fork. Between ages 2 and 3 years they eat with the family and like to help with chores such as setting the table or removing dishes from the dishwasher. However, they lack table manners and may find it difficult to sit through the family's entire meal.

In dressing toddlers also demonstrate strides in independence. The 15-month-old child helps by putting the arm or foot out for dressing and pulls shoes and socks off. The 18-month-old child removes gloves, helps with pullover shirts, and may be able to unzip. By 2 years of age the toddler removes most articles of clothing and puts on socks, shoes, and pants without regard to right or left and back or front. Help is still needed to fasten clothes.

Toddlers also begin to develop concern for the feelings of others and an understanding of how adult expectations for behavior apply to specific situations (e.g., causing a sibling to cry while playing rough). As parents foster their understanding, they are able to develop control. Age-appropriate discipline contributes to healthy social and emotional development. Positive reinforcement, redirecting, and time-out are appropriate for most toddlers. Social and emotional problems can develop in the youngest children. Early screening and intervention promote more positive developmental outcomes as the young child grows and develops.

Play

Play magnifies toddlers' physical and psychosocial development. Interaction with people becomes increasingly important. The solitary play of infancy progresses to **parallel play** (i.e., toddler play alongside, not with, other children). Although sensorimotor play is still prominent, there is much less emphasis on the exclusive use of one sensory modality. Toddlers inspect toys, talk to toys, test toys' strength and durability, and invent several uses for toys. Imitation is one of the most distinguishing characteristics of play and enriches children's opportunity to engage in fantasy. With less emphasis on gender-stereotyped toys, play objects such as dolls, carriages, dollhouses, balls, dishes, cooking utensils, child-size furniture, trucks, and dress-up clothes are suitable for both genders (Fig. 32-4); however, boys may be more interested than girls in activities related to trucks, trailers, action figures, and building blocks, and girls may prefer doll-related activities.

Increased locomotive skills make push-pull toys, straddle trucks or cycles, a small gym and slide, balls of various sizes, and riding toys appropriate for energetic toddlers. Finger paints; thick crayons; chalk; blackboard; paper; and puzzles with large, simple pieces use toddlers' developing fine motor skills. Interlocking blocks in various sizes and shapes provide hours of fun and during later years are useful objects for creative and imaginative play. The most educational toy is the one that fosters the interaction of an adult with a child in supportive, unconditional play. Toys should not be substitutes for the attention of devoted caregivers, but they can enhance these interactions (Glassy, Romano, and AAP Committee on Early Childhood, 2003). Parents and other providers are encouraged to allow children to play with a variety of simple toys that foster creative thinking (e.g., blocks, dolls, and clay) rather than passive toys that the child observes (battery-operated or mechanical). Active play time should also be encouraged over the use of computer or video games, which are more passive (Ginsburg and AAP Committee on Communications, 2007).

Certain aspects of play are related to emerging linguistic abilities. Talking is a form of play for toddlers, who enjoy musical toys such as age-appropriate compact disk (CD) players, "talking" dolls and animals, and toy telephones. Children's television programs are appropriate for some children over 2 years of age who learn to associate words with visual images. However, total media time should be limited to 1 hour or less of quality programming per day. Parents are encouraged to allow the child to engage in unstructured

playtime, which is considered much more beneficial than any electronic media exposure (AAP Council on Communications and Media, 2011). Toddlers also enjoy "reading" stories from a picture book and imitating the sounds of animals.

Tactile play is also important for exploring toddlers. Water toys, a sandbox with a pail and shovel, finger paints, soap bubbles, and clay provide excellent opportunities for creative and manipulative recreation. Adults sometimes forget the fascination of feeling textures such as slippery cream, mud, or pudding; catching air bubbles; squeezing and reshaping clay; or smearing paints. These types of unstructured activities are as important as educational play to allow children the freedom of expression.

Selection of appropriate toys must involve safety factors, especially in relation to size and sturdiness. The oral activity of toddlers puts them at risk for aspirating small objects and ingesting toxic substances. Parents need to be especially vigilant of toys played with in other children's homes and those of older siblings. Toys are a potential source of serious bodily damage to toddlers, who may have the physical strength to manipulate them but not the knowledge to appreciate their danger (Stephenson, 2005). Government agencies do not inspect and police all toys on the market. Therefore adults who purchase play equipment, supervise purchases, or allow children to use play equipment need to evaluate its safety, including toys that are gifts or those that are purchased by the children themselves. Adults should also be alert to notices of toys determined to be defective and recalled by the manufacturers. Parents and health care workers can obtain information on a variety of recalled products and report potentially dangerous toys and child products to the U.S. Consumer Product Safety Commission* or, in Canada, the Canadian Toy Testing Council.† Printable tips on toy safety are also available from Safe Kids Worldwide (www.safekids.org).

Table 32-1 summarizes the major features of growth and development for the age-groups of 15, 18, 24, and 30 months.

TABLE 32-1 GROWTH AND DEVELOPMENT DURING TODDLER YEARS

AGE (mo)	PHYSICAL	GROSS MOTOR	FINE MOTOR	SENSORY	LANGUAGE	SOCIALIZATION
15	Steady growth in height and weight Head circumference 48 cm (19 inches) Weight 11 kg (24 lbs) Height 78.7 cm (31 inches)	Walks without help (usually since age 13 mo) Creeps up stairs Kneels without support Cannot walk around corners or stop suddenly without losing balance Cannot throw ball without falling Runs clumsily; falls often	Constantly casting objects to floor Builds tower of two cubes Holds two cubes in one hand Releases pellet into narrow-necked bottle Scribbles spontaneously Uses cup well but rotates spoon before it reaches mouth	Able to identify geometric forms; places round object into appropriate hole Binocular vision well developed Displays intense and prolonged interest in pictures	Uses expressive jargon Says four to six words, including names "Asks" for objects by pointing Understands simple commands May use head-shaking gesture to denote "no" Uses "no" even while agreeing to the request Uses common repetitive gestures such as putting cup to mouth when empty	Tolerates some separation from parent Less likely to fear strangers Beginning to imitate parents such as cleaning house (sweeping, dusting), folding clothes May discard bottle Kisses and hugs parents; may kiss pictures in a book
18	Picky eater from decreased growth needs Anterior fontanel closed Physiologically able to control sphincters	Assumes standing position without support Walks up stairs with one hand held Pulls and pushes toys Jumps in place with both feet Seats self on chair Throws ball overhand without falling	Builds tower of three or four cubes Release, prehension, and reach well developed Turns pages in book two or three at a time In drawing makes stroke imitatively Manages spoon without rotation		Says 10 or more words Points to common object such as shoe or ball and to two or three body parts Forms word combinations Forms gesture-word combinations Forms gesture-gesture combinations	Expresses emotions; has temper tantrums Great imitator (domestic mimicry) Takes off gloves, socks, and shoes and unzips Temper tantrums may be more evident Beginning awareness of ownership ("my toy") May develop dependence on transitional objects such as "security blanket"

Continued

TABLE 32-1 GROWTH AND DEVELOPMENT DURING TODDLER YEARS—cont'd

AGE (mo)	PHYSICAL	GROSS MOTOR	FINE MOTOR	SENSORY	LANGUAGE	SOCIALIZATION
24	Head circumference 49-50 cm (19.3-20 inches) Chest circumference exceeds head circumference Lateral diameter of chest exceeds anteroposterior diameter Usual weight gain of 1.8-2.7 kg (4-6 lbs) Usual gain in height of 10-12.5 cm (4-5 inches) Adult height approximately double height at 2 years of age May have achieved readiness for beginning daytime control of bowel and bladder Primary dentition of 16 teeth	Goes up and down stairs alone with two feet on each step Runs fairly well, with wide stance Picks up object without falling Kicks ball forward without overbalancing	Builds tower of six or seven cubes Aligns two or more cubes like a train Turns pages of book one at a time In drawing imitates vertical and circular strokes Turns doorknob; unscrews lid	Accommodation well developed In geometric discrimination able to insert square block into oblong space	Has vocabulary of approximately 300 words Uses two- or three-word phrases Uses pronouns "I," "me," "you" Understands directional commands Gives first name; refers to self by name Verbalizes need for toileting, food, or drink Talks incessantly	Stage of parallel play Has sustained attention span Temper tantrums decreasing Pulls people to show them something Increased independence from parent Dresses self in simple clothing Develops visual recognition and verbal self-reference ("Me big")
30	Birth weight quadrupled Primary dentition (20 teeth) completed (30-33 months) May have daytime bowel and bladder control	Jumps with both feet Jumps from chair or step Stands on one foot momentarily Takes a few steps on tiptoe	Builds tower of eight cubes Adds chimney to train of cubes Good hand-finger coordination; holds crayon with fingers rather than fist Moves fingers independently In drawing imitates vertical and horizontal strokes; makes two or more strokes for cross		Gives first and last name Refers to self by appropriate pronoun Uses plurals Names one color	Separates more easily from parent In play helps put things away; can carry breakable objects; pushes with good steering Begins to notice gender differences; knows own gender May attend to toilet needs without help except for wiping Emotions expand to include pride, shame, guilt, embarrassment

Coping with Concerns Related to Normal Growth and Development

Toilet Training

One of the major tasks of toddlerhood is toilet training. Anticipatory guidance and clinical intervention for families surrounding toilet training should begin during routine well-child visits before the child's developmental readiness to toilet train. Preparation and education reveal and allay misconceptions; lead to the development of appropriate expectations; and provide information, guidance, and support to parents for managing this potentially frustrating process.

Voluntary control of the anal and urethral sphincters is achieved sometime after the child is walking, probably between ages 18 and 24 months. However, complex psychophysiologic factors are required for readiness. The child must be able to recognize the urge to let go and hold on and communicate this sensation to the parent. In addition, some motivation is probably involved in the desire to please the parent by holding on rather than pleasing oneself by letting go. Cultural beliefs may also affect the age at which children demonstrate readiness (Feigelman, 2011).

Schmitt (2004) notes that comparative studies over the past 5 decades indicate that children in the 1990s in the United States were toilet trained at a later age (18 months in the 1960s versus 36 months in the 1990s); one possible contributing factor is the availability and convenience of disposable diapers. Another study found that the child's average age at initiation of toilet training was 20.6 months (Horn, Brenner, Rao, et al., 2006).

GUIDELINES

Assessing Toilet Training Readiness

Physical Readiness

- Voluntary control of anal and urethral sphincters, usually by 18 to 24 months of age
- Ability to stay dry for 2 hours; decreased number of wet diapers; waking dry from nap
- Regular bowel movements
- Gross motor skills of sitting, walking, and squatting
- Fine motor skills to remove clothing

Mental Readiness

- Recognizing urge to defecate or urinate
- Verbal or nonverbal communicative skills to indicate when wet or has urge to defecate or urinate
- Cognitive skills to imitate appropriate behavior and follow directions

Psychologic Readiness

- Expressing willingness to please parent
- Ability to sit on toilet for 5 to 10 minutes without fussing or getting off
- Curiosity about adults' or older sibling's toilet habits
- Impatience with soiled or wet diapers; desire to be changed immediately

Parental Readiness

- Recognizing child's level of readiness
- Willingness to invest time required for toilet training
- Absence of family stress or change such as a divorce, moving, new sibling, or imminent vacation

Five markers signal a child's readiness to toilet train: bladder readiness, bowel readiness, cognitive readiness, motor readiness, and psychologic readiness (Schmitt, 2004). According to some experts, physiologic and psychologic readiness is not complete until ages 22 to 30 months (Schum, Kolb, McAuliffe, et al., 2002); however, Schmitt (2004) emphasizes that parents should begin preparing their children for toilet training earlier than 30 months. By this time children have mastered most essential gross motor skills, can communicate intelligibly, are in less conflict with their parents in terms of self-assertion and negativism, and are aware of the ability to control the body and please their parents. Both the AAP and the Canadian Paediatric Society recommend starting toilet training by 18 months of age and suggest that the child must be interested in the process (Kiddoo, 2012). There is no universal right age to begin toilet training or an absolute deadline to complete it. An important role for the nurse is to help parents identify the readiness signs in their children (see Guidelines box).* On average girls are developmentally ready to begin toilet training 2 to 2½ months before boys (Schum, Kolb, McAuliffe, et al., 2002).

Nighttime bladder control normally takes several months to years after daytime training begins. This is because the sleep cycle needs to mature so the child can awake in time to urinate. Feigelman (2011) indicates that bed-wetting is normal in girls up to age 4 years and boys up to age 5 years. Few children have night-wetting episodes after daytime dryness is totally achieved; however, children who do not have nighttime dryness by the age of 6 years are likely to require intervention (Mercer, 2003).

Bowel training is usually accomplished before bladder training because of its greater regularity and predictability. The sensation for defecation is stronger than that for urination and easier for children to recognize. A well-balanced diet that includes dietary fiber helps keep stool soft and supports the development and maintenance of regular bowel movements.

A number of techniques are helpful when initiating training, and cultural differences should be considered. In the United States some of the options recommended by practitioners include the Brazelton child-oriented approach, the AAP guidelines (which are similar to Brazelton method), Dr. Spock's training method, and the intensive "toilet-training-in-a-day" (operant conditioning) approach by Azrin and Foxx (Choby and George, 2008). An extensive study and review by the Agency for Healthcare Research and Quality in 2006 (Klassen, Kiddoo, Lang, et al., 2006) concluded that the child-oriented method and the Azrin and Foxx method were effective at toilet training healthy children (Choby and George, 2008). Another method emerging in the literature involves early assisted toilet training of infants around 2 to 3 weeks of age, but there are no studies assessing this method (Kiddoo, 2012). The following discussion of toilet training methods includes suggestions from the child-oriented approach.

Parents should begin the readiness phase of toilet training by teaching the child about how the body functions in relation to voiding and having a stool. Schmitt (2004) suggests that parents talk about how adults and animals perform such functions on a routine basis. Another suggestion is to make toilet training as easy and simple as possible. Important considerations are the selection of the child's clothing and the potty chair or use of the toilet. A freestanding potty chair allows children a feeling of security (Fig. 32-5, *A*). Planting the feet firmly on the floor also facilitates defecation. Another option is a portable seat attached to the regular toilet, which may ease the transition from potty chair to regular toilet. Placing a small bench under the feet helps stabilize the child's position. It is probably best to keep the potty in the bathroom and let the child observe the excreta being flushed down the toilet to associate these activities with usual practices. If a potty chair is not available, having the child sit facing the toilet tank provides added support (Fig. 32-5, *B*). Practice sessions should be limited to 5 to 8 minutes; a parent should stay with the child, practicing sanitary habits after every session. Children should be praised for cooperative behavior and successful evacuation. Dressing children in easily removed clothing; using training pants, "pull-on" diapers, or underwear; and encouraging imitation by watching others are other helpful suggestions.

When the child begins to experience regular daytime dryness, parents may experiment with underwear during the day. Daytime accidents are common, particularly during periods of intense activity. Young children become so engrossed in play activity that, if they are not reminded, they will wait until it is too late to reach the bathroom. Therefore frequent reminders and trips to the toilet are necessary. Parents often forget to plan ahead when their toddlers are being toilet trained; before trips outside the house it is important to remind children to at least try to urinate to decrease the chance of needing to use the toilet while the car is stuck in traffic.

As the child masters each step of toileting (discussion, undressing, going, wiping, dressing, flushing, and hand washing), he or she gains a sense of accomplishment that parents should reinforce. If the parent-child relationship becomes strained, both may need a break to focus on enjoyable activities together. Regression may coincide

*A helpful book is *Guide to Toilet Training*, available from the AAP, 847-434-4000; www.aap.org/bookstore. Additional resources are listed in the Schmitt (2004) reference.

FIG 32-5 **A,** Children may begin toilet training sitting on a small potty chair. **B,** Sitting in reverse fashion on a regular toilet provides additional support to a young child. (**A,** Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

with a stressful family situation or the child being pushed too hard and too fast. It is a normal part of toilet training and does not mean failure but should be viewed as a temporary setback to a more comfortable place for the child.

Day care providers also play a role in the support and education of parents regarding toilet training practices. It is important for parents to inform all caregivers of their individual family values and the child's specific needs when planning for training away from home. Ensuring consistency in care of toddlers and healthy practices in a sanitary environment allow for safe and effective toilet practices in all settings.

Sibling Rivalry

The natural jealousy and resentment of children to a new child in the family is referred to as *sibling rivalry.* The arrival of a new infant represents a crisis for even the best-prepared toddlers. It is not the infant that toddlers resent but the changes that this additional sibling produces, especially the separation from mother during the birth. The parents now share their love and attention with someone else, the usual routine is disrupted, and toddlers may lose their crib or room, all at a time when they thought they were in control of their world. Sibling rivalry tends to be most pronounced in the firstborn, who experiences *dethronement* (i.e., loss of sole parental attention). It also seems to be most difficult for young children, particularly in terms of mother-child interaction.

Preparation of children for the birth of a sibling is individual, but age dictates some important considerations. Time for toddlers is a vague concept. Tomorrow could be yesterday or next week, and a month from now could be never. Preparing children too soon for the birth may lessen their interest by the time the event occurs. A good time to start talking about the new baby is when the toddler becomes aware of the pregnancy and the changes taking place in the home in anticipation of the new member.

Toddlers need to have a realistic idea of what the newborn will be like. Telling them that a new playmate will come home soon sets up unrealistic expectations. Rather parents should stress the activities that will take place when the baby arrives home such as diapering, bottle-feeding or breastfeeding, bathing, and dressing. At the same time parents should emphasize which routines will stay the same such as reading stories or going to the park. The disruption of the toddler's routine is significant but can be restored with some effort by the parents. It may be helpful for the father to spend more quality time with the toddler in the evening in anticipation of the mother's time being occupied with the new baby. If toddlers have had no contact with an infant, it is a good idea to introduce them to one if feasible.

A new sibling in the home is stressful; thus any additional stresses for the toddler should be avoided or minimized. For example, moving the toddler to a regular bed or a different room should be done well in advance of the infant's arrival.

Pregnancy is an abstraction for toddlers. They need concrete illustrations of how the baby is growing inside the mother. It is an excellent opportunity for introducing aspects of reproduction and sexuality. Seeing simple pictures of the uterus and fetus and feeling the fetus move help the child feel involved in the experience (see Fig. 8-3). Children also benefit from classes for siblings that may be part of prenatal sessions (see Fig. 8-4).

When the newborn arrives, toddlers keenly feel the changed focus of attention. Visitors may initiate problems when they inadvertently shower the infant with attention and presents while neglecting the older child. Parents can minimize this by alerting visitors to the toddler's needs and including the child in the visits as much as possible. The toddler can also help with the care of the newborn by getting diapers and doing other small tasks (Fig. 32-6).

How children exhibit jealousy is complex. Some overtly hit the infant, push the child off the mother's lap, or pull the bottle or breast from the infant's mouth. For this reason infants must be protected by parental supervision of the interaction between the siblings. More often the expressions of hostility and resentment are more subtle and covert. Toddlers may verbally express a wish that the infant "go back inside mommy"; or they revert to more infantile forms of behavior such as demanding a bottle, soiling their underpants, clinging for attention, using baby talk, or aggressively acting out toward others.

Temper Tantrums

Toddlers may assert their independence by violently objecting to discipline. They may lie down on the floor, kick their feet, and scream as loud as possible. Some have learned the effectiveness of holding their breath until the parent relents. Although holding one's

FIG 32-6 To minimize sibling rivalry, parents should include the toddler during caregiving activities.

breath may cause fainting from lack of oxygen, the accumulation of carbon dioxide stimulates the respiratory control center, resulting in no physical harm. Rarely breath-holding spells can involve symmetric tonic-clonic movements, which can be frightening to parents; the child recovers quickly when the spell is over, and there is no residual damage (Stein, 2003). Tantrums are an indication of the child's inability to control emotions; toddlers are particularly prone to tantrums because their strong drive for mastery and autonomy is frustrated by adult figures or lack of motor and cognitive skills (Needlman, Howard, and Zuckerman, 1995).

The best approach toward tapering temper tantrums requires consistency and developmentally appropriate expectations and rewards. Ensuring consistency among all caregivers in expectations, prioritizing which rules are important, and developing consequences that are reasonable for the child's level of development help manage the behavior. For example, a popular time for a tantrum is before bed; mealtime is also a common time for temper tantrums to occur (Luangrath and Hiscock, 2011). Active toddlers often have trouble slowing down and, when placed in bed, resist staying there. Parents can reinforce consistency and expectations by stating, "After this story it is bedtime." Starting at 18 months timeouts work well for managing temper tantrums. One key to handling the child's behavior is to demonstrate consistency in dealing with both the behavior and the situation that seemingly precipitated the tantrum; inconsistency reinforces the negative behavior because the child cannot cognitively comprehend the ambiguous messages being received from the parents. Another favorite time for temper tantrums is in the store, especially at the end of the day when the child is tired. Avoid the "set up" for a negative outcome by recognizing the child's limitations and work around the situation for a positive outcome.

During tantrums ignore the behavior, provided it is not injurious to the child such as violently banging the head on the floor. Continue to be present to provide a feeling of control and security to the child once the tantrum has subsided. (See also Limit Setting and Discipline, Chapter 27.) When the child starts demonstrating appropriate behavior, provide positive feedback about that behavior. During periods of no tantrums practice developmentally appropriate positive reinforcement.

Other suggestions for handling tantrums include (Needlman, Howard, and Zuckerman, 1995):

- Offering the child options instead of an "all or none" position.
- Picking one's battles carefully and ignoring small skirmishes over unimportant issues.
- Giving comfort once the child is able to control emotions but not giving in to the original request.
- Praising the child for positive behavior when he or she is not having a tantrum.

Temper tantrums are common during the toddler years and essentially represent normal developmental behaviors. However, they can be signs of serious problems. Nurses should be alert to situations that require further evaluation.

Negativism

One of the more difficult aspects of rearing children in this age-group is their persistent "no" response to every request. The negativism is not an expression of being stubborn or insolent but a necessary assertion of self-control. Children test limits to gain understanding of the world and to learn to modify their behavior to fit the expectations of society. Negativism begins to subside as most children prepare to enter kindergarten.

One method of dealing with the negativism is to reduce the opportunities for a "no" answer. Asking the child, "Do you want to go to sleep now?" is an example of a question that will almost certainly be answered with an emphatic "no." Instead, tell the child that it is time to go to sleep and proceed accordingly. In their attempt to exert control, children like to make choices. When confronted with appropriate choices such as, "You may have a peanut butter and jelly sandwich or chicken noodle soup for lunch," they are more likely to choose one rather than automatically say no. However, if their response is negative, parents should make the choice for the child.

Nurses working with children and parents can help parents understand this concept by role modeling. For example, when the nurse approaches the toddler to take vital signs, instead of asking, "Can I listen to your heart?" the nurse can say, "I'm going to listen to your heart." Because of normal developmental behavior, toddlers vigorously resist first attempts at taking vital signs because it is an intrusion on their bodies. Second, they are most likely going to answer "no," not because they necessarily fear the procedure itself but because of the tendency to answer all questions with a negative response. If the nurse asks the question, and the toddler says, "No," but the nurse proceeds anyway, the toddler starts to mistrust the nurse's actions because they contradict his or her words.

Regression

The retreat from one's present pattern of functioning to past levels of behavior is referred to as *regression*. It usually occurs in instances of discomfort or stress when one attempts to conserve psychic energy by reverting to patterns of behavior that were successful in earlier stages of development. Regression is common in toddlers because almost any additional stress hinders their ability to master present developmental tasks. Any threat to their autonomy such as illness, hospitalization, separation from parents, or adjustment to a new sibling represents a need to revert to earlier forms of behavior such as increased dependency; refusal to use the potty chair; temper

tantrums; demand for the bottle, stroller, or crib; and loss of newly learned motor, language, social, and cognitive skills.

At first such regression appears acceptable and comfortable for children, but the loss of newly acquired achievements is actually frightening and threatening because they are aware of their helplessness. Parents become concerned about regressive behavior and often, in their efforts to deal with it, force the child to cope with an additional source of stress (i.e., the pressure to live up to expected standards). Brazelton (1999) suggests that these predictable times of regression, or *touchpoints,* are an opportunity to prepare parents for the next step in their child's development.

When regression does occur, the best approach is to ignore it while praising existing patterns of appropriate behavior. Regression is a child's way of saying, "I can't cope with this present stress and perfect this skill as well, but I will if given patience and understanding." For this reason it is advisable not to attempt new areas of learning when an additional crisis is present or expected such as beginning toilet training shortly before a sibling is born or attempting new areas of learning during a brief period of hospitalization.

PROMOTING OPTIMAL HEALTH DURING TODDLERHOOD

Nutrition

During the period from 12 to 18 months of age the growth rate slows, decreasing the child's need for calories, protein, and fluid. However, the protein (13 g/day) and energy requirements are still relatively high to meet the demands for muscle tissue growth and high activity level. The need for minerals such as iron, calcium, and phosphorus may be difficult to meet, considering the characteristic food habits of children in this age-group. Parents may be tempted to rely on vitamin supplementation rather than a well-balanced diet to meet these requirements. Toddlers usually require three meals and two snacks per day; however, the portions consumed are generally much smaller compared with those of older children.

The 2008 Feeding Infants and Toddlers Study (FITS) (Butte, Fox, Briefel, et al., 2010) found that in general toddlers met or exceeded the requirements for daily energy and protein requirements. The FITS recommended that toddlers be fed a more balanced diet of vegetables, fruits, and whole grains.

At approximately 18 months of age most toddlers manifest this decreased nutritional need with a decreased appetite, a phenomenon known as **physiologic anorexia.** They become picky, fussy eaters with strong taste preferences. They may eat large amounts one day and almost nothing the next. They are increasingly aware of the nonnutritive function of food (i.e., the pleasure of eating, the social aspect of mealtime, and the control of refusing food). They are influenced by factors other than taste when choosing food. If a family member refuses to eat something, toddlers are likely to imitate that response. If the plate is overfilled, they are likely to push it away, overwhelmed by its size. If food does not appear or smell appetizing, they will probably not agree to try it. In essence mealtime is more closely associated with psychologic rather than nutritional components.

The ritualism of this age also dictates certain principles in feeding practices. Toddlers like to have the same dish, cup, or spoon every time they eat. They may reject a favorite food simply because it is served in a different dish. If one food touches another, they often refuse to eat it. Mixed foods such as stews or casseroles are rarely favorites. Because toddlers have unpredictable table manners, it is best to use plastic dishes and cups for both economic and safety reasons. For some children a regular mealtime schedule also contributes to their desire and need for predictability and ritualism.

Developmentally by 12 months of age most children eat many of the same foods prepared for the rest of the family. Some may have mastered using a cup with occasional spilling, although most cannot use a spoon adeptly until 18 months of age or later and generally prefer using their fingers.

Nutritional Counseling

The emphasis on preventing childhood obesity and subsequent cardiovascular disease in the United States has prompted a number of changes in dietary recommendations for children and adults alike. It is now recognized that lifetime eating habits may be established in early childhood; and health care workers are increasingly emphasizing the role of food selection choices, exercise, stress reduction, and other lifestyle choices (tobacco and alcohol use) on the quality of adult life and survival. Conditions such as obesity and cardiovascular disease can be prevented by encouraging healthy eating habits in toddlers and their families.

If food is used as a reward or sign of approval, a child may overeat for nonnutritive reasons. If food is forced and mealtime is consistently unpleasant, the usual pleasure associated with eating may not develop. Mealtimes should be enjoyable rather than times for discipline or family arguments. The social aspect of mealtime may be distracting for young children; therefore an earlier feeding hour may be appropriate. Young children are unable to sit through a long meal and become restless and disruptive. This is particularly common when children are brought to the table just after active play. Calling them in from play 15 minutes before mealtime allows them ample opportunity to get ready for eating while settling down their active minds and bodies.

The method of serving food also takes on more importance during this period. Toddlers need to have a sense of control and achievement in their abilities. Giving them large, adult-size portions can overwhelm them. In general, what is eaten is much more significant than how much is consumed. Toddlers usually restrict their food preference to four or five main foods and rarely try new foods; in some cases a toddler may insist on one food such as mashed potatoes for lunch and dinner. Small amounts of meat and vegetables supply greater food value than a large consumption of bread or potato. Serving sizes need to be appropriate for age. Young children tend to like less spicy, bland food, although this is a culturally determined preference. Substitutions can be provided for foods that they do not enjoy, although parents need not cater to all of their desires. Frequent nutritious snacks can replace a meal. Grazing (i.e., nibbling and snacking) is a good way to ensure proper nutrition, provided that appropriate foods are offered.

To determine serving size for young children, use the following guidelines:

- A general guide to the serving size of food is 1 tbsp of solid food per year of age, or one fourth to one third of the adult portion size.
- Use the tablespoon guide for easily measured foods such as vegetables or rice.
- Use the fraction guide for bread or milk.

Mastication skills continue to mature, putting children at risk for choking; therefore large round foods (e.g., hot dogs, grapes, peas, carrots, popcorn, fruit gel snacks) should be avoided until the child is able to chew them effectively. Active play while eating should be discouraged to prevent choking. Appetite and food preferences are sporadic. Often the interest in food parallels a growth spurt; thus periods of good eating are interspersed with phases of poor eating.

If exposed to the same food every day, a young toddler does not learn how to manage the complex sensory information needed to eat new, more difficult foods (e.g., vegetables with a different texture versus pureed, slippery fruits). To help prevent "food jags" it is recommended that parents present food in various physical forms. The child may need to progress to eating new foods in a stepwise fashion such as visually tolerating the food, interacting with it, smelling it, touching it, tasting it, and then eating it.

This period of picky eating can be trying for both parents and child. Many authorities consider it to be a developmental phase and stress that most toddlers will consume the necessary amount of food required for growth (Cathey and Gaylord, 2004). It has also been suggested that parents plan a nutritionally balanced week instead of day because of the way toddlers restrict food intake in their effort to exert control over their environment (Morin, 2007).

Dietary Guidelines

Dietary guidelines are necessary to promote adequate energy and nutrient intake to support physical, emotional, psychologic, and cognitive development. A number of new dietary guidelines have been developed to address the issues of childhood obesity, sedentary lifestyles, and increase in cardiovascular disease mortality in the United States.

The Institute of Medicine (IOM) (2005) has developed guidelines for nutritional intake that encompass the Recommended Daily Allowances (RDAs) yet extend their scope to include additional parameters related to nutritional intake. The Dietary Reference Intakes (DRIs)* are composed of four categories: estimated average requirements (EARs) for age and gender categories, tolerable upper-limit (UL) nutrient intakes that are associated with a low risk of adverse effects, adequate intakes (AIs) of nutrients, and new standard RDAs. The guidelines present information about lifestyle factors that may affect nutrient function such as caffeine intake and exercise and about how the nutrient may be related to chronic disease. An important factor in the development of the DRIs that affects children, particularly infants from birth to age 6 months, is that the AIs are based on the nutrient intake of full-term, healthy, breastfed infants (by well-nourished mothers), which now represents the gold standard for infant nutrition in this age-group. In 2010 new DRIs for vitamin D and calcium were released by the IOM.

The 2010 Dietary Guidelines for Americans may also be used to encourage healthy dietary intakes and regular exercise designed to decrease obesity, cardiovascular risk factors, and subsequent cardiovascular disease, which is now known to occur in both young children and adults. They recommend a caloric intake for a moderately active boy, ages 2 to 3 years, of 1000 to 1400 calories per day. The emphasis in the Dietary Guidelines is in decreasing overall fat and sodium intakes and increasing the amount of daily exercise to reduce the incidence of obesity and cardiovascular disease. The 2010 Dietary Guidelines† are for children ages 2 years and older. They encourage a variety of fruits, vegetables, whole grains, and low-fat and nonfat dairy products in addition to fish, beans, and lean meat.

Additional resources for dietary counseling include MyPlate,‡ recently developed by the U.S. Department of Agriculture to replace MyPyramid. This colorful plate shows the five main food groups (i.e., fruits, grains, vegetable, protein, and dairy) with the intended purpose to involve children and their families in making appropriate food choices for meals and decrease the incidence of overweight and obesity in the United States. MyPlate provides an online interactive feature that allows the individual to select (click on) an individual food group and see choices for foods in that group. Approximate serving sizes are suggested, and vegetarian substitutions are also provided.

Nutrition during toddlerhood involves a transition as a young toddler is weaned off milk- or formula-based diets. Milk intake, the chief source of calcium and phosphorus, should average two or three servings (24 to 30 oz) a day. Consuming more than a quart of milk daily considerably limits the intake of solid foods, resulting in a deficiency of dietary iron and other nutrients. After 2 years of age children can be given low-fat milk to reduce daily total fat to less than 30% of calories, saturated fatty acids to less than 10% of calories, and cholesterol to less than 300 mg. Other measures to reduce dietary fat include using lean meats, fat-modified products (e.g., low-fat cheese), and low-fat cooking. Because less fat in children's diets can also mean fewer calories and nutrients, caregivers must know what kinds of food to choose. However, *trans* fatty acids and saturated fats should be avoided.

Iron-fortified cereals and iron-rich foods are recommended for all children older than 6 months of age. Parents should be encouraged to provide an iron-rich diet that includes heme and nonheme iron sources (red meats, poultry, fish, green leafy vegetables, dried fruit, beans) and limits whole-milk consumption. Iron supplementation may be necessary in some cases (see Community Focus, p. 882).

Calcium and vitamin D are essential for healthy bone development. An AI of calcium for children 1 to 3 years of age is 500 mg/day. Whole milk, cheese, yogurt, legumes (beans), and vegetables (broccoli, collard greens, kale) are good sources for calcium. Popular calcium-fortified foods include waffles, cereals and cereal bars, orange juice, and some white breads. Adequate vitamin D intake is essential to prevent rickets; it is now recommended that children and adolescents have an intake of at least 400 IU of vitamin D daily (AAP, 2008). Multivitamin preparations containing 400 IU of vitamin D (by tablet or liquid) are adequate if food intake is poor or exposure to sunlight is minimal; vitamin D–only preparations containing 400 IU are also available commercially (Wagner, Greer, and AAP Section on Breastfeeding and Committee on Nutrition, 2008). Sources of vitamin D include fish, fish oils, and egg yolks. Fortified cereals, dairy products, and meat are also good sources of zinc and vitamin E.

It is also recommended that toddlers have 1 cup of fruit each day. Vitamin C enhances iron absorption. Toddlers should consume approximately 4 to 6 oz of juice per day. It tastes good to toddlers and is readily available. A 6-oz glass of fruit juice equals one fruit serving; however, juices lack the fiber of whole fruit and should not be a substitution for whole fruit. High intake of juice can contribute to diarrhea, overnutrition or undernutrition, and the development of caries; thus only 4 to 6 oz of 100% fruit juice per day is recommended for toddlers (AAP Committee on Nutrition, 2009). Fruit-flavored drinks advertised as juices may not actually contain 100% juice and should be avoided.

Vegetarian Diets

Vegetarian diets have become increasingly popular in the United States because people are concerned about hypertension; cholesterol; obesity; cardiovascular disease; cancer of the stomach, intestine, and colon; and the influence of the animal rights movement. The American Dietetic Association and Dietitians of Canada (2003) issued a statement endorsing vegetarian diets for adults and

*www.iom.edu/Activities/Nutrition/SummaryDRIs/DRI-Tables.aspx.
†www.cnpp.usda.gov/DietaryGuidelines.htm.
‡www.choosemyplate.gov/.

children; the statement further notes that well-planned vegetarian diets are adequate for all stages of the life cycle and promote normal growth. Children and adolescents on vegetarian diets have the potential for lifelong healthy diets and have been shown to have lower intakes of cholesterol, saturated fat, and total fat and higher intakes of fruits, fiber, and vegetables than nonvegetarians (American Dietetic Association and Dietitians of Canada, 2003). In 2009 the American Dietetic Association published another position paper supporting vegetarian diets in pregnancy, infancy, and childhood, indicating that vegetarian diets in childhood do not result in lower stature. However, the ADA does emphasize that vegetarian diets may vary considerably and that assessment of dietary adequacy is essential to ensure children are receiving adequate nutrients (Craig, Mangels, and American Dietetic Association, 2009).

The major types of vegetarianism are:

- Lacto-ovo vegetarians, who exclude meat from their diet but consume dairy products and rarely fish
- Lactovegetarians, who exclude meat and eggs but drink milk
- Pure vegetarians (vegans), who eliminate all foods of animal origin, including milk and eggs
- Macrobiotics, who are even more restrictive than pure vegetarians, allowing only a few types of fruits, vegetables, and legumes
- Semi-vegetarians, who consume a lacto-ovo vegetarian diet with some fish and poultry. This is an increasingly popular form of vegetarianism and poses little or no nutritional risk to infants unless dietary fat and cholesterol intake is severely restricted.

Many individuals who are concerned about healthy diets subscribe to vegetarian diets that may not be typified by the previous categories. Therefore during nutritional assessment it is necessary to clearly list exactly what the diet includes and excludes.*

The major deficiencies that may occur in the stricter vegan diets are inadequate protein for growth; inadequate calories for energy and growth; poor digestibility of many of the bulky natural, unprocessed foods, especially for infants; and deficiencies of vitamin B_6, niacin, riboflavin, vitamin D, iron, calcium, and zinc. Vitamin D is essential if exposure to sunlight is inadequate (≅5 to 15 min/day on the hands, arms, and face of light-skinned persons; slightly more in darker-pigmented individuals) or in people who are dark skinned or who live in northern latitudes or cloudy or smoky areas. Many of these deficiencies can be avoided with a multivitamin and mineral supplement in children who are not consuming 100% of the RDA of vitamins and minerals (Dunham and Kollar, 2006).

Evaluate for iron-deficiency anemia and rickets in children on strict vegetarian and macrobiotic diets; this may occur as a result of consuming plant foods such as unrefined cereals, which impair the absorption of iron, calcium, and zinc. The American Dietetic Association and Dietitians of Canada (2003) and AAP Committee on Nutrition (2009) recommend iron supplementation of 1 mg/kg/day in infants exclusively breastfed after 4 to 6 months of age by vegetarian mothers and no dietary fat restrictions in vegetarian children younger than age 2 years. Other factors that affect iron absorption are listed in Box 32-2.

Achieving a nutritionally adequate vegetarian diet is not difficult (except with the strictest diets), but it requires careful planning and knowledge of nutrient sources (AAP Committee on Nutrition, 2009). For children the lacto-ovo vegetarian diet is nutritionally adequate; however, the vegan diet requires supplementation with vitamins D and B_{12} for children ages 2 to 12 years.

To ensure sufficient protein in the diet, foods with incomplete proteins (i.e., those that do not have all the essential amino acids) must be eaten at the same meal with other foods that supply the missing amino acids. The three basic combinations of foods consumed by vegetarians that generally provide the appropriate amounts of essential amino acids follow:

1. Grains (cereal, rice, pasta) and legumes (beans, peas, lentils, peanuts)
2. Grains and milk products (milk, cheese, yogurt)
3. Seeds (sesame, sunflower) and legumes

*Additional information regarding vegetarian diets may be found at the Vegetarian Resource Group; 410-366-8343; www.vrg.org. Another helpful resource for adolescents and parents is the KidsHealth website: kidshealth.org/parent/nutrition_center/dietary_needs/vegetarianism.html.

BOX 32-2 FACTORS THAT AFFECT IRON ABSORPTION

Increase

- Acidity (low pH)—Administer iron between meals (gastric hydrochloric acid).
- Ascorbic acid (vitamin C)—Administer iron with juice, fruit, or multivitamin preparation.
- Vitamin A
- Tissue (cellular) need
- Meat, fish, poultry
- Cooking in cast iron pots

Decrease

- Alkalinity (high pH)—Avoid any antacid preparation.
- Phosphates—Milk is unfavorable vehicle for iron administration.
- Phytates—Found in cereals
- Oxalates—Found in many fruits and vegetables (plums, currants, green beans, spinach, sweet potatoes, tomatoes)
- Tannins—Found in tea, coffee
- Tissue (cellular) saturation
- Malabsorptive disorders
- Disturbances that cause diarrhea or steatorrhea
- Infection
- Calcium (possibly dose-dependent, therefore some recommend taking calcium supplements at bedtime and limiting dietary calcium intake to 300 mg or less at each meal [Hallberg, 1998]; long-term calcium supplementation has no effect on iron absorption [Lönnerdal, 2010])

Complementary and Alternative Medicine

There are four complementary and alternative medicine (CAM) domains according to the National Center for Complementary and Alternative Medicine (NCCAM); this discussion centers only on one of those biologically based practices that include herbs, vitamins, and foods. The NCCAM (2010) classifies probiotics as a type of natural product and CAM. Many CAM products are sold over the counter as dietary supplements, but the use of some dietary supplements such as calcium for bone health or a multivitamin supplement are not considered to be CAM (NCCAM, 2010). The NCCAM (2010) reports that natural products are the most commonly used CAM products in children and most often these products are used for chronic conditions such as neck and back pain and for head and chest colds. Other surveys confirm that CAM is often used for children's chronic remedies for which traditional therapy is not effective (Huillet, Erdie-Lalena, Norvell, et al., 2011).

The misuse of vitamins as a part of CAM has the potential for placing some children at risk for health problems. Sawni,

Ragothaman, Thomas, et al. (2007) noted that of people reportedly using CAM, the most common CAM remedies used in children seen in the emergency department were home or folk remedies (59%), herbs (41%), prayer for healing (14%), and massage therapy (10%). A survey in a Women, Infants, and Children (WIC) clinic found that child herbal use was common, especially among Hispanic children attending the clinic. Some of the herbs used by the children in the survey (St. John's wort, dong quai, and kava) have questionable safety (Lohse, Stotts, and Priebe, 2006). A recent study of CAM use in children on a military base found that 23% of parents reported using CAM in their children, with herbal therapy being the most common type of CAM reported; 50% of the parents who used CAM for their children reported the use of vitamins and minerals in amounts that exceeded the RDA (Huillet, Erdie-Lalena, Norvell, et al., 2011).

There is concern that terms often used to market supplements such as megavitamins may mislead parents regarding the actual benefits (or harm) of such therapies. The intention herein is not to discredit the use of CAM such as vitamin supplements; rather it is to ensure safety and efficacy in children who may experience inadvertent harm. The use of various herbal therapies, or intake of herbs, is also becoming more popular; many of these have been a part of medicine since early days and are beneficial in some cases. Many mind-body CAM therapies (e.g., guided imagery, distraction) have proved beneficial for children undergoing cancer treatment, but the small sample sizes of the groups being studied may preclude generalization to a larger population group until further studies are undertaken (Landier and Tse, 2010).

Herbs known to have adverse effects in children include ephedra, comfrey, and pennyroyal; some herbs may not be harmful taken alone but may counteract or potentiate prescription medications when taken together. Parents should be fully informed of the use of herbs to ensure that there is more benefit than potential harm in the ingredients being used. Health care workers also need to be knowledgeable of the benefits or potential harm in herbs to counsel parents and address their concerns appropriately. Little research has been performed in children on many over-the-counter (OTC) herbal medicines, yet some herbs are known to cause harm (Gardiner and Kemper, 2011; Lanski, Greenwald, Perkins, et al., 2003; Loman, 2003). Parents should be cautioned not to exceed the ULs of vitamin intake according to the new DRIs (see p. 935).*

Sleep and Activity

Total sleep decreases only slightly during the second year and averages about 11 to 12 hours a day. Most children take one nap a day but may relinquish this habit by the end of the second or third year. Children reach an adult pattern of sleep by 3 to 4 years of age.

Sleep problems are common, especially going to bed and falling asleep, and are a response to fears and awareness of separation. Toddlers are more prone to having bedtime resistance (refusal to go to bed) and frequent night waking; during later toddlerhood this group of children may become more resistant about going to bed and express fears about monsters (Meltzer and Mindell, 2006). Sleep problems, especially going to bed and falling asleep, are common and probably related to fears of separation. Fears can be provoked by a child's daily stressors such as pressure to toilet train, moves, sibling birth, experiences of loss, or separation from parents. Establishing a regular bedtime and routine before bedtime is helpful, and providing transitional objects such as a favorite stuffed animal or blanket can ease the child's insecurity at bedtime (see Fig. 32-3). Children may need a light snack before bedtime; a heavy meal immediately before bedtime may interfere with sleep. Other suggestions to help small children sleep better include keeping the television out of the child's room, making the hour before bedtime a quiet time of reading stories, and avoiding stimulating activities such as computer games and roughhousing (Owens, 2011). Toddlers no longer sleeping in a crib may come out of their rooms after being put to bed. Limit prolonged bedtime rituals by defining a length of time and set of activities (one more story, one more drink of water). Toddlers who are too immature to respond to the measures identified may need their doorways gated.

A toddler's activity level is high, and there is rarely a problem with too little physical exercise, provided inappropriate restrictions are not instituted. However, recently there has been concern that decreased time spent in actual physical play and more time involved with computers and television watching have increased the tendency toward being overweight. This is especially true in large urban centers during the winter months where there may not be adequate "safe" play and physical exercise space. With increasing numbers of young children being cared for outside the home, attention to the kinds of activity provided is important. For example, children with high activity levels may benefit from an environment that encourages vigorous play, whether outside or in a large indoor play area.

Sleep Problems

A number of sleep problems are identified in small children. The two major categories are the dyssomnias: the child has trouble either falling or staying asleep at night or has difficulty staying awake during the day. The second category, parasomnias, is characterized as confusional arousals, sleepwalking, sleep terrors, nightmares, and rhythmic movement disorders; these typically occur in children 3 to 8 years old (Ward, Rankin, and Lee, 2007) and decline in incidence as the child matures (Davis, Parker, and Montgomery, 2004). This discussion focuses on minor sleep issues in toddlers such as refusal to go to sleep and frequent waking during the night (Table 32-2). Other sleep disturbances such as obstructive sleep-disordered breathing and sleep terrors are discussed elsewhere in this text.

Concerns regarding sleep are common during infancy. Sometimes these concerns are as basic as parents' questioning whether the infant needs additional sleep. In this case it is best to investigate the reason for their concern, stressing the individual needs of each child. Infants who are active during wakeful periods and growing normally are sleeping a sufficient amount of time.

When a sleeping problem is presented, a careful assessment is essential. Charting sleep habits both before and after interventions is also an important strategy. Questions regarding the frequency and duration of waking, the usual bedtime routine, the number of nighttime feedings, the perceived problem (e.g., how much disruption the behavior generates), and the attempted interventions are important in planning effective approaches designed for the specific sleep problem.

One suggestion given for any type of sleep problem, "Let the child cry until he or she falls asleep," is very difficult to implement and is inappropriate for certain conditions. After the parents relent and console the child, they have only reinforced the crying. This approach is called the *extinction method* and is still used by some; parental consistency is essential for this approach (Moore, Meltzer, and Mindell, 2008).

TABLE 32-2 SELECTED SLEEP DISTURBANCES DURING INFANCY AND EARLY CHILDHOOD

CONDITION AND DESCRIPTION	MANAGEMENT
Nighttime Feeding	
Child has prolonged need for middle-of-night bottle or breastfeeding. Child goes to sleep at breast or with bottle. Awakenings are frequent (may be hourly). Child returns to sleep after feeding; other comfort measures (e.g., rocking or holding) are usually ineffective.	Increase daytime feeding intervals to 4 hours or more (may need to be done gradually). Offer last feeding as late as possible at night; may need to gradually reduce amount of formula or length of breastfeeding. Offer no bottles in bed. Put to bed awake. When child is crying, check at progressively longer intervals each night; reassure child but do not hold, rock, take to parent's bed, or give bottle or pacifier.
Developmental Nighttime Crying	
Child age 6-12 months with undisturbed nighttime sleep now awakens abruptly; may be accompanied by nightmares.	Reassure parents that this phase is temporary. Enter room immediately to check on child but keep reassurances brief. Avoid feeding, rocking, taking to parent's bed, or any other routine that may initiate trained nighttime crying.
Refusal to Go to Sleep	
Child resists bedtime and comes out of room repeatedly. Nighttime sleep may be continuous, but frequent awakenings and refusal to return to sleep may occur and become a problem if parent allows child to deviate from usual sleep pattern.	Evaluate if hour of sleep is too early (child may resist sleep if not tired). Help parents establish consistent before-bedtime routine and enforce consistent limits regarding child's bedtime behavior. If child persists in leaving bedroom, close door for progressively longer periods. Use reward system with child to provide motivation.
Trained Nighttime Crying (Inappropriate Sleep Associations)	
Child typically falls asleep in place other than own bed (e.g., rocking chair or parent's bed) and is brought to own bed while asleep; on awakening, cries until usual routine is instituted (e.g., rocking).	Put child in own bed when awake. If possible, arrange sleeping area separate from other family members. When child is crying, check at progressively longer intervals each night; reassure child but do not resume usual routine.
Nighttime Fears	
Child resists going to bed or wakes during night because of fears. Child seeks parent's physical presence and falls asleep easily with parent nearby unless fear is overwhelming.	Evaluate if hour of sleep is too early (child may fantasize when nothing to do but think in dark room). Calmly reassure frightened child; keeping night light on may be helpful. Use reward system with child to provide motivation to deal with fears. Avoid patterns that can lead to additional problems (e.g., sleeping with child or taking child to parent's room). If child's fear is overwhelming, consider desensitization (e.g., progressively spending longer periods of time alone; consult professional help for protracted fears). Distinguish between nightmares and sleep terrors (confused partial arousals).

Modified from Ferber R: Behavioral "insomnia" in the child, *Psychiatr Clin North Am* 10(4):641–653, 1987.

Another approach to night crying is known as graduated extinction. This involves letting the child cry for progressively longer times between brief parental interventions that consist only of reassurance—not rocking, holding, or using a bottle or pacifier. For example, the parents may check on the child every 5 minutes (of crying) during the first night and progressively extend this interval by 5 minutes on successive nights.

Families that cannot tolerate unexpected crying spells while everyone else is asleep can try the two-step approach. Graduated extinction is used during naps and at bedtime until the parents retire for the night. If the child cries during the night, the parents use comforting measures. However, after the child is partially trained, step 2 is initiated (i.e., the use of graduated extinction at all times).

Another approach includes the positive routine and faded bedtime. In this approach the parents schedule some quiet activities close to bedtime to calm the child for approximately 20 minutes and then place him or her to sleep. Gradually the bedtime is moved 10 to 15 minutes earlier until a suitable time is set. This approach requires parental consistency and cooperation (Moore, Meltzer, and Mindell, 2008). It is appropriate for toddlers who thrive on rituals and routines. Additional methods for dealing with specific sleep problems may be found in the Moore, Meltzer, and Mindell (2008) reference.

Children who learn to fall asleep on their own at bedtime have longer sustained sleep periods than those who fall asleep with a parent present (Davis, Parker, and Montgomery, 2004). In addition, comforting children outside their own bed at night when they awaken was associated with poor sleep consolidation. Feeding 5-month-old infants after awakening at night has been associated with fewer consecutive sleep hours (Touchette, Petit, Paquet, et al., 2005). The authors of this study recommend parental presence at

bedtime until the child is drowsy and then placing the child in his or her own bed for a night's sleep.

The best way to prevent sleep problems is to encourage parents to establish bedtime rituals that do not foster problematic patterns. One of the most constructive is placing infants awake in their own crib. When infants are accustomed to falling asleep somewhere else such as in their parent's arms and then being transferred to their crib, they awaken in unfamiliar surroundings and are unable to fall asleep until the routine is repeated. In addition, the bed should be used for sleeping only—not as a play yard. It is advisable not to hang playthings over or on the bed so the child associates the bed with sleep and not with activity. Although the interventions described previously and in Table 32-2 are usually successful, it is much easier to prevent the problem with appropriate counseling during the early months of the infant's life.

Dental Health

Regular Dental Examinations

The American Academy of Pediatric Dentistry (2011a) recommends that every child have an oral health examination by a practitioner by 6 months of age; if the child is in a high-risk category for caries, it is recommended that an initial visit to a dentist or pedodontist (pediatric dentist) occur by age 6 months or within 6 months of the eruption of the first tooth. Every child should have an established dental home by the age of 12 months (American Academy of Pediatric Dentistry, 2011a). Initial visits to the dentist should be nontraumatizing. Because toddlers react negatively to new and potentially frightening experiences, the initial visit can center around meeting the dentist, seeing the equipment, and sitting in the chair. If the child is cooperative, the dentist may just look at the teeth but reserve a more thorough examination for another visit. Modeling, in which the child observes procedures performed on the parent or a cooperative sibling, can also be effective but may not work on all toddlers.

Plaque Removal

Oral hygiene measures should be implemented according to the suggested schedule noted in the previous paragraph to remove plaque (i.e., soft bacterial deposits that adhere to the teeth and cause dental caries [decay or cavities] and periodontal [gum] disease). Poor oral hygiene and dietary habits are associated with the development of caries in children.

The most effective methods for plaque removal are brushing and flossing. Several brushing techniques exist, although there is no universal agreement regarding the best method. One that is suitable for cleaning the primary teeth is the scrub method. The tips of the bristles are placed firmly at a 45-degree angle against the teeth and gums and moved back and forth in a vibratory motion. The ends of the bristles should be wiggling but not moving forcefully back and forth, which can damage the gums and enamel. All the surfaces of the teeth are cleaned in this manner except the lingual (inner) surfaces of the anterior teeth. To clean these surfaces the toothbrush is placed vertical to the teeth and moved up and down. Only a few teeth are brushed at one time, using six to eight strokes for each section. A systematic approach is used so all surfaces are thoroughly cleaned (Fig. 32-7).

For young children the most effective cleaning is done by parents (Fig. 32-8). Several positions can be used that facilitate access to the mouth and help stabilize the head for comfort:

- Stand with the child's back toward the adult. (When done in front of a bathroom mirror, both the child and adult can see what is being done in the mirror.)

FIG 32-7 Young children can participate in toothbrushing, but parents need to brush all the child's teeth thoroughly. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

FIG 32-8 The most effective teeth cleaning is done by parents.

- Sit on a couch or bed with the child's head resting in the adult's lap.
- Sit on the floor or a stool with the child's head resting between the adult's thighs.

Use one hand to cup the chin and one to brush the teeth. For easier access to back teeth, hold the mouth partially open. After brushing with an appropriate amount of fluoridated paste or gel, avoid rinsing the mouth to maximize the beneficial effects of the fluoride (American Academy of Pediatric Dentistry, 2011b).

For effective cleaning a small toothbrush with soft, rounded, multitufted nylon bristles that are short and uniform in length is recommended. Nylon bristles dry more rapidly after use and retain their shape better than natural bristles. Toothbrushes are replaced as soon as the bristles are frayed or bent. With young children brushing may be accomplished more easily using only water because many children dislike the foam from toothpaste, and the foam interferes with visibility. Introduce toothpaste around 2 years of age and allow

TABLE 32-3 FLUORIDE SUPPLEMENTATION*

	WATER FLUORIDE CONTENT (PPM)	
AGE	**0.3**	**0.3–0.6**
Birth–6 months	0	0
6 months–3 years	0.25	0
3-6 years	0.50	0.25
6-16 years	1.00	0.50

*Fluoride daily doses are given in milligrams.
ppm, Parts per million.

children to select the flavor they like to encourage the brushing habit. Use a pea-size amount of toothpaste for children 2 to 5 years of age (apply across the narrow width of the toothbrush rather than along its length to decrease the chance of applying an excessive amount); only a "smear" of toothpaste should be used in children younger than 2 years of age if paste is used.

After the teeth have been cleaned, they are flossed to remove plaque and debris from between the teeth and below the gum margin, where brushing is ineffective. Because young children do not have the dexterity to manipulate dental floss, parents must perform the procedure.

Ideally the teeth should be cleaned after each meal and especially before bedtime, and the child should be given nothing to eat or drink after the night brushing except water. At times when brushing is impractical, the "swish-and-swallow" method of cleaning the mouth is taught; with a mouthful of water the child rinses the mouth and swallows, repeating the procedure 3 or 4 times.*

Fluoride

Fluoride supplementation should be considered for any child older than the age of 6 months whose drinking water is deficient in fluoride. Supplementation based on fluoride concentration of water supply less than 0.3 ppm (parts per million) is 0.25 mg for a child 6 months to 3 years of age and 0.5 mg for a child 3 to 6 years of age (American Academy of Pediatric Dentistry, 2011b).

Fluoride, a mineral, is found in water, foods, or drinks in which fluoridated water was used as part of the processing system. Because the water fluoridation process and manufacturing of fluoride toothpaste are almost impossible to standardize in the United States, the dosage of fluoride supplements has been lowered to reduce the incidence of fluorosis (Table 32-3). Increased fluoride ingestion leads to enamel protein retention, hypomineralization of the enamel and dentin, and disturbance of crystal formation. The effects caused by this change range from barely discernible white fiberlike lines or spots to gray-brown stains or pitted areas. Parents should be cautioned against regular use of fluoridated water or beverages such as bottled water containing fluoride if the community water supply already has an adequate amount of fluoride.

Topical fluoride treatments (e.g., fluoride varnish) performed in the dental home are also effective in decreasing caries (American Academy of Pediatric Dentistry, 2011b).

*More detailed information can be obtained from the American Academy of Pediatric Dentistry, *www.aapd.org*.

FIG 32-9 Nursing caries. Note extensive carious involvement of maxillary primary incisors. (Courtesy Bruce Carter, DDS, Texas Children's Hospital, Houston, TX.)

Dietary Factors

Diet is critical to developing good teeth because the carious process depends primarily on fermentable sugars, especially sucrose, and other carbohydrates. Refined table sugar, honey, molasses, corn syrup, and dried fruits such as raisins are highly cariogenic. Complex carbohydrates such as breads, potatoes, and pasta also contribute to caries because they lower the plaque pH. Beverages that are commonly consumed by children and adolescents and snacks are also highly cariogenic and may contribute to the incidence of overweight and obesity (American Academy of Pediatric Dentistry, 2011c).

Ideally highly cariogenic foods, especially those containing complex sugars, should be eliminated. However, because this is impractical some suggestions can be helpful. First, *the frequency with which sugar is consumed is more important than the total amount eaten.* Therefore, when sweets are eaten, they are less damaging if consumed immediately after a meal rather than as a snack between meals. When they are served as the dessert, the teeth can be cleaned afterward, decreasing the amount of time the sugar is in the mouth.

Second, the form of sugar (sucrose) is important. The more cariogenic foods are those that are sticky or hard because they remain in the mouth longer. Consequently sucking on lollipops is more cariogenic than eating a chocolate bar. Sometimes the source of the sugar is "hidden," as in numerous prescription and nonprescription drugs and many popular cereals, including the "all-natural" variety. Reading food labels is essential in eliminating sources of sucrose.

Some snacks do not contribute to tooth decay. Aged cheeses such as cheddar may alter the pH and retard bacterial growth. Sugarless gum chewed after eating may actually protect against cavities by stimulating saliva that neutralizes acid.

A special form of tooth decay in children between 18 months and 3 years of age is early childhood caries (ECC) (historically called *nursing caries* or *baby bottle tooth decay*) (Fig. 32-9). This often occurs when a child is routinely given a bottle of milk or juice at naptime or bedtime or uses the bottle as a pacifier while awake. Frequent nocturnal breastfeeding for prolonged periods also leads to extensive destruction of the teeth. The practice of coating pacifiers in honey can also contribute to caries and may be a potential source of botulism poisoning. As the sweet liquid pools in the mouth, the teeth are bathed for several hours in this cariogenic environment. Prolonged bottle-feeding well into toddler years in some cultures may contribute to significant ECC (Brotanek, Schroer, Valentyn, et al., 2009). In one group prolonging bottle-feeding into toddlerhood was perceived as "buying time" to decrease the child's crying (Freeman and Stevens, 2008). The maxillary (upper) incisors and

molars are affected most because the mandibular (lower) incisors are protected by the lower lip, tongue, and saliva. Severely decayed teeth may require the application of stainless steel bands to preserve the spacing until the permanent teeth erupt.

Early childhood caries is now considered to be an infectious disease of childhood. There is evidence that *Streptococcus mutans* is a highly cariogenic bacteria (American Academy of Pediatric Dentistry, 2011d). One of the early origins of *S. mutans* is the mother's saliva; infants of mothers with high counts of the bacteria have a greater incidence of ECC. Therefore it is important to discuss oral hygiene with pregnant women because of its impact on their children's tooth development.

Prevention involves eliminating the bedtime bottle completely, feeding the last bottle before bedtime, substituting a bottle of water for milk or juice, not using the bottle as a pacifier, and never coating pacifiers in sweet substances. Juice in bottles, especially commercially available ready-to-use bottles, is discouraged; these beverages are especially damaging because the sugar is more readily converted to acid. Juice should always be offered in a cup to avoid prolonging the bottle-feeding habit. Toddlers should be encouraged to drink from a cup at the first birthday and weaned from a bottle by 14 months of age. Nurses are in an excellent position to counsel parents regarding the dangers of this habit and other aspects of dental care.*

Safety Promotion and Injury Prevention

According to recent data from the Centers for Disease Control and Prevention (CDC) (Borse, Gilchrist, Delinger, et al., 2008), children ages 1 to 4 years had the second highest rate of deaths from accidental injuries in the United States during the period from 2000 to 2006; the group with the highest number of deaths (56%) from accidental injuries were children ages 15 to 19 years. Boys were involved almost twice as often as girls in deaths attributed to unintentional injury. Among children ages 1 to 4 years of age, the leading causes for death were transportation related (including motor vehicle occupant, pedestrian, and pedal cyclist), drowning, and fires or burns. Deaths from accidental poisoning were higher among infants and adolescents than among toddlers. Nonfatal injuries in children ages 1 to 4 years of age occurred as a result of falls (leading cause), followed by being struck by or against something and bites or stings (including dog bites and bee or other insect attacks). Nonfatal drowning injury rates and nonfatal poisoning were higher among children ages 1 to 4 years than any other age-group.

A major factor in the critical increase of injuries during early childhood is the unrestricted freedom achieved through locomotion combined with an unawareness of danger within the environment. Toddlers delight in the repetitive use of gross motor skills, and with increasing age these skills are refined. This age-group is also very curious about how things work, and exploration of previously unknown or unseen objects and places is common. Toddlers also have not fully developed or do not understand the cause-and-effect principles that older children have and often are unable to gauge danger; poorly developed depth perception may also contribute to falls and tumbles as does the general bodily structure of toddlers.

Nonaccidental trauma is a term used to denote child physical abuse, whether the etiology is suspected or confirmed, yet without the stigma of the term *child abuse*. Toddlers are at particular risk for nonaccidental trauma because of their tendency to be mobile and curious yet clumsy and uncoordinated; the toddlers' inability to control emotions at times and the tendency toward negativism further place the child at high risk for nonaccidental trauma.

Specific categories of injuries and appropriate prevention are best understood by associating them with the major growth and developmental achievements of this age (Table 32-4). The discussions of injuries in Chapters 31 and 33 are also relevant to safety concerns at this age.

Motor Vehicle Safety

Motor vehicle injuries cause more accidental deaths in all pediatric age-groups after 1 year of age than any other type of injury or disease and are responsible for almost half of all accidental deaths among children ages 1 to 4 years. Many of the deaths are caused by injuries within the car when restraints have not been used or have been used improperly. Unrestrained children riding in the front seat of the vehicle are at highest risk for injury. Approved restraints properly installed and applied can prevent many fatalities and injuries. Motor vehicle back-over injuries and deaths, along with deaths or serious injury resulting from heat stroke when left in a car, account for a large number of motor vehicle–related injuries in children (CDC, 2005; McLaren, Null, and Quinn, 2005).

Car Restraints. Nurses are responsible for educating parents regarding the importance of car restraints and their proper use. Five types of restraints are available: (1) infant-only devices, (2) convertible models for both infants and toddlers, (3) boosters, (4) safety belts, and (5) devices for children with disabilities (see Chapter 36). Chapter 31 discusses the infant-type restraints; convertible restraints and boosters are included here. Convertible restraints are suitable for infants and toddlers in the rearward-facing position (Fig. 32-10). It is now recommended that all infants and toddlers ride in rear-facing car safety seats until they reach the age of 2 years or height recommended by the car seat manufacturer (Durbin and AAP Committee on Injury, Violence, Poison Prevention, 2011). Many rear-facing car safety seats can accommodate children weighing up to a maximum of 35 pounds (according to manufacturer specifications).* Studies indicate that toddlers up to 24 months of age are safer riding in convertible seats in the rear-facing position (Bull and Durbin, 2008; Henary, Sherwood, Crandall, et al., 2007). In Sweden children ride in a rear-facing car safety seat until the age of 4 years, at which time they transition to a booster seat (Durbin and Committee on Injury, Violence, and Poison Prevention, 2011).

Children 2 years old and older (or those younger than 2 years) who have outgrown the rear-facing height or weight limit for their car safety seat should use a forward-facing car safety seat with a harness up to the maximum height or weigh recommended by the manufacturer (Durbin and Committee on Injury, Violence, and Poison Prevention, 2011).

Convertible restraints use different types of harness systems: a five-point harness that consists of a strap over each shoulder, one on each side of the pelvis, and one between the legs (all five come together at a common buckle) and a padded overhead shield that uses shoulder straps attached to a shield that is held in place by a crotch strap. The overhead shield convertible seats are no longer

TABLE 32-4 INJURY PREVENTION DURING EARLY CHILDHOOD

DEVELOPMENTAL ABILITIES RELATED TO RISK OF INJURY	INJURY PREVENTION
Motor Vehicles	
Walks, runs, and climbs Able to open doors and gates Can ride tricycle and other toy vehicles Can throw ball and other objects	Use federally approved car restraint. Supervise child while playing outside. Do not allow child to play on curb or behind parked car. Do not permit child to play in pile of leaves, snow, or large cardboard container in trafficked area. Supervise tricycle riding. Lock fences and doors if not directly supervising children. Teach child to obey pedestrian safety rules: • Obey traffic regulations; cross only at crosswalks and only when traffic signal indicates that it is safe. • Stand back a step from curb until it is time to cross. • Look left, right, and left again and check for turning cars before crossing street. • Use sidewalks; when there is no sidewalk, walk on left, facing traffic. • Wear light colors at night and attach fluorescent material to clothing.
Drowning	
Able to explore if left unsupervised Has great curiosity Helpless in water; unaware of its danger—may consider "play" in any body of water same as in bath; depth of water has no significance	Supervise closely when near any source of water regardless of depth, including buckets. Keep bathroom doors closed and lid down on toilet (or install latch). Have fence around swimming pool and lock gate. Teach swimming and water safety (however, this is not a substitute for safety). Supervise small children when swimming by "touch" (adult can reach out and touch child at all times).
Burns	
Able to reach heights by climbing, stretching, and standing on toes Pulls objects Explores any holes or opening Can open drawers and closets Unaware of potential sources of heat or fire Plays with mechanical objects	Turn pot handles toward back of stove. Place electrical appliances such as coffee maker and popcorn machine toward back of counter. Place guardrails in front of radiators, fireplaces, or other heating elements. Store matches and cigarette lighters in locked or inaccessible area; discard carefully. Place burning candles, incense, hot foods, and cigarettes out of reach. Do not let tablecloth hang within child's reach. Do not let electric cord from iron, curling iron, or other appliance hang within child's reach. Cover electrical outlets with protective plastic caps. Keep electrical wires hidden or out of reach. Do not allow child to play with electrical appliance, wires, or lighters. Stress danger of open flames; teach what "hot" means. Always check bath-water temperature; adjust water heater temperature to 49° C (120° F) or lower; do not allow children to play with faucets. Apply sunscreen when child is exposed to sunlight.
Accidental Poisoning	
Explores by putting objects in mouth Can open drawers, closets, boxes, and most containers Climbs Cannot read labels Does not know safe dose or amount	Place all potentially toxic agents out of reach or in locked cabinet. Caution against eating nonedible items such as plants. Replace medications or poisons immediately in proper storage and out of child's reach; replace child-guard caps properly. Administer medications as drug, not as candy. Do not store surplus toxic agents. Promptly discard empty poison containers; never reuse to store food item or other poison. Teach child not to play in trash containers. Never remove labels from containers of toxic substances. Do not store toxic liquids in containers not specifically intended for their storage (e.g., empty soda bottle that child may drink from, unaware of difference in contents). Know number of nearest poison control center (800-222-1222).

TABLE 32-4 INJURY PREVENTION DURING EARLY CHILDHOOD—cont'd

DEVELOPMENTAL ABILITIES RELATED TO RISK OF INJURY	INJURY PREVENTION
Falls	
Able to open doors and some windows	Use window guardrail; fasten securely.
Goes up and down stairs	Place gates at top and bottom of stairs.
Depth perception unrefined	Keep doors locked or use child-proof doorknob covers at entry to stairs, high porch, or other elevated area, including laundry chute.
Climbs on higher surfaces	Remove unsecured or scatter rugs.
	Apply nonskid decals in bathtub or shower.
	Keep crib rails fully raised and mattress at lowest level.
	Place carpeting under crib and in bathroom.
	Keep large toys and bumper pads out of crib or play yard (child can use these as "stairs" to climb out); move child to youth bed when he or she is able to climb out of crib.
	Avoid using wheeled walkers, especially near stairs and floor furnace.
	Dress in safe clothing (soles that do not "catch" on floor, tied shoelaces, pant legs that do not touch floor).
	Keep child restrained in vehicles; never leave unattended in shopping cart.
	Supervise at playgrounds; select play areas with soft ground cover and safe equipment.
Choking and Suffocation	
Puts things in mouth	Avoid large, round chunks of meat such as whole hot dogs (slice lengthwise into short pieces).
May swallow hard or nonedible pieces of food	Avoid fruit with pits, fish with bones, dried beans, hard candy, chewing gum, nuts, popcorn, grapes, marshmallows.
	Choose large, sturdy toys without sharp edges or small removable parts.
	Discard old refrigerators, ovens, and other appliances after removing door.
	Select safe toy boxes or chests without heavy, hinged lids.
	Keep Venetian blind (or shade) cords out of child's reach. Use split cords.
	Remove drawstrings from clothing.
Bodily Damage	
Still clumsy in many skills	Avoid giving sharp or pointed objects such as knives, scissors, or toothpicks, especially when walking or running.
Easily distracted from tasks	Do not allow lollipops or similar objects in mouth when walking or running.
Unaware of potential danger from strangers or other people	Teach safety precautions (e.g., to carry knife or scissors with pointed end away from face).
	Store all dangerous tools, garden equipment, and firearms in locked cabinet.
	Be alert to danger of supervised animals and household pets.
	Use safety glass and decals on large glassed areas such as sliding glass doors.
	Teach child name, address, and phone number and to ask for help from appropriate people (cashier, security guard, policeman) if lost; have identification on child (sewn in clothes, inside shoe).
	Teach stranger safety: • Avoid personalized clothing in public places. • Never go with a stranger. • Tell parents if anyone makes child feel uncomfortable in any way.
	Always listen to child's concerns regarding others' behavior.
	Teach child to say "no" when confronted with uncomfortable situations.

manufactured but if in one's possession may be used until the manufacturer's weight limit is reached. With both the infant and toddler restraints it is important not to add extra blankets, head cushions, or padding between the child and the restraint straps that did not come as original equipment because these "add-ons" create spaces of air between the child and the restraint and decrease support for the back, head, and neck. Cars with free-sliding latch plates on the lap or shoulder belt require the use of a metal locking clip to keep the belt in a tight-holding position. The locking clip is threaded onto the belt above the latch plate (Fig. 32-11, *A*). If parents have newer cars with automatic lap and shoulder belts, they need to have additional lap belts installed to properly secure the restraint. A 3-in-1 convertible seat is also available and can be used rear-facing, forward-facing, and as a belt-positioning seat for toddlers. This seat is larger than other convertible seats, so it is important to verify that the seat fits in the car in the rear-facing position (AAP, 2013).

Booster seats are not restraint systems like the convertible devices because they depend on the vehicle belts to hold the child and booster seat in place. Three booster models have been approved by the National Highway Traffic Safety Administration (NHTSA): the high-back belt-positioning seat (Fig. 32-11, *B*), which provides head and neck support for the child riding in a vehicle seat without a head rest; the no-back belt-positioning seat, which should be used only if the vehicle seat has a head rest; and a combination seat, which converts from a forward-facing toddler seat to a booster seat. This last model is equipped with a harness for use by toddlers; the harness may be removed, and a belt used when the child outgrows the harness. The belt-positioning booster seats are used for children who are less than 145 cm (4 feet, 9 inches) tall and weigh

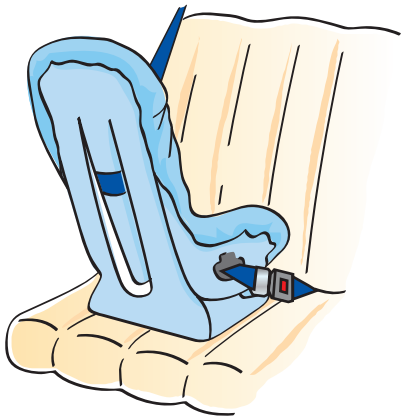

FIG 32-10 Rear-facing convertible car seat.

FAMILY-CENTERED CARE

Using Car Safety Seats

- Read manufacturer directions and follow them exactly.
- Anchor safety seat securely to automobile seat and apply harness snugly to child.
- Do not start the car until everyone is properly restrained.
- *Always* use the restraint, even for short trips.
- If child begins to climb out or undo the harness, firmly say, "No." It may be necessary to stop the car to reinforce the expected behavior. Use rewards to encourage cooperative behavior.
- Encourage child to help attach buckles, straps, and shields but always double-check fastenings.
- Decrease boredom on long trips. Keep soft toys in the car for quiet play; talk to child; point out objects and teach child about them. Stop periodically. If child wishes to sleep, make certain that he or she stays in the restraint.
- Insist that others who transport children also follow these safety rules.

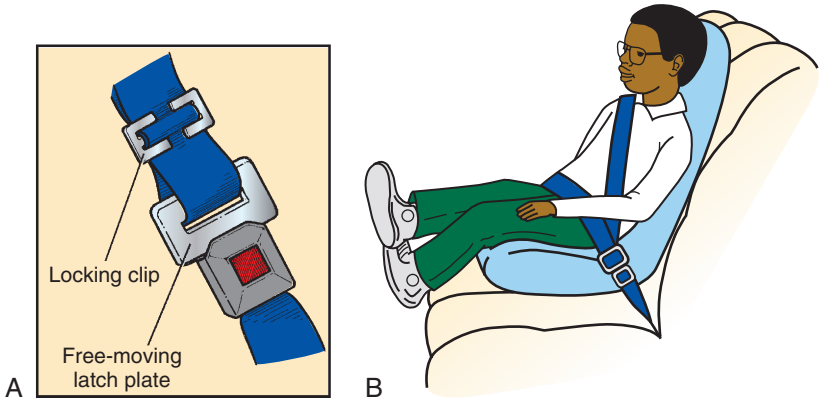

FIG 32-11 **A,** Locking clip used with free-sliding lap or shoulder belt to keep the belt in a tight-holding position. **B,** Automobile booster seat. Note placement of the shoulder strap (away from the neck and face).

15.9 kg to 36.3 kg (35 to 80 lbs, depending on the type of booster seat). In general school-age children should ride in a belt-positioning booster seat until approximately 7 to 8 years of age. However, note that, because children's sizes vary considerably, manufacturer recommendations should be followed regarding height and weight limitations. A booster seat should be used until the child is able to sit against the back of the seat with feet hanging down and legs bent at the knees. The belt-positioning booster model raises a child higher in the seat, moving the shoulder part of the belt off the neck and the lap portion off the abdomen onto the pelvis. Children who outgrow the convertible restraint may still be able to ride safely in a booster seat until the midpoint of the head is higher than the vehicle seat back.

Children should use specially designed car restraints until they are 145 cm (4 feet, 9 inches) in height or 8 to 12 years old (AAP, 2013). Shoulder-lap safety belts should be worn low on the hips, snug, and not on the abdominal area. Children should be taught to sit up straight to allow for proper fit. The shoulder belt is used only if it does not cross the child's neck or face.

Shoulder-only automatic belts are designed to protect adults. Children should use the manual shoulder belts in the rear seat. Air bags do not take the place of child safety seats or seat belts and can be lethal to young children. The safest area of the car for children is the back seat.

For any restraint to be effective, it must be used consistently and properly. Examples of misuse include misrouting the vehicle seat belt through the restraint; failing to use the vehicle seat belt to secure the restraint; failing to use a tether strap; failing to use the restraint harness system; and incorrectly positioning the child, especially by facing infants forward instead of rearward. To address these issues nurses must stress correct use of car restraints and rules that ensure compliance (see Family-Centered Care box). Children riding in car safety seats are generally much better behaved than children left unrestrained, which can be a major benefit to parents and should be emphasized as an additional advantage of restraints. Additional information about child safety restraints is available from various sources.*

The LATCH (lower anchors and tethers for children) universal child safety seat system was implemented as a requirement starting in 2002 for all new automobiles and child safety seats. This system provides uniform anchorage consisting of two lower anchorages and one upper anchorage in the rear seat of the vehicle (Fig. 32-12). When used appropriately the top anchor (tether) strap prevents the

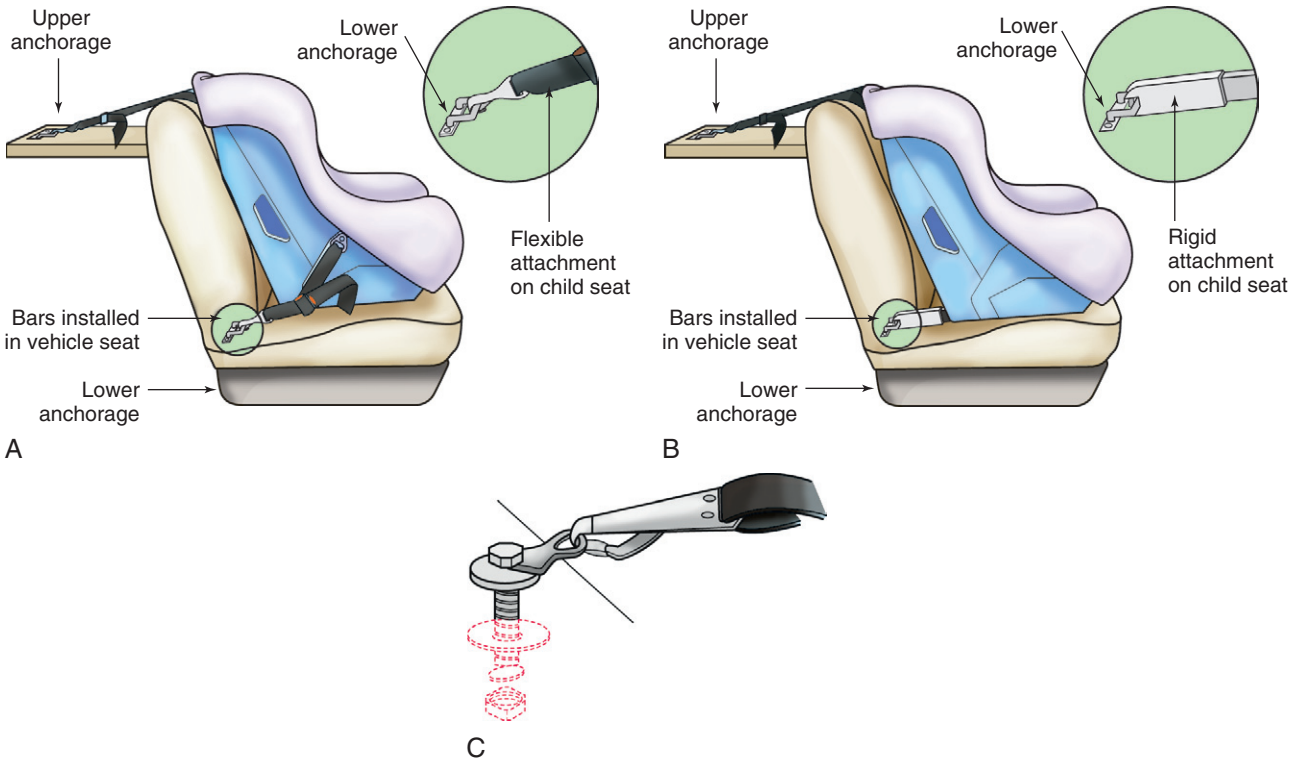

FIG 32-12 Lower anchors and tethers for children (LATCH). **A,** Flexible two-point attachment with top tether. **B,** Rigid two-point attachment with top tether. **C,** Top tether. (Courtesy U.S. Department of Transportation, National Highway Traffic Safety Administration.)

child from pitching forward in a crash. If the tether strap is not used, up to 90% of the protection of the restraint is lost. Instructions for proper installation of the tether strap and permanent bracket are included with the car restraint. New child safety seats have a hook, buckle, strap, or other connector that attaches to the anchorage. Concerns about the increased weight of children in the United States has led some to question the safety of the LATCH system with child restraints (car seats) and the child whose combined weight is more than 29.5 kg (65 lbs). The NHTSA recently changed the rule about the use of the LATCH system if the child's weight and that of the car seat weighs more than 65 lbs; in 2014 parents will be instructed to use the shoulder-lap belt restraint to restrain the child in the car seat instead of relying on the LATCH system for maximum protection if the combined weight of the child and car seat is more than 29.5 kg (65 lbs).

Children with disabilities may require a restraint system that secures them appropriately in the event of a crash. Examples of such devices include car-bed restraints for infants who cannot tolerate a semireclining position and specially adapted molded-plastic chairs for children who have spica casts. The E-Z-On vest is a special safety harness for larger children with poor trunk control. A HIPPO (Spica Cast) Car Seat is available for transporting children with spica casts; these are sold only in the United States. Additional safety restraints and a list of distributors are available at the SafetyBeltSafe U.S. website.* See also Chapter 25 for a discussion of preterm infants being discharged home and car-seat evaluation.

*www.carseat.org.

Optimally children should not ride in the front seat of any car with an activated air bag; if they do, the seat should be pushed as far back as possible to prevent serious harm or critical injury from front seat air bags. Many of the newer-model vehicles have side impact air bags for collision protection; these air bags are reported to be safe as long as the child is in a proper restraint system. The NHTSA (2010) recommends that children not lean on chest-only or head-chest combination side air bags. Some of the newer-model child car seats include side bumpers at head and neck height to protect children in side-impact collisions. Built-in seats are available in some cars and vans. They eliminate installation problems; however, weight and height limits vary. Reinforce that owners must verify with vehicle manufacturers details about built-in seats.

Motor Vehicle–Related Injuries. Injuries may also occur during sudden stops when objects are left unrestrained. On sudden impact a loose ball becomes a projectile missile. Therefore all items should be secured or stored in the trunk or behind a barrier such as netting in vans and wagons.

Children older than 3 years of age are often involved in pedestrian traffic injuries. Because of their gross motor skills of walking, running, and climbing and their fine motor skills of opening doors and fence gates, they are likely to be in hazardous areas when unsupervised. Unaware of danger and unable to approximate the speed of cars, they are hit by moving vehicles. Running after a ball, riding a tricycle, and playing behind a parked car are common activities that may result in a vehicular tragedy.

Toddlers playing in driveways or farmyards are at risk of backover injury from vehicles in reverse gear. A precaution when children are playing in driveways is attaching to the tricycle a pole with a

bright flag that is high enough to be visible through the back window of an automobile. Another safeguard is the use of a device that beeps when the vehicle is driven in reverse to alert children to the oncoming car, van, tractor, or truck. Some models now come equipped with rearview motion cameras so the driver can see the driveway clearly while backing out.

Preventing vehicular injuries involves protecting and educating children and adults about the danger of moved or parked vehicles. Children should never ride in the open back of a truck; the danger of falls can be compounded by another vehicle striking the child or the truck rolling over. In addition, leaving children unsupervised in a parked vehicle, especially in a private driveway, provides an opportunity for the child to release the brake or put the car in gear. Children in bicycle-towed trailers or bicycle-mounted child seats can also be injured by collisions or falls.

One type of injury that has become more commonplace occurs when children crawl into an open trunk and pull it closed. Asphyxia may occur in such cases; therefore car trunks should not be left open when children are not being supervised. Some cars are equipped with a safety switch that can be activated from inside the trunk to open a closed trunk door.

Another automobile-related hazard for toddlers is overheating (hyperthermia) and subsequent death when left in a vehicle in hot weather (>27°C [80°F]). Small children dissipate heat poorly, and an increase in body temperature can cause death in a few hours. From 1998 to 2011 (June), a total of 506 children died from hyperthermia when left alone in parked cars; in 2010 the total number of child deaths was 49, and it is estimated that an average of 38 children die each year from overheating in cars (Null, 2011). It is estimated that, with the ambient temperature at 22° to 35.5°C (72° to 96°F), the vehicle interior temperature rises by 10.5° to 11°C (19° to 20°F) for each 10 minutes, even with a window cracked (Null, 2011). In a study of 171 child fatalities from overheating in a car, 50% of adults who left a child in a car either forgot or were unaware that the child was still in the car. A significant number of those children (32) were left by family members who intended to take the child to day care but forgot the child in the car at the workplace; 22 children were left in the car by a day care worker or driver (Guard and Gallagher, 2005). Parents are cautioned against leaving infants alone in a vehicle for *any reason*.

Preventing vehicular injuries involves protecting and educating children about the danger of moving and parked vehicles. Although preschool children are too young to be trusted to always obey, parents should emphasize looking for moving vehicles before crossing the street, recognizing the stop and go colors of traffic lights, and following traffic officers' signals. Physical barriers limiting children from playing near vehicles help prevent these injuries. Most important, what is preached must be practiced. Children learn through imitation, and consistency reinforces learning.

Drowning

The highest rate of drowning in the years 2000 to 2006 was in children ages 0 to 4 years; children ages 12 to 36 months are at highest risk for drowning during the same time period (Weiss and AAP Committee on Injury, Violence, and Poison Prevention, 2010). Drowning deaths in infants occur most commonly in the bathtub and large buckets. With well-developed skills of locomotion, toddlers are able to reach potentially dangerous areas such as bathtubs, toilets, buckets, swimming pools, hot tubs, and ponds or lakes. Toddlers' intense drive for exploration and investigation combined with an unawareness of the danger of water and their helplessness in water makes drowning always a viable threat. It is also one category of injury that results in death within minutes, diminishing the chance for rescue and survival. Close adult supervision of children when near any source of water is essential; many drownings in this age-group occur when a supervising adult becomes distracted. Teaching swimming and water safety can be helpful but cannot be regarded as sufficient protection. Pool fencing, although critical, does not always deter fast-moving children (see Table 32-4).

Burns

Burns rank second among girls and third among boys in this age-group as a cause of accidental death. Toddlers' ability to climb, stretch, and reach objects above their heads makes any hot surface a potential source of danger. Scalds from children pulling pots on top of themselves are a major source of burns. As a precaution pot handles should be turned toward the back of the stove.

Other sources of heat such as radiators, fireplaces, accessible furnaces, kerosene heaters, and wood-burning stoves should have guards placed in front of them. Portable electric heaters must be placed in a high area, well out of reach of climbing young children. Hair curling irons and hot curlers may also be reached easily and can burn the hands of curious toddlers.

Hot objects such as candles, incense, cigarettes, pots of tea or coffee, and irons must be placed away from children. The flame of a candle and the smoke of a cigarette invite investigation. Flame burns represent one of the most fatal types of burns and commonly occur when children play with matches and accidentally set themselves (and the home) on fire. To prevent flame burns, matches and lighters must be stored safely away from children, and parents need to teach children the dangers of playing with such objects. In addition, all homes, apartments, and any other type of dwelling where people sleep should have smoke detectors installed to alert the occupants of a fire. A safety plan for immediate escape is also essential.

Electrical burns represent an immediate danger to children. Young toddlers may explore outlets with conductive articles and wires by mouthing them. Because water is an excellent conductor, the chance for a severe circumoral electrical burn is great. Electrical outlets should have protective guards (or sliding guards) plugged into them when not in use (Fig. 32-13) or be made inaccessible by having furniture placed in front of them when feasible.

Scald burns are the most common type of thermal injury in children. A scalding burn is often caused by high-temperature tap water, with which children come in contact as a result of turning on the hot-water faucet, falling into a bathtub of hot water, pulling hot pots onto themselves, or suffering deliberate abuse. Limiting household water temperatures to less than 49°C (120°F) is highly recommended. At this temperature it takes 10 minutes of exposure to the water to cause a full-thickness burn. Conversely water temperatures of 54°C (130°F), the usual setting of most water heaters, expose household members to the risk of full-thickness burns within 30 seconds. Nurses can help prevent such burns by advising parents of this common household danger and recommending that they readjust their water heaters to a safe temperature.

Sunburns are a year-round concern in certain regions. Children spend a large amount of time outdoors. Their increased mobility makes it difficult to prevent sun exposure. Sunburn can be prevented by applying a sunscreen with a sun protection factor (SPF) of 15 or

FIG 32-13 Special plastic caps in electrical sockets prevent young fingers from exploring dangerous areas. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

FIG 32-14 Children are most likely to ingest substances that are on their level such as cleaning agents stored under sinks, rat poison, plants, or diaper pail deodorants.

greater, dressing in protective clothing (wide-brimmed hat, protective cotton clothing with a tight weave), and avoiding sun exposure between 10 AM and 2 PM.

Accidental Poisoning

Toddlers are at the highest risk for accidental poisoning because of their innate curiosity and ability to open "childproof" containers. Mouthing activity continues to be prevalent after 1 year of age, and exploring objects by tasting them is part of children's curious investigation. Toddlers' curiosity and inability to understand logical consequences further place them at risk for ingesting harmful substances. Many household products, medications, and plants can be poisonous if swallowed, if they come in contact with the skin or eyes, or if they are inhaled. Although in many instances poisoning does not result in death, it may cause significant morbidity such as esophageal stricture from lye ingestion. Toddlers are able to climb most heights, open most drawers or closets, and unscrew most lids. By trial and error younger children also manage to undo tops of bottles, plastic containers, aerosol cans, and jars, including those with child-resistant lids. Newer forms of drugs such as transdermal patches and cough-suppressant lozenges have created additional dangers because they are not packaged with safety caps and the lozenges look like candy.

The major reason for poisoning is improper storage (Fig. 32-14). The guidelines suggested in Chapter 31 apply to children in this age-group as well. However, unlike infants, who are confined to certain heights and unable to unlatch inventive locks, young children manage to find access to many high-level, tight-security places. For this age-group only a locked cabinet is safe.

Recent attention has focused on the use of OTC medications used for cough and colds as a common cause of accidental poisonous ingestion in toddlers. Ingestion of acetaminophen is also a common cause of morbidity because it is found in many combination OTC products; caregivers may unknowingly administer a dose of acetaminophen in addition to an OTC drug containing the product without knowing the danger.

Emergency and preventive measures for accidental poisoning are discussed in Chapters 31 and 41. Parents should have ready access to the telephone number for the poison control center (National Poison Control, 800-222-1222) and be prepared to act on the advice of the center.

Falls

Falls are still a hazard to children in this age-group, although by the later part of early childhood gross and fine motor skills are well developed, decreasing the incidence of falls down stairs and from chairs. However, playground injuries are common. Children need to be taught safety at play areas such as no horseplay on high slides or jungle gyms, *sitting* on swings, and staying away from moving swings. Passive prevention includes placement of grass, sand, or wood chips under play equipment. Swing seats should be made of plastic, canvas, or rubber and have smooth or rounded edges. Slides should have inclines of no more than 30 degrees, evenly spaced rungs for climbing, and protective "tunnels."

The climbing and running of the typical toddler are complicated by the child's total disregard and lack of appreciation for danger. Gates must be placed at both ends of stairs. Accessible windows must have window guards, not screens, to prevent falls to the ground below. Falling from open windows is a major cause of accidental death in urban, lower socioeconomic groups. Doors leading to stairwells or porches must be locked because preschoolers can open them easily. A convenient type of lock is a sliding bar or hook that can be attached to the door and frame at a level higher than the child can reach; such locks also have safety clasps or devices that prevent children from being able to open them. Falls from balconies, porches, decks, and bleachers are all possible for active toddlers.

Cribs and vehicles are other sources of falls. To avoid injury crib rails should be fully raised, the mattress should be kept at the lowest position, and toys or bumper pads that may be used as steps to climb out should be removed. Rails need to be sized appropriately because most children younger than 6 years of age can slip through a 6-inch opening; however, no children older than 1 year can usually pass through a 4-inch opening. Ideally the floor under the crib should be carpeted or have a throw rug. Cribs, bassinets, and play yards were

associated with a large number of accidental falls (66% of all fall injuries to children) (Yeh, Rochette, McKenzie, et al., 2011). The manufacture and sale of drop-side cribs has been banned by the Consumer Product Safety Commission (2010). When children reach a height of 89 cm (35 inches), they should sleep in a bed rather than a crib. If a bunk bed is selected, parents should be aware of possible dangers, including falls from the top bed and the ladder and head entrapment between the mattress and guardrail or between the supporting mattress slats.

Children can fall from high chairs, shopping carts, carriages, car seats, and strollers if not properly restrained or because of a change in balance created by weighting the object down with heavy objects. Therefore proper restraint and adequate supervision are essential. Children, especially older infants who are mobile, should not be placed in an infant seat on top of a shopping cart because the infant seat may fall off the cart; the safest place for an infant seat is inside the bed of the cart.

Aspiration and Suffocation

Foreign body aspiration is most common during the second year of life. Usually by 1 year of age children chew well, but they may have difficulty with large pieces of food (e.g., meat and whole hot dogs) and hard foods (e.g., nuts). Young children cannot discard pits from fruit or bones from fish. It takes practice to learn how to chew gum without swallowing it. Gel snacks that are sealed in plastic wrappers can also be difficult to manage, and the plastic wrapper can be aspirated. Therefore parents must implement the same precautions as discussed for infants regarding food selection (see Chapter 31).

Play objects for toddlers must still be chosen with an awareness of danger from small parts. Large, sturdy toys without sharp edges or removable parts are safest. Small plastic toys such as Legos can cause choking or be aspirated; such plastic items often do not appear on radiographic films. Balloons, coins, paper clips, pins, bells, button batteries, pull-tabs on cans, thumbtacks, nails, screws, jewelry (especially pierced earrings), and all types of pins are common household objects that can cause significant harm if swallowed or aspirated. Because of the danger of aspiration, parents should be taught emergency procedures for choking.

Suffocation from causes seen during infancy is less frequent; but old refrigerators, ovens, and other large appliances are an ever-present threat. Toddlers can climb inside these appliances and, if they close the door behind them, can be trapped. Removing all doors before discarding or storing old appliances prevents such tragic deaths. Toddlers may also suffocate when unsafe toy box lids accidentally close on their heads or necks.

Because some of the older heating systems and hot-water heaters may emit carbon monoxide, which is undetectable by human smell, each house should have a carbon monoxide detector in addition to a smoke detector.

Bodily Injury

Toddlers are still clumsy in many of their skills and can seriously harm themselves when walking while holding a sharp or pointed object or having food or objects such as spoons in their mouths. Preventing such occurrences is the best approach. With preschoolers teaching safety is most important. The child should be taught that, when walking with a pointed object such as a knife or scissors, the pointed end is held away from the face. Dangerous garden or workshop equipment and all firearms should be stored in locked cabinets. Power lawn mowers and weed eaters are especially dangerous because they can throw rocks and other solid items (projectiles), and young children should not be allowed in an area where such tools are in use; nor should they be taken for a ride on a mower or allowed to operate the device. Television tip-overs are a source of head trauma in toddlers and preschool age-group (Rutkoski, Sippey, and Gaines, 2011).

Safety education should include respect for firearms and their appropriate use, including nonpowder guns such as air guns, rifles (BB and pellet), and paintball guns, which can cause serious penetrating injuries. Firearm safety devices such as trigger locks and personalized locks should be used to prevent unintentional firing of guns and subsequent injuries or fatalities. In addition, the child should be warned of and protected against potential danger from animals (see Animal Bites, Chapter 47).

An additional safeguard for young children is the use of safety glass in doors, windows, and tabletops and the application of decals on glass doors and windows to reduce the likelihood of running through glass. In addition, children should not be allowed to run, jump, wrestle, or play ball near glass structures.

A discussion of bodily injury must also include alerting the parent to threats to the child's well-being from adults or other children who might take advantage of the toddler who cannot protect himself or herself. Because toddlers are often not able to verbalize their emotions and feelings or may not understand inappropriate touching behavior by a family member or friend, it is important for parents to protect children by not leaving them in situations where there is a potential for bodily harm. The "stranger danger" concept is still important to teach, yet statistics show that personal harm more often comes from relatives or family friends who are not considered strangers. Therefore it is important to discuss appropriate and inappropriate touching (what feels comfortable and what does not) in a manner that will not frighten or overwhelm the child. Child abductions can be prevented with close adult supervision; additional safeguards include screening for risk factors for missing children such as divorce, family discord, and substance abuse. Encourage parents to have a current, high-quality picture of the child. The goal is not to induce fear about such events but to make nurses and parents aware so they can take steps to keep each child safe from bodily harm.

Household safety should be practiced and includes the usual precautions recommended for any age-group (see Patient Teaching box: Child Home Safety Checklist, p. 904).

Anticipatory Guidance—Care of Families

Understanding toddlers is fundamental to successful child rearing. Nurses, particularly those in ambulatory or child health centers, are in a favorable position to help parents facilitate the tasks and meet the needs of children in this age-group. Prevention yields better results than treatment. Anticipatory guidance is paramount if one wishes to prevent future problems (see Family-Centered Care box).

Advice is sometimes not the sole answer. Actual assistance such as being available for home visiting or telephone consulting should be part of the nurse's flexible repertoire of interventions. Whether parents are experiencing the dilemmas of rearing a first or a subsequent child, they benefit from sharing their feelings, frustrations, and satisfactions. They need adult companionship, freedom from childrearing responsibilities, and periodic separations from their children. Part of a nurse's responsibility is to provide opportunities for parents to express their feelings and to meet their physical, mental, and spiritual needs.

FAMILY-CENTERED CARE

Guidance During Toddler Years

Ages 12 to 18 Months

- Prepare parents for expected behavioral changes of toddler, especially negativism and ritualism.
- Assess present feeding habits and encourage gradual weaning from bottle and increased intake of solid foods.
- Stress expected feeding changes of picky eating habits, food fads, and strong taste preferences; need for scheduled routine at mealtimes; inability to sit through an entire meal; and lack of table manners.
- Prepare parents for potential dangers of the home, particularly motor vehicle injuries, poisoning, and falling injuries; give appropriate suggestions for safety proofing the home.
- Discuss need for firm but gentle discipline and ways to deal with negativism and temper tantrums; stress positive benefits of appropriate discipline.
- Emphasize importance for both child and parents of brief, periodic separations.
- Discuss new toys that use developing gross and fine motor, language, cognitive, and social skills.
- Emphasize need for dental supervision, types of basic dental hygiene at home, and food habits that predispose to caries; stress importance of supplemental fluoride (according to age [older than 6 months] and fluoride content of local water supply).

Ages 18 to 24 Months

- Stress importance of peer companionship in play.
- Explore need for preparation for additional sibling (as appropriate); stress importance of preparing child for new experiences.
- Assess sleep patterns at night, particularly the habit of a bedtime bottle, which is a major cause of dental caries, and behaviors that delay hour of sleep.
- Discuss present discipline methods, their effectiveness, and parents' feelings about child's negativism; stress that negativism is an important aspect of developing self-assertion and independence and is not a sign of spoiling.
- Discuss signs of readiness for toilet training; emphasize importance of waiting for physical and psychologic readiness.
- Discuss development of fears such as fear of darkness or loud noises and habits such as security blanket or thumb sucking; stress normalcy of these transient behaviors.
- Prepare parents for signs of regression in time of stress.
- Assess child's ability to separate easily from parents for brief periods under familiar circumstances.
- Allow parents opportunity to express their feelings of weariness, frustration, and exasperation; be aware that it is often difficult to love toddlers when they are not asleep!
- Point out some of the expected changes of the next year such as longer attention span, somewhat less negativism, and increased concern for pleasing others.

Ages 24 to 36 Months

- Discuss importance of imitation and domestic mimicry and need to include child in activities.
- Discuss approaches toward toilet training, particularly realistic expectations and attitude toward accidents.
- Stress uniqueness of toddlers' thought processes, especially through their use of language, poor understanding of time, view of causal relationships in terms of proximity of events, and inability to see events from another's perspective.
- Stress that discipline still must be structured and concrete and that relying solely on verbal reasoning and explanation leads to injuries, confusion, and misunderstanding.
- Discuss investigation of preschool or day care center toward completion of second year.

KEY POINTS

- The toddler stage, extending from 12 to 36 months, is a period of intense exploration of the environment.
- Biologic development during the toddler years is characterized by the acquisition of fine and gross motor skills that allow children to master a wide range of activities.
- Although most of the physiologic systems are mature by the end of toddlerhood, development of certain areas of the brain is still occurring, allowing for greater intellectual capacity.
- Locomotion is the major gross motor skill acquired during toddlerhood, followed by increased eye-hand coordination.
- Specific tasks in the psychosocial development of a toddler include differentiating self from others, tolerating separation from parent, coping with delayed gratification, controlling bodily functions, acquiring socially acceptable behavior, communicating verbally, and interacting with others in a less egocentric manner.
- According to Erikson the major developmental task of toddlerhood is acquiring a sense of autonomy while overcoming a sense of doubt and shame.
- In Piaget's sensorimotor and preconceptual phases of development, the toddler experiments by incorporating the old learning of secondary circular reactions with new skills and applies this knowledge to new situations. There is the beginning of rational judgment, an understanding of causal relationships, and discovery of objects as objects.
- Preconceptual thought is characterized by egocentrism, centration, global organization of thought processes, animism, and irreversibility.
- Language is the major cognitive achievement in toddlerhood.
- The most striking characteristic of language development during early childhood is the increasing level of comprehension.
- Development of body image occurs with increasing motor ability, at which point toddlers recognize the importance and capacity of body parts.
- The two phases of differentiation of self from significant others are separation and individuation.
- Parental concerns during the toddler years include toilet training; coping with sibling rivalry; limit setting and discipline; and dealing with temper tantrums, negativism, and regression.
- Effective discipline techniques for toddlers include reward, ignoring or extinction, and time-out.
- Nutrition is important during the toddler stage because eating habits established in this period have lasting effects in subsequent years.

- Regular dental examinations, fluoride supplementation, removal of plaque, and provision of a low-cariogenic diet promote optimum dental health.
- Common sleep problems that develop during early childhood (and that are easily prevented) are associated with night crying and refusal to go to sleep.
- Because of increased locomotion, toddlers are at high risk for sustaining injuries. Fatal injuries are primarily a result of motor vehicle accidents, drownings, and burns.
- Motor vehicle injuries are responsible for almost half of all accidental deaths among children ages 1 to 4 years.

CHAPTER

33

The Preschooler and Family

David Wilson

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify the major biologic, psychosocial, cognitive, moral, spiritual, and social developments that occur during the preschool years.
- List the benefits of imaginary playmates.
- Prepare preschoolers for preschool or day care experience.
- Provide parents with guidelines for sex education.
- Provide parents with guidelines for dealing with a child's fears, stresses, aggression, and sleep problems.
- Recognize the causes of stuttering during the preschool years.
- Offer parents suggestions for preventing speech problems.
- Recognize feeding patterns of preschoolers.
- Provide anticipatory guidance to parents regarding injury prevention based on the preschooler's developmental achievements.

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

The combined biologic, psychosocial, cognitive, spiritual, and social achievements during the *preschool period* (3 to 5 years of age) prepare preschoolers for their most significant change in lifestyle: entrance into school. Their control of bodily functions, experience of brief and prolonged periods of separation, ability to interact cooperatively with other children and adults, use of language for mental symbolization, and increased attention span and memory prepare them for the next major period: the school years. Successful achievement of previous levels of growth and development is essential for preschoolers to refine many of the tasks that were mastered during the toddler years.

Biologic Development

The rate of physical growth slows and stabilizes during the preschool years. The average *weight* is 14.5 kg (32 lbs) at 3 years, 16.7 kg (36.8 lbs) at 4 years, and 18.7 kg (41.5 lbs) at 5 years. The average weight gain per year remains approximately 2 to 3 kg (4.5 to 6.5 lbs). Growth in *height* also remains steady, with an annual increase of 6.5 to 9 cm (2.5 to 3.5 inches), and generally occurs by elongation of the legs rather than the trunk. The average height is 95 cm (37.5 inches) at 3 years, 103 cm (40.5 inches) at 4 years, and 110 cm (43.5 inches) at 5 years.

Physical proportions no longer resemble those of the squat, pot-bellied toddler. The preschooler is slender but sturdy, graceful, agile, and posturally erect. There is little difference in physical characteristics according to gender, except as dictated by such factors as dress and hairstyle.

Most organ systems can adjust to moderate stress and change. During this period most children are toilet trained. For the most part motor development consists of increases in strength and refinement of previously learned skills such as walking, running, and jumping. However, muscle development and bone growth are still far from mature. Excessive activity and overexertion can injure delicate tissues. Good posture, appropriate exercise, and adequate nutrition and rest are essential for optimal development of the musculoskeletal system.

Gross and Fine Motor Skills

Walking, running, climbing, and jumping are well established by age 36 months. Refinement in eye-hand and muscle coordination is evident in several areas. At age 3 the preschooler rides a tricycle,

FIG 33-1 A 4-year-old child has sufficient balance to stand or hop on one foot.

walks on tiptoe, balances on one foot for a few seconds, and broad jumps. By age 4 the child skips and hops proficiently on one foot (Fig. 33-1) and catches a ball reliably. By age 5 he or she skips on alternate feet, jumps rope, and begins to skate and swim.

Fine motor development is evident in the child's increasingly skillful manipulation such as in drawing and dressing. These skills provide readiness for learning and independence for entry into school.

Psychosocial Development

Developing a Sense of Initiative (Erikson)

After preschoolers have mastered the tasks of the toddler period, they are ready to face the developmental endeavors of the preschool period. Erikson (1963) maintained that the chief psychosocial task of this period is acquiring a sense of *initiative.* Children are in a stage of energetic learning. They play, work, and live to the fullest and feel a real sense of accomplishment and satisfaction in their activities. Conflict arises when they overstep the limits of their ability and inquiry and experience a sense of *guilt* for not having behaved appropriately. Feelings of guilt, anxiety, and fear may also result from thoughts that differ from expected behavior.

A particularly stressful thought is wishing one's parent dead. As a sense of rivalry or competition develops between the child and same-sex parent, the child may think of ways to get rid of the interfering parent. In most situations this rivalry is resolved when the child strongly identifies with the same-sex parent and peers during the school years. However, if that parent dies before the identification process is completed, the preschooler may be overwhelmed with guilt for having wished and therefore "caused" the death. Clarifying for children that wishes cannot and do not make events occur is essential in helping them overcome their guilt and anxiety.

Development of the *superego,* or *conscience,* begins toward the end of the toddler years and is a major task for preschoolers (see Cultural Competence box). Learning right from wrong and good from bad is the beginning of morality (see section on Moral Development).

CULTURAL COMPETENCE

Learning Sociocultural Mores

Developing a conscience implies learning the sociocultural mores of the family's heritage. Depending on the type of attitudes conveyed, children learn not only appropriate behaviors but also tolerant, biased, or prejudicial values concerning their ethnic, religious, and social background and those of other groups. Much of this influence may remain dormant until they associate with children or adults of a different ethnic background. Then, depending on the particular group, they may be accepted or ostracized for their attitudes.

Cognitive Development

One of the tasks related to the preschool period is readiness for school and scholastic learning. Many of the thought processes of this period are crucial for achieving such readiness, and it is intentional that the child begins school between ages 5 and 6 rather than at an earlier age.

Preoperational Phase (Piaget)

Piaget's cognitive theory does not include a period specifically for children who are 3 to 5 years old. The *preoperational phase* covers the age span from 2 to 7 years and is divided into two stages: the *preconceptual phase,* ages 2 to 4, and the phase of *intuitive thought,* ages 4 to 7. One of the main transitions during these two phases is the shift from totally egocentric thought to social awareness and the ability to consider other viewpoints. However, egocentricity is still evident.

Language continues to develop during the preschool period. Speech remains primarily a vehicle of egocentric communication. Preschoolers assume that everyone thinks as they do and that a brief explanation of their thinking makes the entire thought understood by others. Because of this self-referenced, egocentric verbal communication, it is often necessary to explore and understand the young child's thinking through other, nonverbal approaches. For children in this age-group, the most enlightening and effective method is *play,* which becomes the child's way of understanding, adjusting to, and working out life's experiences.

Preschoolers increasingly use language without comprehending the meaning of words, particularly concepts of right and left, causality, and time. Children may use the concepts correctly but only in the circumstances in which they have learned them. For example, they may know how to put on shoes by remembering that the buckle is always on the outside of the foot. However, if different shoes have no buckles, they cannot reason which shoe fits which foot. In other words, they do not understand the concept of *right and left.*

Superficially, *causality* resembles logical thought. Preschoolers explain a concept as they heard it described by others, but their understanding is limited. An example is the concept of time. Because *time* is still incompletely understood, the child interprets it according to his or her own frame of reference, such as "A long time means until Christmas." Consequently time is best explained in relationship to an event such as, "Your mother will visit you after you finish your lunch." Avoiding words such as *yesterday, tomorrow, next week,* or *Tuesday* to express when an event is expected to occur and instead associating time with expected daily events help children learn about temporal relationships while increasing their trust in others' predictions.

Preschoolers' thinking is often described as *magical thinking.* Because of their egocentrism and **transductive reasoning,** they

believe that thoughts are all-powerful. Such thinking places them in the vulnerable position of feeling guilty and responsible for bad thoughts, which may coincide with the occurrence of a wished event. Their inability to logically reason the cause and effect of an illness or injury makes it especially difficult for them to understand such events.

! NURSING ALERT

Counseling children whose parents are going through a divorce or separation should involve a discussion with the child about her or his role. Because of magical thinking the child may believe that she or he wished the other parent away. The child should be reassured that this is not the case.

Preschoolers believe in the power of words and accept their meaning literally. An example of this type of thinking is calling children "bad" because they did something wrong. In the preschooler's mind calling them bad means that he or she is a bad person; thus it is better to say that the actions were bad (e.g., "That was a bad thing to do").

Moral Development

Preconventional or Premoral Level (Kohlberg)

Young children's development of moral judgment is at the most basic level. They have little, if any, concern about why something is wrong. They behave because of the freedom or restriction that is placed on actions. In the *punishment and obedience orientation,* children (from about 2 to 4 years) judge whether an action is good or bad depending on whether it results in reward or punishment. If children are punished for it, the action is bad. If they are not punished, the action is good regardless of the meaning of the act. For example, if parents allow hitting, the child perceives that hitting is good because it is not associated with punishment.

From approximately 4 to 7 years of age children are in the stage of *naive instrumental orientation,* in which actions are directed toward satisfying their needs and less frequently the needs of others. They have a concrete sense of justice and fairness during this period of development.

Spiritual Development

Children generally learn about faith and religion from significant others in their environment, usually from parents and their religious beliefs and practices. However, young children's understanding of spirituality is influenced by their cognitive level. Preschoolers have a concrete concept of a God with physical characteristics, often similar to an imaginary friend. They understand simple Bible stories, memorize short prayers, and imitate the religious practices of their parents without fully understanding the significance of these rituals. Preschoolers benefit from concrete representations of religious practices such as picture Bible books and small statues such as those of the Nativity scene.

Development of the conscience is strongly linked to spiritual development. At this age children are learning right from wrong and behaving correctly to avoid punishment. Wrongdoing provokes feelings of guilt, and preschoolers often misinterpret illness as a punishment for real or imagined transgressions. Observing religious traditions and participating in a religious community can help children cope during stressful periods such as illness and hospitalization (Speraw, 2006).

In many religious faiths cultural practices and religion are closely intertwined (McEvoy, 2003) and are an important part of the child's and family's life.

Development of Body Image

The preschool years play a significant role in the development of body image. With increasing comprehension of language, preschoolers recognize that individuals have desirable and undesirable appearances. They recognize differences in skin color and racial identity and are vulnerable to learning prejudices and biases. They are aware of the meaning of words such as *pretty* or *ugly,* and they reflect the opinions of others regarding their own appearance. By 5 years of age children compare their size with that of their peers and can become conscious of being large or short, especially if others refer to them as "so big" or "so little" for their age. Research indicates that girls as young as preschool age already show concern about appearance and weight (Skouteris, McCabe, Swinburn, et al., 2010). Because these are formative years for both boys and girls, parents should make efforts to instill *positive* principles regarding body image, give their children encouraging feedback regarding their appearance, and emphasize the importance of accepting individuals no matter how their appearances differ. Children at this age should be educated regarding the benefits of physical activity and nutrition on health rather than focusing on weight.

Despite the advances in body-image development, preschoolers have poorly defined body boundaries and little knowledge of their internal anatomy. Intrusive experiences are frightening, especially those that disrupt the integrity of the skin such as injections and surgery. They fear that, if their skin is "broken," all of their blood and "insides" can leak out. Therefore bandages are critical to "keep everything from coming out."

Development of Sexuality

Sexual development during these years is an important phase in the formation of a person's overall sexual identity and beliefs. Preschoolers are forming strong attachments to the opposite-sex parent while identifying with the same-sex parent. *Sex-typing,* or the process by which an individual develops the behavior, personality, attitudes, and beliefs appropriate for his or her culture and sex, occurs through several mechanisms during this period. Probably the most powerful mechanisms are childrearing practices and imitation. Gender identification is a result of complex prenatal and postnatal psychologic factors and biologic or genetic factors. Most children are aware of their gender and the expected sets of related behaviors by 1.5 to 2.5 years of age.

As sexual identity develops beyond gender recognition, modesty may become a concern. Sex-role imitation and "dressing up" like Mommy or Daddy are important activities. Attitudes and responses of others to role-playing can condition the child to accept the views of others. For example, comments such as "Boys shouldn't play with dolls" can influence a boy's self-concept of masculinity.

Sexual exploration may be more pronounced now than ever before, particularly in terms of exploring and manipulating the genitalia. Questions about sexual reproduction may come to the forefront in the preschooler's search for understanding (see Chapters 34 and 35).

Social Development

During the preschool period the *separation-individuation process* is completed. Preschoolers have overcome much of the anxiety associated with strangers and the fear of separation of earlier years. They relate to unfamiliar people easily and tolerate brief separations from parents with little or no protest. However, they still need parental security, reassurance, guidance, and approval, especially when entering preschool or elementary school. Prolonged separation such as that imposed by illness and hospitalization is difficult, but

FIG 33-2 Preschool children enjoy friends and often use nonverbal messages to communicate.

preschoolers respond to anticipatory preparation and concrete explanation. Maintaining an established routine is still important in early preschoolers regardless of home, school, or hospital environment. They can cope with changes in daily routine much better than toddlers, although they may develop more imaginary fears. Preschoolers gain security and comfort from familiar objects such as toys, dolls, or photographs of family members. They are able to work through many of their unresolved fears, fantasies, and anxieties through play, especially if guided with appropriate play objects (e.g., dolls, puppets) that represent family members, health care professionals, and other children.

Language

During the preschool years language becomes more sophisticated and complex and the major mode of communication and social interaction (Fig. 33-2). Through language preschool children learn to express feelings of frustration or anger without acting them out. Both cognitive ability and environment—particularly consistent role models—influence vocabulary, speech, and comprehension. Vocabulary increases dramatically, from 300 words at age 2 years to more than 2100 words at the end of 5 years. Sentence structure, grammatic usage, and intelligibility also advance to a more adult level. Language development during these early years predicts school readiness (Harrison and McLeod, 2010) and sets the stage for later success in school (Reilly, Wake, Ukoumunne, et al., 2010).

Children between the ages of 3 and 4 years form sentences of about three or four words and include only the most essential words to convey a meaning. Such speech is often termed telegraphic for its brevity. Three-year-old children ask many questions and use plurals, correct pronouns, and the past tense of verbs. They name familiar objects such as animals, parts of the body, relatives, and friends. They can give and follow simple commands. They talk incessantly regardless of whether anyone is listening or answering them. They enjoy musical or talking toys or dolls and imitate new words proficiently. Preschoolers also benefit from "reading" picture books with a parent or adult figure; this provides immediate feedback to the child and helps develop vocabulary as he or she hears the pronunciation of words from an adult (Feigelman, 2011). There is evidence that reading and speaking to a child in early life programs words into the child's memory bank for use at a later time.

From ages 4 to 5 years preschoolers use longer sentences of four or five words and more parts of speech to convey a message (e.g., prepositions, adjectives, and a variety of verbs). They can follow

FIG 33-3 Most preschoolers are able to dress themselves but need help with more difficult items of clothing.

simple directional commands such as, "Put the ball on the chair," but can carry out only one request at a time. They answer questions such as, "What do you do when you're hungry?" by describing the appropriate action. The pattern of asking questions is at its peak, and children usually repeat a question until they receive an answer. Preschoolers also are incapable of understanding figurative speech and are very literal in their understanding of the meaning of words (Feigelman, 2011). For example, saying that an IV cannula to be inserted for hydration is a straw is interpreted by the preschooler as literally a drinking straw because that is his or her common frame of reference for that object.

By 6 years of age children can use all parts of speech correctly except for deviations from the rule. They can define simple things by describing their use, shape, or general category of classification rather than simply describing their outward appearance. For example, they define a ball as "round," "something you bounce," or "a toy," rather than only describing its color. They can give some opposites such as, "If Mommy is a woman, Daddy is a man." They can also describe an object according to its composition such as, "A spoon is made of metal."

Personal-Social Behavior

The pervasive ritualism and negativism of toddlerhood gradually diminish during the preschool years. Although self-assertion is still a major theme, preschoolers demonstrate their sense of autonomy differently. They are able to verbalize their request for independence and perform independently because of their much-refined physical and cognitive development. By 4 or 5 years of age they need little if any assistance with dressing, eating, or toileting (Fig. 33-3). They can be trusted to obey warnings of danger, although 3- or 4-year-old children may exceed their boundaries at times.

They are also much more sociable and willing to please. They have internalized many of the standards and values of the family and culture. However, by the end of early childhood they begin to question parental values and compare them with those of their peer

FIG 33-4 Preschoolers enjoy play activities that promote motor skills such as jumping and running. Water play is an exciting activity for preschooler.

group and other authority figures. As a result they may be less willing to abide by the family's code of conduct. Preschoolers become increasingly aware of their position and role within the family. Although this is a more secure age for experiencing the addition of another sibling, relinquishing the position of first or youngest is still difficult and requires appropriate preparation (see Sibling Rivalry, Chapter 32).

Play

Various types of play are typical of this period, but preschoolers especially enjoy **associative play** (i.e., group play in similar or identical activities but without rigid organization or rules). Play should provide for physical, social, and mental development.

Play activities for physical growth and refinement of motor skills include jumping, running, and climbing. Tricycles, wagons, gym and sports equipment, sandboxes, wading pools, and activities at water parks can help develop muscles and coordination (Fig. 33-4). Activities such as swimming and skating teach safety and muscle development and coordination. Children involved in the work of play do not require expensive toys and gadgets to keep them entertained but often enjoy playing with common household items such as a broom handle or even items that adults consider junk (boxes, sticks, rocks, and dirt). The imaginative mind of the preschooler enjoys playing for play's sake.

Manipulative, constructive, creative, and educational toys provide for quiet activities, fine motor development, and self-expression. Easy construction sets, large blocks of various sizes and shapes, a counting frame, alphabet or number flash cards, paints, crayons, simple carpentry tools, musical toys, illustrated books, simple sewing or handicraft sets, large puzzles, and clay are suitable toys. Electronic games and computer programs are especially valuable in helping children learn basic skills such as letters and simple words.

Probably the most characteristic and pervasive preschool activity is imitative, imaginative, and dramatic play. Dress-up clothes, dolls, housekeeping toys, dollhouses, play store toys, telephones, farm animals and equipment, village sets, trains, trucks, cars, planes, hand puppets, and medical kits provide hours of self-expression (Fig. 33-5). Probably at no other time is the reproduction of adult

FIG 33-5 Imaginative and imitative play is typical of preschoolers.

behavior so faithful and absorbing as in 4- and 5-year-old children. Toward the end of the preschool period children are less satisfied with make-believe or pretend objects and enjoy doing the actual activity such as cooking and carpentry.

Television and other media also have their place in children's play, although each should be only one part of children's total repertoire of social and recreational activities. Parents and other caregivers should supervise the selection of programs, watch and discuss programs with their children, schedule limited time for television viewing, and set a good example of television viewing (American Academy of Pediatrics [AAP], 2007). Children enjoy and learn from educational programs; however, television viewing may limit time spent in other meaningful activities such as reading, physical activity, and socialization (AAP, 2007). Prolonged television viewing by young children has been linked to an increase in psychologic distress and decreased time spent in active playing, which increases the risk for obesity among certain children (Hamer, Stamatakis, and Mishra, 2009). Fast-paced television cartoons have been linked to a temporary decrease in executive functioning in 4-year-olds (self-regulation and working memory) (Lilard and Peterson, 2011).

Although the potential negative effects of television viewing have been well documented in literature, research has also shown that prosocial behavior and later academic achievement can result from viewing educational media during the preschool years; however, positive effects depend on the media content, the age of the viewer, the length of viewing time, and the presence of a co-viewing parent (Kirkorian, Wartella, and Anderson, 2008). When parents view media with their children, the activity can become interactive, with parents and children discussing program content. Considering the significant increase in media accessibility through various portable electronic devices and cell phones, parents need to be aware of the potential positive and negative effects of media exposure.

Play is so much a part of young children's lives that reality and fantasy become blurred. Make-believe is reality during play and only becomes fantasy when the toys are put away or the dress-up clothes

are removed. It is no wonder that imaginary playmates are so much a part of this age period. The appearance of imaginary companions usually occurs between 2½ and 3 years of age, and for the most part such playmates are relinquished when the child enters school. Differences in birth order and gender have been noted in studies of imaginary companion play. Firstborn children have a higher incidence of imaginary companions as do young girls; young boys more often tend to impersonate characters (Trionfi and Reese, 2009).

Imaginary companions serve many purposes: they become friends in times of loneliness, accomplish what the child is still attempting, and experience what the child wants to forget or remember. It is not unusual for the "friend" to have myriad vices and be blamed for wrongdoing. Sometimes the child hopes to escape punishment by saying, "My friend George broke the glass." At other times the child may fantasize that the companion misbehaved and play the role of the parent. This becomes a way of assuming control and authority in a safe situation.

Parents often worry about the imaginary playmates, not realizing how normal and useful they are. They need to be reassured that the child's fantasy is a sign of health that helps differentiate make-believe and reality. Parents can acknowledge the presence of the imaginary companion by calling him or her by name and even agreeing to simple requests such as setting an extra place at the table, but they should not allow the child to use the playmate to avoid punishment or responsibility. For example, if the child blames the companion for messing up a room, parents need to state clearly that the child is the only one they see; therefore the child is responsible for cleaning up.

Children also benefit from play that occurs between them and a parent. Mutual play fosters development from birth through the school years and provides enriched opportunities for learning. Through mutual play parents can provide tactile and kinesthetic experiences, maximize verbal and language abilities, and offer praise and encouragement for exploration of the world. In addition, mutual play encourages positive interactions between the parent and child, strengthening their relationship.

Table 33-1 summarizes the major developmental achievements for children 3, 4, and 5 years of age.

Coping with Concerns Related to Normal Growth and Development

Preschool and Kindergarten Experience

Some children are home schooled, but many attend some type of early childhood program, usually preschool or a day care center. Group care has become commonplace with the large number of parents currently employed outside the home (see Alternate Child Care Arrangements, Chapter 31). The effects of early education and stimulation on children have increasingly gained recognition. (For a discussion of the effects of day care on young children, see Working Mothers, Chapter 27.) Because social development widens to include age mates and other significant adults, preschool provides an excellent vehicle for expanding children's experiences with others. It is also excellent preparation for entrance into elementary school.

In preschool or day care centers children are exposed to opportunities for learning group cooperation; adjusting to sociocultural differences; and coping with frustration, dissatisfaction, and anger. If activities are tailored to provide mastery and achievement, children increasingly have feelings of success, self-confidence, and personal competence. Whether structured learning is imposed is less important than the social climate, type of guidance, and attitude toward the children that is fostered by the teacher or leader. With a teacher who is aware of preschoolers' developmental abilities and needs, children learn from the activity that is provided. Most programs incorporate a daily schedule of quiet play, active outdoor activity, group activities such as games and projects, creative or free play, and snack and rest periods. Preschool is particularly beneficial for children who lack a peer-group experience such as only children and for children from impoverished homes.

One of the issues that parents face is their children's readiness for preschool or kindergarten. There are no absolute indicators for school readiness; but children's social maturity, especially attention span, is as important as their academic readiness. Using a developmental screening tool that addresses cognitive (especially language), social, and physical milestones can identify children who may benefit from diagnostic testing and early-intervention programs before starting school. Parents play an integral role in their children's school readiness. They should promote a positive attitude toward learning, read to their children, encourage their children to participate in a variety of activities to explore their talents and interests, and choose appropriate child care or preschool programs (Hagan, Shaw, and Duncan, 2008).

Nurses and other health care workers can guide parents in selecting enriched social and educational early-intervention programs, schools, and child care centers. Careful selection of early-childhood education is intrinsic to future learning and development. Licensed and regulated programs are mandated to abide by established standards, which represent minimum requirements and safeguards. Regulation is important to protect children from harm and promote the conditions essential for a child's healthy development and learning. The National Association for the Education of Young Children (NAEYC) serves as the model for optimal care of small children.*

Areas for parents to evaluate include the daily program of the facility, teacher qualifications, staff-to-student ratio, discipline policy, environmental safety precautions, provision of meals, sanitary conditions, adequate indoor and outdoor space per child, safety and injury prevention, and fee schedule. A plan for emergency response in case of fire or other hazard [flooding, tornado] should also be well established (with evacuation drills) by the program. References from other parents help in evaluating a facility, but personal observation of the facility is recommended. Encourage parents to meet the director and some of the employees at a few facilities to make an informed choice.

Evaluation of the health practices of the facility is extremely important. Children in day care centers have more illnesses than those not in day care centers, especially gastrointestinal tract infections; respiratory tract infections; and hepatitis A, varicella-zoster virus, and cytomegalovirus infections (Nesti and Goldbaum, 2007). Nurses play an important role in infection control. Not only can they advise parents regarding the evaluation of the sanitary practices of a facility, but they can also take an active part in educating staff in measures to minimize transmission of infection (Fig. 33-6). Proactive infection control measures and education of staff have been effective in reducing the incidence of upper respiratory tract infections, diarrhea, and rotavirus (Kotch, Isbell, Weber, et al., 2007). Day care staff should also have updated routine immunizations according to the adult immunization recommendations, including the annual influenza vaccine, to protect the children in the center (AAP

*Information about accreditation criteria and procedures of the NAEYC Academy for Early Childhood Program Accreditation is available from the National Association for the Education of Young Children, 1313 L St. NW, Suite 500, Washington, DC 20005, 800-424-2460 or 202-232-8777, fax: 202-328-1846, www.naeyc.org. These criteria are excellent guidelines for evaluating preschools and day care centers.

TABLE 33-1 GROWTH AND DEVELOPMENT DURING PRESCHOOL YEARS

PHYSICAL	GROSS MOTOR	FINE MOTOR	LANGUAGE	SOCIALIZATION	COGNITION	FAMILY RELATIONSHIPS
Age 3 Yr						
Usual weight gain of 1.8-2.7 kg (4-6 lbs) Average weight of 14.5 kg (32 lbs) Usual gain in height of 7.5 cm (3 inches) per year Average height of 95 cm (37.5 inches) May have achieved nighttime control of bowel and bladder	Rides tricycle Jumps off bottom step Stands on one foot for a few seconds Goes up stairs using alternate feet; may still come down using both feet on step Broad jumps May try to dance, but balance may not be adequate	Builds tower of 9-10 cubes Builds bridge with three cubes Adeptly places small pellets in narrow-necked bottle In drawing, copies a circle, imitates a cross, names what has been drawn; cannot draw stick figure but may make circle with facial features	Has vocabulary of about 900 words Uses primarily telegraphic speech Uses complete sentences of three or four words Talks incessantly regardless of whether anyone is paying attention Repeats sentence of six syllables Asks many questions	Dresses self almost completely if helped with back buttons and told which shoe is right or left Pulls on shoes Has increased attention span Feeds self completely Can prepare simple meals such as cold cereal and milk Can help to set table; can dry dishes without breaking any May have fears, especially of dark and going to bed Knows own gender and gender of others Play is parallel and associative; begins to learn simple games but often follows own rules; begins to share	Is in preconceptual phase Is egocentric in thought and behavior Has beginning understanding of time; uses many time-oriented expressions, talks about past and future as much as about present, pretends to tell time Has improved concept of space, as demonstrated by understanding of prepositions and ability to follow directional command Has beginning ability to view concepts from another perspective	Attempts to please parents and conform to their expectations Is less jealous of younger sibling Is aware of family relationships and sex-role functions Boys tend to identify more with father or other male figure Has increased ability to separate easily and comfortably from parents for short periods
Age 4 Yr						
Pulse and respiration rates decrease slightly Growth rate is similar to that of previous year Average weight of 16.7 kg (36.8 lbs) Average height of 103 cm (40.5 inches) Birth length has doubled Maximum potential for development of amblyopia	Skips and hops on one foot Catches ball reliably Throws ball overhead Walks down stairs using alternate footing	Uses scissors successfully to cut out picture following outline Can lace shoes but may not be able to tie bow In drawing, copies a square, traces a cross and diamond, adds three parts to stick figure	Has vocabulary of 1500 words or more Uses sentences of four or five words Questioning is at peak Tells exaggerated stories Knows simple songs May be mildly profane if associates with older children Obeys four prepositional phrases such as under, on top of, beside, in back of, or in front of Names one or more colors Comprehends analogies such as, "If ice is cold, fire is _____."	Very independent Tends to be selfish and impatient Aggressive physically and verbally Takes pride in accomplishments Has mood swings Shows off dramatically, enjoys entertaining others Tells family tales to others with no restraint Still has many fears Play is associative Imaginary playmates are common Uses dramatic, imaginative, and imitative devices Sexual exploration and curiosity demonstrated through play such as being "doctor" or "nurse" (see text)	Is in phase of intuitive thought Causality is still related to proximity of events Understands time better, especially in terms of sequence of daily events Unable to conserve matter Judges everything according to one dimension such as height, width, or order Immediate perceptual clues dominate judgment Is beginning to develop less egocentrism and more social awareness May count correctly but has poor mathematic concept of numbers Obeys because parents have set limits, not because of understanding of right or wrong	Rebels if parents expect too much such as impeccable table manners Takes aggression and frustration out on parents or siblings Do's and don'ts become important May have rivalry with older or younger siblings; may resent older sibling's privileges and younger sibling's invasion of privacy and possessions May "run away" from home Identifies strongly with parent of opposite sex Is able to run simple errands outside the home

TABLE 33-1 GROWTH AND DEVELOPMENT DURING PRESCHOOL YEARS—cont'd

PHYSICAL	GROSS MOTOR	FINE MOTOR	LANGUAGE	SOCIALIZATION	COGNITION	FAMILY RELATIONSHIPS
Age 5 Yr						
Pulse and respiration rates decrease slightly Average weight of 18.7 kg (41.2 lbs) Average height of 110 cm (43.5 inches) Eruption of permanent dentition may begin Handedness is established (about 90% are right-handed)	Skips and hops on alternate feet Throws and catches ball well Jumps rope Skates with good balance Walks backward with heel to toe Jumps from height of 12 inches and lands on toes Balances on alternate feet with eyes closed	May begin to tie shoelaces but still needs some help Uses scissors, simple tools, or pencil very well In drawing copies a diamond and triangle; adds seven to nine parts to stick figure; prints a few letters, numbers, or words such as first name	Has vocabulary of about 2100 words Uses sentences of six to eight words, with all parts of speech Names coins (e.g., nickel, dime) Names four or more colors Describes drawing or pictures with much comment and elaboration Knows days of week, months, and other time-associated words Knows composition of objects, such as "A shoe is made of _____." Can follow three commands in succession	Less rebellious and quarrelsome than at age 4 yr More settled and eager to get down to business Not as open and accessible in thoughts and behavior as in earlier years Independent but trustworthy, not foolhardy; more responsible Has fewer fears; relies on outer authority to control world Eager to do things right and to please; tries to "live by the rules" Has better manners Cares for self totally, occasionally needing supervision in dress or hygiene Not ready for concentrated close work or small print because of slight farsightedness and still unrefined eye-hand coordination Play is associative; tries to follow rules but may cheat to avoid losing	Begins to question what parents think by comparing them with age-mates and other adults May notice prejudice and bias in outside world Is more able to view other's perspective but tolerates rather than understands differences May begin to show understanding of conservation of numbers through counting objects regardless of arrangement Uses time-oriented words with increased understanding Cautious about accepting or believing information	Gets along well with parents May seek out parent more often than at age 4 yr for reassurance and security, especially when entering school Begins to question parents' thinking and principles Strongly identifies with parent of same sex, especially boys with their fathers Enjoys activities such as sports, cooking, and shopping with parent of same sex

FIG 33-6 Thorough hand washing is the single most effective method of preventing infection.

Committee on Infectious Diseases, 2012). Parents should inquire about the policy of the center regarding the attendance and care of sick children.

The American Academy of Pediatrics' *2012 Red Book: Report of the Committee of Infectious Diseases* (2012) contains additional infection control guidelines regarding day care hand washing; cleaning sleep equipment, toys, and food; care of pets; and conditions or illnesses for which children should be kept out of day care to prevent the spread of illness.

Children need preparation for the preschool or kindergarten experience. For young children it represents a change from their usual home environment and prolonged separation from their parents. Before children begin school, parents should present the idea as exciting and pleasurable. Talking to children about activities such as painting, building with blocks, or enjoying swings and other outdoor equipment allows children to fantasize about the forthcoming event in a positive manner. When the first day of school arrives, parents should behave confidently. Such behavior requires them to have resolved their own feelings regarding the experience.

Parents should introduce their child to the teacher and the facility. In some instances it is helpful for parents to remain with the child for at least part of the first day until the child is comfortable and at ease. Other specific actions that can help reduce separation anxiety include providing the school with detailed information about the child's home environment such as familiar routines, favorite activities, food preferences, names of siblings or pets, and personal habits. Such information helps the child feel familiar in the strange surroundings. When schools automatically request this information, the parent has a valuable clue to evaluating the quality of the program because the request represents the staff's awareness of each child's needs. Transitional objects such as a favorite toy may also help the child bridge the gap from home to school.

Sex Education

Preschoolers have assimilated a tremendous amount of information during their short lifetimes. Although their thinking may not be mature, they search constantly for explanations and reasons that are logical and reasonable to them. The word "why" seems to supplant the word "no," which was common in toddlerhood. It is only natural that, as they learn about "me," they will also want to know "why me" and "how me." Questions such as, "Where do babies come from?" are as casual as, "What makes it rain?" or "Who is that?" It is the *way* in which questions about procreation are answered that conditions children, even the youngest, to separate these questions from others about their world.

Two rules govern answering sensitive questions about topics such as sex. The first is to *find out what children know and think.* By investigating the theories that children have produced as a reasonable explanation, parents can give correct information and help them understand why their explanation is inaccurate. Another reason for ascertaining what the child thinks before offering any information is that the "unasked for" answer may be given. For example, 4-year-old Sally asked her father, "Where did I come from?" Both parents quickly took this inquiry as a clue for offering sex education. After the explanation Sally exclaimed, "I don't know about all that! All I know is that Mary came from New York, and I want to know where I was born."

The second rule for giving information is to *be honest.* It is true that the preschooler will forget or misunderstand much of the correct information, but the correct information can be restated until the child absorbs and comprehends the facts. Even though the correct anatomic words may be hard to pronounce or even more difficult to remember, they become foundational content for explaining other concepts at a later time.

Honesty does not imply imparting to children every fact of life or allowing excessive permissiveness in sexual curiosity. When children ask one question, they are looking for one answer. When they are ready, they will ask about the other "unfinished" parts of the story. Sooner or later they will wonder how the "sperm meets the egg" and "how the baby gets out," but during this period it is best to wait until they ask.

Regardless of whether or not children are given sex education, they will engage in games of sexual curiosity and exploration. At about 3 years of age children are aware of the anatomic differences between the sexes and concerned with how the other "works." This is not really "sexual" curiosity because many children are still unaware of the reproductive function of the genitalia. Their curiosity is for the eliminative function of the anatomy. Little boys wonder how girls can urinate without a penis, so they watch girls go to the bathroom. Because they cannot see anything but the stream of urine coming out, they want to observe further. "Doctor play" is often a game invented for just such investigation. Little girls are no less curious about boys' anatomy. It is intriguing to closely inspect this "thing" that girls do not have.

One question that parents often have is how to handle such sexual curiosity. A positive approach is to neither condone nor condemn it but to express that if children have questions, they should ask the parents; the parents should then encourage them to engage in some other activity. In this way children can be helped to understand that there are ways to satisfy their sexual curiosity other than through investigative games. This in no way condemns the act but stresses alternate methods to seek solutions and answers. Allowing children unrestricted permissiveness only intensifies their anxiety and concern, since exploring and searching usually yield little evidence to satisfy their curiosity.

Many excellent books on sex education are available for preschool children at public libraries. The Sexuality Information and Education Council of the United States (SIECUS)* and the AAP†

*SIECUS, 1706 R St., NW, Washington, DC 20009, 202-265-2405, fax: 202-462-2340, www.siecus.org.

†AAP, 141 Northwest Point Blvd, Elk Grove Village, IL 60007, 847-434-4000, fax: 847-434-8000, www.aap.org.

have bibliographies of suggested reading material. Parents should read the book themselves *before* giving or reading them to their children.

Another concern for some parents is *masturbation*, or self-stimulation of the genitalia. This occurs at any age for a variety of reasons and, if not excessive, is normal and healthy. It is most common at 4 years of age and during adolescence. For preschoolers it is a part of sexual curiosity and exploration. If parents are concerned about their children masturbating, it is essential for nurses to investigate the circumstances associated with the activity because it may be an expression of anxiety, boredom, or unresolved conflicts. Children who openly and publicly masturbate are inviting a reaction such as discipline, punishment, or criticism. They may be overwhelmed by their sexual feelings and are asking others to help channel them into more constructive outlets. Like other forms of sex play, masturbation is a private act, and parents should emphasize this to children when teaching them socially acceptable behavior.

Fears

A great number and variety of real and imagined fears are present during the preschool years, including fear of the dark, being left alone (especially at bedtime), animals (particularly large dogs), ghosts, sexual matters (castration), and objects or persons associated with pain. The exact cause of children's fears is often unknown. Parents often become perplexed about handling the fears because no amount of logical persuasion, coercion, or ridicule sends away the ghosts, boogeymen, monsters, and devils. Inappropriate television viewing by preschoolers may increase fears and anxieties because of the inability to separate reality-based experiences from fantasy portrayed on television.

The concept of **animism** (i.e., ascribing lifelike qualities to inanimate objects) helps explain why children fear objects. For example, a child may refuse to use the toilet after watching a television commercial in which the toilet bowel is portrayed as turning into a monster.

Preschoolers also experience fear of annihilation. Because of poorly defined body boundaries and improved cognitive abilities, young children develop concerns related to loss of body parts. They fear losing body parts with certain medical procedures such as an intravenous insertion or cast application on a limb and may see these procedures as real threats to their existence. Preschoolers are often fearful when approaching the health care environment (office or hospital) and are especially fearful of pain. Because of their inability to sometimes discern reality from the imagined, a painful procedure such as a vaccination may be perceived as the end of existence (death) *to* the child; the preschooler is often unable to see beyond that experience. It is helpful to discuss the child's fears but maintain honesty and openness when working with preschoolers in the health care setting.

The best way to help children overcome their fears is by actively involving them in finding practical methods to deal with the frightening experience. This may be as simple as keeping a night-light on in the child's bedroom for assurance that no monsters lurk in the dark. Exposing children to the feared object in a safe situation also provides a type of conditioning, or *desensitization*. For instance, children who are afraid of dogs should never be forced to approach or touch one, but they may be introduced gradually to the experience by watching other children play with the animal. This type of modeling, with others demonstrating fearlessness, can be effective if the child is allowed to progress at his or her own rate.

Usually by 5 or 6 years of age children relinquish many of their fears. Explaining the developmental sequence of fears and their gradual disappearance may help parents feel more secure in handling preschoolers' fears. Sometimes fears do not subside with simple measures or developmental maturation. When children experience severe fears that disrupt family life, professional help is required.

Stress

Although for parents the preschool years generally are less troublesome than toddlerhood, this period of life presents children with many unique stresses. Some such as fears are innate and stem from preschoolers' unique understanding of the world. Others such as beginning school are imposed. Although minimal amounts of stress are beneficial during the early years to help children develop effective coping skills, excessive stress is harmful. Young children are especially vulnerable because of their limited capacity to cope. Expression of frustration, fear, or anxiety is hampered by inadequate expressive language.

To help parents deal with stress in their child's life, they must be aware of its signs (see Stress in Childhood, Chapter 28) and be helped to identify the source. Any number of stressors may be present such as the birth of a sibling, marital discord, divorce and separation, relocation, or illness.

The best approach to dealing with stress is prevention (i.e., monitoring the amount of stress in children's lives so levels do not exceed their coping ability and informing them of anticipated changes on a short-term basis) and education. In many instances structuring children's schedules to allow rest and preparing them for change such as entering school are sufficient measures.

Aggression

The term *aggression* refers to behavior that attempts to hurt a person or destroy property. Aggression differs from anger, which is a temporary emotional state, but anger may be expressed through aggression. Hyperaggressive behavior in preschoolers is characterized by unprovoked physical attacks on other children and adults, destruction of others' property, frequent intense temper tantrums, extreme impulsivity, disrespect, and noncompliance. Aggression is influenced by a complex set of biologic, sociocultural, and familial variables. Factors that tend to increase aggressive behavior are gender, frustration, modeling, and reinforcement.

Evidence indicates that types of aggression differ between genders. Boys exhibit more physical aggression than girls during preschool years (Benzies, Keown, and Magill-Evans, 2009); however, preschool girls exhibit more relational aggression than preschool boys (Ostrov and Bishop, 2008). Frustration, or the continual thwarting of self-satisfaction by disapproval, humiliation, punishment, or insults, can lead children to act out against others as a means of release. Especially if they fear their parents, these children displace their anger on others, particularly peers and other authority figures. This type of aggression often applies to children who are well-behaved at home but have a discipline problem at school or are bullies among their playmates.

Modeling, or imitating the behavior of significant others, is a powerful influencing force in preschoolers. Children who see their parents as physically abusive are observing behavior that they come to know as acceptable and therefore may exhibit with others (Benzies, Keown, and Magill-Evans, 2009). Another aspect of modeling is the "double standard" for acceptable conduct. For example, in some families aggression is synonymous with masculinity, and boys are encouraged to defend themselves. Television is also a significant source for modeling at this impressionable age. Research indicates that there is a direct correlation between media exposure, both

violent and educational media, and preschoolers exhibiting physical and relational aggression (Ostrov, Gentile, and Crick, 2006). Therefore parents should be encouraged to supervise television viewing. The AAP (2007) offers a list of recommendations for healthy television viewing.

Reinforcement can also shape aggressive behavior. Sometimes the reward for aggression is negative (e.g., punishment) yet reinforcing because it brings attention. For example, children who are ignored by a parent until they hit a sibling or the parent learn that this act garners attention.

When children exhibit extreme behaviors such as aggression, parents may be concerned about the need for professional help. Generally the difference between "normal" and "problematic" behavior is not the behavior itself but its quantity (number of occurrences), severity (interference with social or cognitive functioning), distribution (different manifestations), onset (when behavior started), and duration (at least 4 weeks).*

Speech Problems

The most critical period for speech development occurs between 2 and 4 years of age. During this period children are using their rapidly growing vocabulary faster than they can produce the words. Failure to master sensorimotor integrations results in stuttering or stammering as children try to say the word about which they are already thinking. This **dysfluency** in speech pattern is common during language development in children 2 to 5 years of age (National Institute on Deafness and Other Communication Disorders, 2010). Stuttering affects boys more frequently than girls, has been shown to have a genetic link, and usually resolves during childhood (Prasse and Kikano, 2008). The National Institute on Deafness and Other Communication Disorders (2010) encourages parents and caregivers of children who stutter to speak slowly and relaxed, refrain from criticizing the child's speech, resist completing the child's sentences, and take time to listen attentively.

The best therapy for speech problems is prevention and early detection. Common causes of speech problems include hearing loss or impairment, oropharyngeal structural anomalies, developmental disorders such as autism, brain injuries and other neuromotor impairments, lack of a verbally stimulating environment, and change in language exposure as in international adoption (Sharp and Hillenbrand, 2008). Referral for further evaluation and treatment may be necessary to prevent a problem from interfering with learning. Anticipatory preparation of parents for expected developmental norms may allay caregiver concerns.

Children pressured into producing sounds ahead of their developmental level may develop **dyslalia** (articulation problems) or revert to using infantile speech. Prevention involves educating parents regarding the usual achievement of speech production during childhood. The Denver Articulation Screening Exam is an excellent tool for assessing articulation skills of a child and explaining to parents the expected progression of sounds.

PROMOTING OPTIMAL HEALTH DURING THE PRESCHOOL YEARS

Nutrition

Healthy nutrition during childhood should include eating a variety of foods and consuming sufficient energy to promote growth and development while avoiding the development of obesity (AAP Committee on Nutrition, 2009). The 2010 Dietary Guidelines for Americans (U.S. Department of Agriculture, 2010) recommend an average intake of 1400 to 1600 calories per day for a moderately active child 4 to 8 years of age; these guidelines emphasize the reduction of sugar-sweetened beverages and excess intake of juices for young children and an overall increase in the amount of whole grains, vegetables, and fruits.* A daily intake of 16 oz/day of milk for preschoolers is recommended; this can be whole milk, 2%, or 1% milk. The Dietary Guidelines indicate that there is moderate evidence that consumption of milk and other dairy products does not contribute significantly to weight gain in young children. Fluid requirements may also decrease slightly to approximately 100 mL/kg/day but depend on the child's activity level, climatic conditions, and state of health. Protein requirements increase with age, and the recommended intake for preschoolers is 13 to 19 g/day (0.45 to 0.67 oz/day) (Otten, Hellwig, and Meyers, 2006).

The AAP Committee on Nutrition (2009) recommends the following guidelines for children older than 2 years of age: saturated fatty acid consumption should be less than 10% of total caloric intake; total fat over several days should be 20% to 30% of total caloric intake; and cholesterol consumption should be less than 300 mg/day. Fiber intake for children 3 years of age should be 19 mg/day and 25 mg/day for children 4 to 8 years of age (AAP, 2009). Research supports the efficacy of following these recommendations, and negative health effects have not been reported (American Heart Association, Gidding, Dennison, et al., 2006). These efforts are important in preventing childhood obesity, cardiovascular disease, diabetes, and metabolic syndrome. There is now sufficient evidence that the incidence of coronary heart disease, obesity, and chronic health problems such as diabetes mellitus can be influenced by early eating patterns (Barlow and Expert Committee, 2007). Evidence suggests that children who participate in family meal times in the home (three or more meals together) have a decreased risk for obesity and unhealthy eating patterns that may contribute to overweight and subsequent cardiovascular disease (Dattilo, Birch, Krebs, et al., 2012).

In addition to limiting fat consumption, it is also important to ensure that diets contain adequate nutrients such as calcium. The recommendation for daily calcium intake for children 1 to 3 years of age is 500 mg; for children 4 to 8 years of age is it 800 mg (Otten, Hellwig, and Meyers, 2006). Milk and dairy products are excellent sources of calcium and vitamin D (fortified). Low-fat milk may be substituted; thus the quantity of milk may remain the same while limiting fat intake overall.

Excessive consumption of fruit juices and other sweetened beverages has been associated with adverse health effects such as dental caries, gastrointestinal conditions such as chronic diarrhea, and diets poor in nutritive value (Allen and Myers, 2006). The AAP recommends limiting the intake of 100% fruit juice to 4 to 6 oz/day for children 1 to 6 years of age (AAP, 2009). Parents should be educated regarding nonnutritious fruit drinks, which usually contain less than 10% fruit juice yet are often advertised as healthy and nutritious; sugar content is dramatically increased and often precludes an adequate intake of milk by the child. When counseling parents regarding moderation in fruit juice consumption, providers should offer suggestions for more appropriate sources of nutrients such as ascorbic acid, folate, and potassium. In young children intake of

*Information on child development and behavior can be obtained through the AAP Section on Developmental and Behavioral Pediatrics, www.aap.org/sections/dbpeds.

*For a more comprehensive understanding, readers are urged to review Promoting Optimal Health During Toddlerhood, Chapter 32.

FIG 33-7 Preschool-age children enjoy helping adults and are more likely to try new foods if they can help in the preparation.

carbonated beverages that are acidic or contain high amounts of sugar is also known to contribute to dental caries; large amounts of nonnutritive calories in such beverages may also displace or preclude intake of nutrients necessary for growth.

An additional resource for dietary counseling includes MyPlate,* recently developed by the U.S. Department of Agriculture to replace MyPyramid. This colorful plate shows the five main food groups—fruits, grains, vegetable, protein, and dairy—with the intended purpose to involve children and their families in making appropriate food choices for meals and decrease the incidence of overweight and obesity in the United States. MyPlate provides an online interactive feature that allows the individual to select an individual food group and see choices for foods in that group. Approximate serving sizes are suggested, and vegetarian substitutions are also provided. This system is comprehensive and provides information for developing a healthy lifestyle at an early age. Parents can use this information to help their children make healthy lifestyle choices and prevent adverse health conditions secondary to poor nutrition. The importance of role-modeling by parents cannot be overemphasized in regard to food intake and dietary habits; if parents will not eat a particular food or if their dietary habits are poor, children are likely to develop the same habits.

Some preschoolers still have food habits that are typical of toddlers such as food fads and strong taste preferences. When they reach 4 years of age, they seem to enter another period of finicky eating, which is generally characteristic of the more rebellious behavior of children in this age-group. As with toddlers, small portions of each item being served should be offered. The practice of having children remain at the table until the "plate is clean" should be avoided because this may contribute to overeating and the development of poor eating habits that contribute to poor health later in life. By 5 years of age children are more agreeable to trying new foods, especially if they are encouraged by an adult who allows them to help with food preparation or experiment with a new taste or different dish (Fig. 33-7). Mealtimes can become battlegrounds if parents expect perfect table manners.† Usually 5-year-old children are ready for the "social" side of eating, but 3- or 4-year-old children still have difficulty sitting quietly through long family meals.

The amount and variety of foods consumed by young children vary greatly from day to day. Consequently parents sometimes worry about the quantity and quality of food that preschoolers consume. In general the quality is much more important than the quantity, a fact that should be stressed during nutrition counseling. Eating habits are well established by 5 years of age, with the major contributing factor being the family, especially the parents.

! NURSING ALERT

Obesity has increased over the past several decades in young children. Efforts to provide a healthy diet and encourage physical activity should begin early to help children achieve optimal health.

One way to lessen parental concern is to advise parents to keep a weekly record of everything the child eats. In particular the parents can measure the amount of food such as setting aside a half cup of vegetables and serving the child from this premeasured amount to provide a more accurate estimate of food intake at each meal. When parents look at the food chart at the end of the week, they are usually amazed by how much the child has consumed. In general preschoolers consume only slightly more than toddlers, or about half an adult's portion.

In addition to unhealthy eating habits, experts recognize that a sedentary lifestyle contributes to cardiovascular disease and obesity. Therefore the 2010 Dietary Guidelines also encourage 60 minutes of physical activity per day for children 6 years of age and older (U.S. Department of Agriculture, 2010). One program recommends that preschoolers be encouraged to be involved in at least 2 hours of cumulative activity per 8-hour day in day care, including unstructured free playtime (Larson, Ward, Neelon, et al., 2011).

Sleep and Activity

Sleep patterns vary widely, but the average preschooler sleeps about 12 hours a night and infrequently takes daytime naps. Waking during the night is common throughout early childhood and may be related to social and environmental factors rather than developmental or physiologic causes (Moore, Meltzer, and Mindell, 2008). Motor activity levels continue to be high and allow preschoolers to explore their environment, begin learning physical games and sports, and interact with others. Sedentary activities such as television and video or computer games are increasingly appealing and can become unhealthy substitutes for active play.

Preschoolers' increased gross motor abilities and coordination allow them to engage in many physical activities, if only at a novice level. Whether young children should begin formalized training in an activity at this early age is controversial. Training programs must consider the child's physical and psychologic immaturity, and readiness to participate in organized sports should be determined individually. The decision to participate should be based on the child's, not the parent's, motivation and enjoyment. The AAP Committee on Sports Medicine and Fitness and the AAP Committee on School Health (2006) encourages free play and a variety of physical activities; however, the AAP also supports organized play when it is developmentally appropriate and occurs in a nonthreatening, fun, and safe environment.

Sleep Problems

The preschool years are a prime time for sleep disturbances. Such disturbances are typically related to increasing autonomy, negative sleep associations, nighttime fears, inconsistent bedtime routines,

*http://www.choosemyplate.gov/.

†Excellent resources for parents related to mealtimes with toddlers and preschoolers include Jana LA, Shu J: *Food fights: winning the nutritional challenges of parenthood armed with insight, humor, and a bottle of ketchup*, Elk Grove Village, Ill, 2008, AAP; and Satter E: *How to get your kid to eat . . . but not too much,* Boulder, CO, 1987, Bull Publishing.

and lack of limit setting (Moore, Meltzer, and Mindell, 2008). Sleep disturbances may also be caused by nightmares and sleep terrors. Consequences of inadequate sleep include daytime tiredness, irritability and other negative behaviors, hyperactivity, difficulty concentrating, impaired learning ability, poor control of emotions and impulses, and strain on family relationships (Mindell, Kuhn, Lewin, et al., 2006).

Recommendations for handling sleep disturbances are offered only *after* a thorough assessment of the problem. Cultural traditions may dictate sleep practices that are contrary to certain well-accepted professional recommendations; therefore parents may not perceive a particular sleep practice to be a problem.

Interventions differ greatly; for example, nightmares (frightening dreams that are followed by full arousal) and sleep terrors (partial arousal from deep, nondreaming sleep) require different approaches (see Table 32-2).

For children who delay going to bed, a recommended approach involves counseling parents about the importance of a consistent bedtime ritual and emphasizing the normalcy of this type of behavior in young children. Parents should ignore attention-seeking behavior and not take the child into the parents' bed or allow him or her to stay up past a reasonable hour. Other measures that may be helpful include keeping a light on in the room, providing transitional objects such as a favorite toy, or leaving a drink of water by the bed. Parental consistency is paramount to all treatment approaches.

Helping children slow down *before* bedtime also reduces the resistance to going to bed. One strategy is to establish limited rituals that signal readiness for bed such as a bath or story. Parents can reinforce the pattern by stating, "After this story it's bedtime," and consistently carrying out the routine. If anticipated extra stimulation such as having visitors arrive at bedtime disrupts this routine, it is advisable to settle children in bed beforehand. Television viewing before bedtime may cause bedtime resistance and delay sleep.

Dental Health

By the beginning of the preschool period the eruption of the deciduous (primary) teeth is complete. Dental care is essential to preserve these temporary teeth and teach good dental habits (see Chapter 32). Although preschoolers' fine motor control is improved, they still require assistance and supervision with brushing, and flossing should be performed by parents. Professional care and prophylaxis, especially fluoride supplements (if needed), should be continued. The frequency of professional dental care should be based on a child's individual risk assessment, including family history, socioeconomic status, dental development, presence or absence of dental disease, special health care needs, and dietary habits (Kagihara, Niederhauser, and Stark, 2009). For children cared for away from home, parents should be encouraged to monitor the dental care provided by others, including minimizing cariogenic foods in the diet. Trauma to teeth during this period is common, and prompt evaluation by a dentist is warranted if oral trauma occurs. Preservation of the space previously occupied by an avulsed tooth is necessary for proper eruption of the secondary tooth.

Safety Promotion and Injury Prevention

Because of improved gross and fine motor skills, coordination, and balance, preschoolers are less prone to falls than toddlers. They tend to be less reckless; listen more to parental rules; and are aware of potential dangers such as hot objects, sharp instruments, and dangerous heights. Putting objects in the mouth as part of exploration has all but ceased, although accidental poisoning is still a danger. Pedestrian motor vehicle injuries increase because of activities such as playing in the parking lot, driveway, or street; riding tricycles, bicycles, and other play vehicles; running after balls; or forgetting safety regulations when crossing streets.

In general the guidelines suggested for injury prevention in Table 32-4 apply to children in this age-group as well. However, emphasis is now on *education* concerning safety and potential hazards *in addition* to appropriate protection. This is an excellent time to start enforcing the use of safety items such as bicycle helmets to prevent head trauma; children are less likely to warm to the idea later in life because of peer pressure. Because preschoolers are great imitators, it is essential that parents set a good example by "practicing what they preach." Children quickly observe discrepancies in what they are told to do and what they see others do. Establishing habits at this time such as wearing protective equipment can create long-term safety behaviors.

Anticipatory Guidance—Care of Families

The preschool years present fewer childrearing difficulties than do earlier years, and this stage of development is facilitated by appropriate anticipatory guidance in the areas already discussed (see Family-Centered Care box). There is a shift in childrearing practices from protection to education, but protection is still often needed. Injury prevention previously focused on safeguarding the immediate environment with less emphasis on reasoning; now the protective guardrails or electrical outlet caps may be replaced by verbal explanations of why danger exists and how to avoid it.

During this period an emotional transition between parent and child occurs. Although children are still attached to their parents and accept all their values and beliefs, they are nearing the period of life when they will question previous teachings and prefer the companionship of peers. Entry into school marks a separation for parents and for children. Parents may need help in adjusting to this change, particularly if one parent has focused his or her daily activities primarily on home responsibilities. All family members must adjust to changes, which is part of the process of growth and development.

INFECTIOUS CONDITIONS: COMMUNICABLE DISEASES

The incidence of childhood communicable diseases has declined significantly since the advent of immunizations. Serious complications resulting from such infections have been reduced further with the use of antibiotics and antitoxins. However, infectious diseases do occur, and nurses must be familiar with the infectious agent to recognize the disease and institute appropriate preventive and supportive interventions (Table 33-2).

CARE MANAGEMENT

Table 33-2 describes the more common communicable diseases of childhood, their therapeutic management, and specific nursing care. The following is a general discussion of nursing care management for communicable diseases.

Identification of the infectious agent is of primary importance to prevent exposure of susceptible individuals. Nurses in ambulatory care settings, child care centers, and schools are often the first people to see signs of a communicable disease such as a rash or sore throat. The nurse must operate under a high index of suspicion for common childhood diseases to identify potentially infectious cases and recognize diseases that require medical intervention. An example is the

FAMILY-CENTERED CARE

Guidance During Preschool Years

Age 3 Years

- Prepare parents for child's increasing interest in widening relationships.
- Encourage enrollment in preschool.
- Emphasize importance of setting limits.
- Prepare parents to expect exaggerated tension-reduction behaviors such as need for a "security blanket."
- Encourage parents to offer child choices.
- Prepare parents to expect marked changes at 3½ years, when child becomes insecure and exhibits emotional extremes.
- Prepare parents for normal dysfluency in speech and advise them to avoid focusing on the pattern.
- Prepare parents to expect extra demands on their attention as a reflection of child's emotional insecurity and fear of loss of love.
- Warn parents that the equilibrium of a 3-year-old will change to the aggressive, out-of-bounds behavior of a 4-year-old.
- Inform parents to anticipate a more stable appetite with more food selections.
- Stress need for protection and education of child to prevent injury (see Safety Promotion and Injury Prevention, Chapter 32).

Age 4 Years

- Prepare parents for more aggressive behavior, including motor activity and offensive language.
- Prepare parents to expect resistance to parental authority.
- Explore parental feelings regarding child's behavior.
- Suggest some type of respite for primary caregivers such as placing child in preschool for part of the day.
- Prepare parents for child's increasing sexual curiosity.
- Emphasize importance of realistic limit setting on behavior and appropriate disciplinary techniques.
- Prepare parents for the highly imaginative 4-year-old who indulges in "tall tales" (to be differentiated from lies) and develops imaginary playmates.
- Prepare parents to expect nightmares or an increase in them.
- Help parents understand the nature of the child's fears and how to deal with them effectively and in a constructive manner.
- Provide reassurance that period of calmness begins at 5 years of age.

Age 5 Years

- Inform parents to expect tranquil period at 5 years of age.
- Help parents prepare children for entrance into school environment.
- Make certain that childhood immunizations are up to date before child enters school.
- Suggest that unemployed parental caregivers consider own activities when children begin school.

common complaint of sore throat. Although most often a symptom of a minor viral infection, it can signal an infection such as group A streptococcal pharyngitis. Each of these bacterial conditions requires appropriate medical treatment to prevent serious sequelae.

When a communicable disease is suspected, it is important to assess:

- Recent exposure to a known case.
- Prodromal symptoms (symptoms that occur between early manifestations of the disease and its overt clinical syndrome) or evidence of constitutional symptoms such as a fever or rash (see Table 33-2).
- Immunization history.
- History of having the disease.

Immunizations are available for many diseases, and infection usually confers lifelong immunity; therefore the possibility of many infectious agents can be eliminated based on these criteria.

Prevent Spread

Prevention consists of two components: prevention of the disease and control of its spread to others. Primary prevention rests almost exclusively on immunization. (Chapter 31 discusses the nurse's role in childhood immunization.)

Control measures to prevent spread of disease should include techniques to reduce risk of cross-transmission of infectious organisms between patients and protect health care workers from organisms harbored by patients. If a child is hospitalized, facility policies for infection control should be followed (see Chapter 39). The most important procedure is *hand washing*. People directly caring for children and handling contaminated articles must wash their hands and practice effective Standard Precautions in care of their patients.

Instruct children to practice good hand-washing technique before eating and after toileting. For diseases spread by droplets, instruct the parents in measures to reduce airborne transmission. Children who are old enough should use a tissue to cover their faces when coughing or sneezing; otherwise the parent should cover the child's mouth with a tissue and then discard it. Stress to the family the usual hygiene measures of not sharing eating and drinking utensils.

Prevent Complications

Although most children recover without difficulty, certain groups are at risk for serious, even fatal, complications from communicable diseases, especially the viral diseases chickenpox and erythema infectiosum (EI) (fifth disease) caused by human parvovirus B19.

Children with immunodeficiency (i.e., those receiving steroid or other immunosuppressive therapy, those with a generalized malignancy such as leukemia or lymphoma, and those with an immunologic disorder) are at risk for viremia from replication of the varicella-zoster virus (VZV)* in the blood. VZV is so named because it causes two distinct diseases: varicella (chickenpox) and zoster (herpes zoster or shingles). Varicella occurs primarily in children younger than 15 years of age. However, it leaves the threat of herpes zoster, an intensely painful varicella that is localized to a single dermatome (body area innervated by a particular segment of the spinal cord). In children the dermatomes most likely affected by herpes zoster are the cervical and sacral dermatomes (Leung, Robson, and Leong, 2006). Immunocompromised patients and healthy infants younger than 1 year of age (who also have reduced immunity) are at a higher risk for reactivation of VZV-causing herpes zoster, probably as a result of a deficiency in cellular immunity (AAP Committee on Infectious Diseases, 2012). One population-based study found that the incidence of herpes zoster infection in children was rare; rates were higher among children vaccinated after 5 years of age (versus those vaccinated at 12 to 18 months of age), children with severe asthma, or those with developmental disorders (Tseng, Smith, Marcy, et al., 2009). Complications of herpes zoster virus in children include secondary bacterial infection, depigmentation, and scarring. Postherpetic neuralgia in children is uncommon (Leung, Robson,

TABLE 33-2 COMMUNICABLE DISEASES OF CHILDHOOD

DISEASE	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT AND COMPLICATIONS	NURSING CARE MANAGEMENT
Chickenpox (Varicella) (Fig. 33-8)			
Agents—Varicella-zoster virus (VZV) **Source**—Primary secretions of respiratory tract of infected people; to a lesser degree skin lesions (scabs not infectious) **Transmission**—Direct contact, droplet (airborne) spread, and contaminated objects **Incubation period**—2-3 wk, usually 14-16 days **Period of communicability**—Probably 1-2 days before eruption of lesions (prodromal period) until all lesions have crusted	**Prodromal stage**—Slight fever, malaise, and anorexia for first 24 hr; rash highly pruritic; begins as macule, rapidly progresses to papule and then vesicle (surrounded by erythematous base, becomes umbilicated and cloudy, breaks easily and forms crusts); all three stages (papule, vesicle, crust) present in varying degrees at one time **Distribution**—Centripetal, spreading to face and proximal extremities but sparse on distal limbs and less on areas not exposed to heat (i.e., from clothing or sun) **Constitutional signs and symptoms**—Elevated temperature from lymphadenopathy, irritability from pruritus Breakthrough varicella seen in previously vaccinated; primarily maculopapular, with 50 lesions or fewer that often appear to be insect bites; heals faster than varicella and fever lasts fewer days; one-third less contagious to other people	**Supportive**—Diphenhydramine hydrochloride or antihistamines to relieve itching; skin care to prevent secondary bacterial infection **Specific**—Antiviral agent acyclovir or valacyclovir for children at high risk (see text); varicella-zoster immunoglobulin or immunoglobulin intravenous (IGIV) after exposure in high risk children only (see text) **Complications**—Secondary bacterial infections (group A streptococcus; abscesses, cellulitis, necrotizing fasciitis, pneumonia, sepsis) Encephalitis Varicella pneumonia (rare in healthy children) Hemorrhagic varicella (tiny hemorrhages in vesicles and numerous petechiae in skin) Chronic or transient thrombocytopenia	Maintain Standard, Airborne, and Contact Precautions if hospitalized until all lesions are crusted; for immunized child with mild breakthrough varicella, isolate until no new lesions are seen. Keep child in home away from susceptible individuals until vesicles have dried (usually 1 wk after onset of disease) and isolate high risk children from infected children. Provide skin care; give bath and change clothes and linens daily; administer topical calamine lotion; keep child's fingernails short and clean; apply mittens if child scratches. Goal is to prevent secondary infection and make child comfortable. Administer antipyretics and mild antihistamine for pruritus. Keep child cool (may decrease number of lesions). Minimize pruritus; keep child distracted; use oatmeal or baking soda baths to minimize pruritus. Remove loose crusts that rub and irritate skin. *Avoid use of aspirin* (possible association with Reye syndrome). Administer acetaminophen for fever.

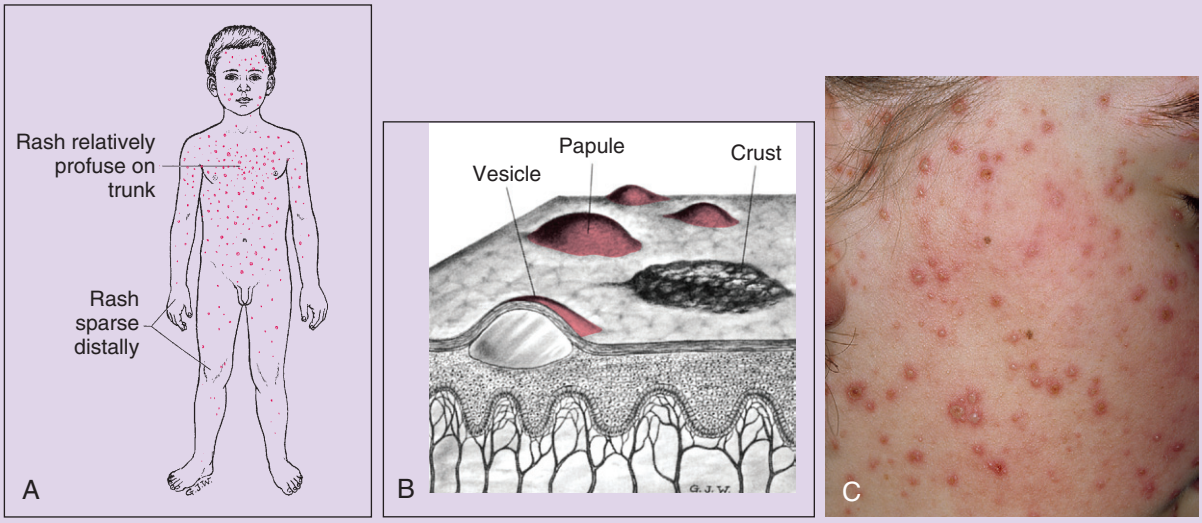

FIG 33-8 Chickenpox (varicella). **A,** Progression of disease. **B,** Simultaneous stages of lesions. **C,** Clinical view. (*C* From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

TABLE 33-2 COMMUNICABLE DISEASES OF CHILDHOOD—cont'd

DISEASE	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT AND COMPLICATIONS	NURSING CARE MANAGEMENT
Diphtheria			
Agent—*Corynebacterium diphtheriae* **Source**—Discharges from mucous membranes of nose and nasopharynx, skin, and other lesions of infected person **Transmission**—Direct contact with infected person, a carrier, or contaminated articles **Incubation period**—Usually 2-7 days, possibly longer **Period of communicability**—Varies; until virulent bacilli are no longer present (identified by three negative cultures); usually 2 wk but as long as 4 wk	Vary according to anatomic location of pseudomembrane **Nasal**—Resembles common cold, serosanguineous mucopurulent nasal discharge without constitutional symptoms; may be frank epistaxis **Tonsillar/pharyngeal**—Malaise; anorexia; sore throat; low-grade fever; pulse increased above expected within 24 hr; smooth, adherent, white or gray membrane; lymphadenitis possibly pronounced ("bull's neck"); in severe cases toxemia, septic shock, and death within 6-10 days **Laryngeal**—Fever, hoarseness, cough, with or without previous signs listed; potential airway obstruction, apprehensive, dyspneic retractions, cyanosis	Equine antitoxin (usually intravenously); preceded by skin or conjunctival test to rule out sensitivity to horse serum (antitoxin available only through CDC in United States) Antibiotics (penicillin G procaine, penicillin G, or erythromycin) in addition to equine antitoxin Tracheostomy for airway obstruction Treatment of infected contacts and carriers **Complications**—Toxic cardiomyopathy (second to third week) Toxic neuropathy	Follow Standard and Droplet Precautions until two cultures are negative for *C. diphtheriae;* Contact Precautions with cutaneous manifestations. Administer antibiotics in timely manner. Participate in sensitivity testing; have epinephrine available. Observe respiration for signs of obstruction.
Erythema Infectiosum (Fifth Disease) (Fig. 33-9)			
Agent—Human parvovirus B19 **Source**—Infected persons, mainly school-age children **Transmission**—Respiratory secretions, blood, blood products **Incubation period**—4-14 days; may be as long as 21 days **Period of communicability**—Uncertain but before onset of symptoms in children with aplastic crisis	Rash appearing in three stages: **I**—Erythema on face, chiefly on cheeks, "slapped face" appearance; circumoral pallor; disappears by 1-4 days **II**—About 1 day after rash appears on face maculopapular red spots appear, symmetrically distributed on upper and lower extremities; rash progresses from proximal (trunk) to distal surfaces and may last a week or more **III**—Rash subsiding but reappearing if skin is irritated or traumatized (sun, heat, cold, friction) In children with aplastic crisis rash usually absent; and prodromal illness includes fever, myalgia, lethargy, nausea, vomiting, and abdominal pain Possible concurrent vasoocclusive crisis in child with sickle cell disease	**Symptomatic and supportive**—Antipyretics, analgesics, antiinflammatory drugs Possible blood transfusion for transient aplastic anemia **Complications**—Self-limited arthritis and arthralgia (arthritis may become chronic); more common in adult women May result in serious complications (anemia, hydrops) or fetal death if mother infected during pregnancy (primarily second trimester) Aplastic crisis in children with hemolytic disease or immunodeficiency Myocarditis (rare)	Isolation of child is not necessary, except that hospitalized child (immunosuppressed or with aplastic crises) suspected of human parvovirus infection is placed on Droplet Precautions and Standard Precautions. Pregnant women need not be excluded from workplace where human parvovirus infection is present; they should not care for patients with aplastic crises; explain low risk of fetal death to those in contact with affected children; help with routine fetal ultrasound for detection of fetal hydrops. Neonate with intrauterine hydrops does not need to be isolated.

FIG 33-9 Erythema infectiosum. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

TABLE 33-2 COMMUNICABLE DISEASES OF CHILDHOOD—cont'd

DISEASE	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT AND COMPLICATIONS	NURSING CARE MANAGEMENT
Exanthem Subitum (Roseola Infantum; Sixth Disease) (Fig. 33-10)			
Agent—Human herpesvirus type 6 (HHV-6; rarely HHV-7) **Source**—Possibly acquired from saliva of healthy adult; entry via nasal, buccal, or conjunctival mucosa **Transmission**—Year-round; no reported contact with infected individual in most cases (virtually limited to children under 3 yr, but peak age is between 6 and 15 mo of life) **Incubation period**—Usually 9-10 days for HHV-6; unknown for HHV-7 **Period of communicability**—Unknown	Persistent high fever for 3-4 days in child who appears well Precipitous drop in fever to normal with appearance of rash **Rash**—Discrete rose-pink macules or maculopapules appearing first on trunk, then spreading to neck, face, and extremities; nonpruritic, fades on pressure, lasts 1-2 days **Associated signs and symptoms**—Cervical/postauricular lymphadenopathy, inflamed pharynx, cough, coryza	Nonspecific Antipyretics to control fever **Complications**—Recurrent febrile seizures (possibly from latent infection of central nervous system that is reactivated by fever) Encephalitis, myocarditis, hepatitis, acute cerebellitis (all rare)	Teach parents measures for lowering temperature (antipyretic drugs); ensure adequate parental understanding of specific antipyretic dosage to prevent accidental overdose. If child is prone to febrile seizures, discuss appropriate precautions and possibility of recurrent febrile seizures. Ensure adequate oral fluid intake.
Measles (Rubeola) (Fig. 33-11)			
Agent—Virus **Source**—Respiratory tract secretions, blood, and urine of infected person **Transmission**—Usually by direct contact with droplets of infected person; primarily in winter **Incubation period**—8-12 days **Period of communicability**—From 4 days before to 4 days after rash appears but mainly during prodromal (catarrhal) stage	**Prodromal (catarrhal) stage**—Fever and malaise, followed in 24 hr by coryza, cough, conjunctivitis, Koplik's spots (small, irregular red spots with a minute, bluish-white center first seen on buccal mucosa opposite molars 2 days before rash); symptoms gradually increasing in severity until second day after rash appears, when they begin to subside **Rash**—Appears 3-4 days after onset of prodromal stage; begins as erythematous maculopapular eruption on face and gradually spreads downward; more severe in earlier sites (appears confluent) and less intense in later sites (appears discrete); after 3-4 days assumes brownish appearance, and fine desquamation occurs over area of extensive involvement **Constitutional signs and symptoms**—Anorexia, abdominal pain, malaise, generalized lymphadenopathy	Vitamin A supplementation for children with acute illness (WHO recommendation): 200,000 IU for children 12 months and older, 100,000 IU for children 6 through 11 months of age, 50,000 IU for infants younger than 6 months (AAP Committee on Infectious Diseases, 2012) **Supportive**—Bed rest during febrile period; antipyretics Antibiotics to prevent secondary bacterial infection in high risk children **Complications**—Otitis media Pneumonia (bacterial) Obstructive laryngitis and laryngotracheitis Encephalitis (rare but has high mortality)	Isolate until fourth day of rash; if hospitalized, institute Droplet and Airborne Precautions. Encourage rest during prodromal stage; provide quiet activity. **Fever**—Instruct parents to administer antipyretics; avoid chilling; if child is prone to seizures, institute appropriate precautions. **Eye care**—Dim lights if photophobia present; clean eyelids with warm saline solution to remove secretions or crusts; keep child from rubbing eyes. **Coryza, cough**—Use cool-mist vaporizer; protect skin around nares with layer of petrolatum; encourage fluids and soft, bland foods. **Skin care**—Keep skin clean.

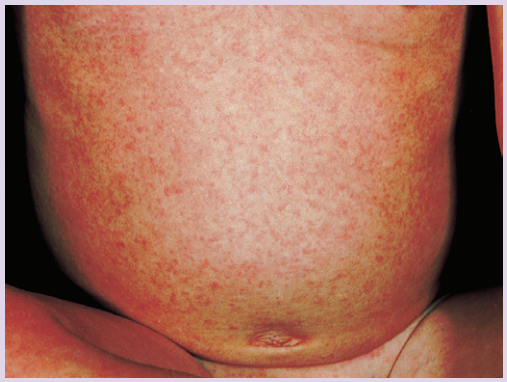

FIG 33-10 Roseola infantum. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

TABLE 33-2 COMMUNICABLE DISEASES OF CHILDHOOD—cont'd

DISEASE	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT AND COMPLICATIONS	NURSING CARE MANAGEMENT
Mumps **Agent**—Paramyxovirus **Source**—Saliva of infected persons **Transmission**—Direct contact with or droplet spread from an infected person **Incubation period**—16-18 days **Period of communicability**—Most communicable immediately before and after swelling begins	**Prodromal stage**—Fever, headache, malaise, and anorexia for 24 hr, followed by "earache" that is aggravated by chewing **Parotitis**—Parotid gland(s) (either unilateral or bilateral) enlarges and reaches maximum size in 1-3 days; accompanied by pain and tenderness; other exocrine glands (submandibular) possibly swollen	**Symptomatic and supportive**—Analgesics for pain and antipyretics for fever Intravenous fluid may be necessary for child refusing to drink or vomiting because of meningoencephalitis **Complications**—Sensorineural hearing loss (rare) Postinfectious encephalitis Myocarditis Arthritis Hepatitis Orchitis Oophoritis Pancreatitis Sterility is extremely rare in adult males Meningitis Thyroiditis (rare)	Isolate during period of communicability; institute Droplet and Contact Precautions during hospitalization. Encourage rest and decreased activity during prodromal phase until swelling subsides. Give analgesics for pain; if child is unable to swallow pills or tablets, use elixir form. Encourage fluids and soft, bland foods; avoid foods requiring chewing. Apply hot or cold compresses to neck or groin, whichever are more comforting.

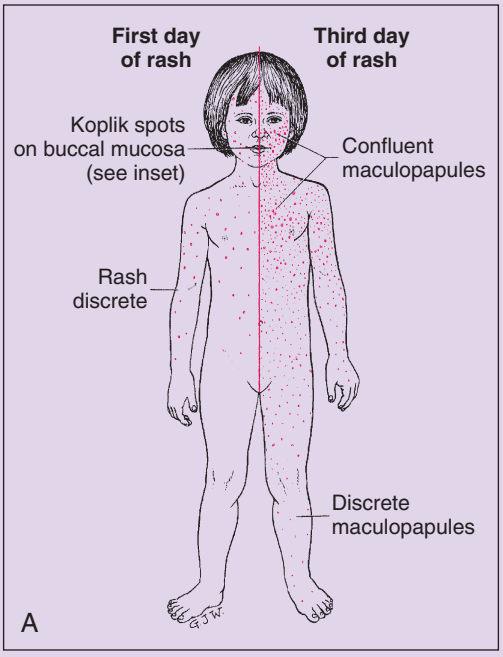

FIG 33-11 Measles (rubeola). **A,** Progression of disease. **B,** Exanthem first appears at hairline and spreads from head to toe over 3 days. **C,** Measles ultimately involves palms and soles. TABLE 33-2 COMMUNICABLE DISEASES OF CHILDHOOD—cont'd

DISEASE	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT AND COMPLICATIONS	NURSING CARE MANAGEMENT
Pertussis (Whooping Cough) **Agent**—*Bordetella pertussis* **Source**—Discharge from respiratory tract of infected person **Transmission**—Direct contact or droplet spread from infected person; indirect contact with freshly contaminated articles **Incubation period**—7-10 days, range 5-21 days **Period of communicability**—Greatest during catarrhal stage and the first 2 weeks after cough onset	**Catarrhal stage**—Begins with symptoms of upper respiratory tract infection (cold) such as coryza, sneezing, lacrimation, cough, and low-grade fever; symptoms continue for 1-2 wk when dry, hacking cough becomes more severe **Paroxysmal stage**—Cough most often occurs at night and consists of short, rapid coughs followed by sudden inspiration associated with a high-pitched crowing sound or "whoop"; during paroxysms cheeks become flushed or cyanotic, eyes bulge, and tongue protrudes; paroxysm may continue until thick mucus plug is dislodged; vomiting frequently follows attack; stage generally lasts 4-6 wk, followed by convalescent stage Infants under 6 mo of age may not have characteristic whoop cough but have difficulty maintaining adequate oxygenation with amount of secretions, frequent vomiting of mucus and formula or breast milk (see also Immunization, Chapter 31 for discussion of pertussis in adolescents)	Antimicrobial therapy (e.g., erythromycin, clarithromycin, azithromycin) **Supportive treatment**—Hospitalization sometimes required for infants, children who are dehydrated, or those who have difficulty maintaining adequate oxygenation Supplemental oxygen Adequate fluid intake Intensive care and mechanical ventilation may be necessary for infant <6 mo **Complications**—Pneumonia (usual cause of death) **Adolescents and adults**—complications include syncope, pneumonia, sleep disturbances, fractured ribs, incontinence; complications increase with age Atelectasis Otitis media Seizures Hemorrhage (scleral, conjunctival, epistaxis; pulmonary hemorrhage in neonate) Weight loss and dehydration Hernias (umbilical and inguinal) Prolapsed rectum	Isolate during catarrhal stage; if hospitalized, institute Droplet Precautions and Standard Precautions. Obtain nasopharyngeal culture for diagnosis. Encourage oral fluids; offer small amount of fluids frequently. Ensure adequate oxygenation during paroxysms; position infant on side to decrease chance of aspiration with vomiting. Provide high humidity (humidifier); suction as needed to prevent choking on secretions. Observe for signs of airway obstruction (infants), such as increased restlessness, apprehension, retractions, cyanosis. Encourage compliance with antibiotic therapy for household contacts. Encourage adolescents to obtain pertussis booster (Tdap) (see also Chapter 31, Immunizations). Use Standard Precautions and Droplet Precautions in health care workers exposed to children with persistent cough and high suspicion of pertussis.
Polioviruses **Agent**—Enteroviruses, three types: type 1, most frequent cause of paralysis (paralytic form), both epidemic and endemic; type 2, least frequently associated with paralysis (nonparalytic form); type 3, second most frequently associated with paralysis **Source**—Feces, urine, CNS, and oropharyngeal secretions of infected persons, especially young children	May be manifested in three different forms: **Abortive or inapparent**—Fever, uneasiness, sore throat, headache, anorexia, vomiting, abdominal pain; lasts few hours to few days **Nonparalytic**—Same manifestations as abortive but more severe, with pain and stiffness in neck, back, and legs	Treatment supportive Mechanical or assisted ventilation in case of respiratory paralysis Physical therapy for muscles following acute stage of nonparalytic form	Nursing care for paralytic form similar to child with muscular dystrophy, spinal muscular atrophy, and prolonged immobilization (see Chapter 49). Participate in physical therapy procedures (use of moist hot packs and range-of-motion exercises).

Continued

TABLE 33-2 COMMUNICABLE DISEASES OF CHILDHOOD—cont'd

DISEASE	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT AND COMPLICATIONS	NURSING CARE MANAGEMENT
Transmission—Direct contact with persons with apparent or inapparent active infection; spread is via fecal-oral and pharyngeal-oropharyngeal routes Vaccine-acquired paralytic polio may occur as result of live oral polio vaccination (no longer available in the United States) **Incubation period**—nonparalytic form, 6-7 days; paralytic form, usually 7-21 days **Period of communicability**—Not exactly known; virus present in throat and feces shortly after infection and persists for about 1 wk in throat and 4-6 wk in feces **1993**—Last known imported polio case in United States; child was transported to the United States for medical care **1979**—Last cases of indigenously acquired polio in the United States	**Paralytic**—Initial course similar to nonparalytic type, followed by recovery and then signs of central nervous system paralysis	**Complications**—Permanent paralysis Respiratory arrest Kidney stones from demineralization of bone during prolonged immobility	Position child to maintain body alignment and prevent contractures or skin breakdown; use footboard or appropriate orthoses to prevent footdrop; use pressure mattress for prolonged immobility. Encourage child to perform activities of daily living to capability, early ambulation with adjuncts; administer analgesics for maximum comfort during physical activity. Provide high-protein diet and bowel management for prolonged immobility. Observe for respiratory paralysis (difficulty in talking, ineffective cough, inability to hold breath, shallow and rapid respirations); report such signs and symptoms to practitioner.
Rubella (German Measles) (Fig. 33-12)			
Agent—Rubella virus **Source**—Primarily nasopharyngeal secretions of person with apparent or inapparent infection; virus also present in blood, stool, and urine **Incubation period**—14-21 days **Period of communicability**—2-3 days before to about 7 days after appearance of rash Congenital rubella syndrome-may result in mild-to-severe ophthalmologic, cardiac, auditory, and neurologic complications; chance of congenital defects highest (50% to 85%) if mother acquires illness (rubella) in first two trimesters of pregnancy	**Constitutional signs and symptoms**—Occasionally low-grade fever, headache, malaise, and lymphadenopathy **Prodromal stage**—Absent in children, present in adults and adolescents; consists of low-grade fever, headache, malaise, anorexia, mild conjunctivitis, coryza, sore throat, cough, and lymphadenopathy; lasts 1-5 days, subsides 1 day after appearance of rash **Rash**—First appears on face and rapidly spreads downward to neck, arms, trunk, and legs; by end of first day body is covered with discrete, pinkish-red, maculopapular exanthema; disappears in same order as it began and is usually gone by third day	No treatment necessary other than antipyretics for low-grade fever and analgesics for discomfort **Complications**—Rare (arthritis, encephalitis, or purpura); most benign of all childhood communicable diseases; greatest danger is teratogenic effect on fetus; miscarriage and fetal death may occur	Reassure parents of benign nature of illness in affected child. Use comfort measures as necessary. Avoid contact with pregnant woman. Monitor rubella titers in pregnant adolescent. Standard Precautions for hospitalized child; Droplet Precautions for 7 days after onset of rash. Contact isolation for infant with suspected or confirmed congenital rubella or until two cultures are negative for rubella.

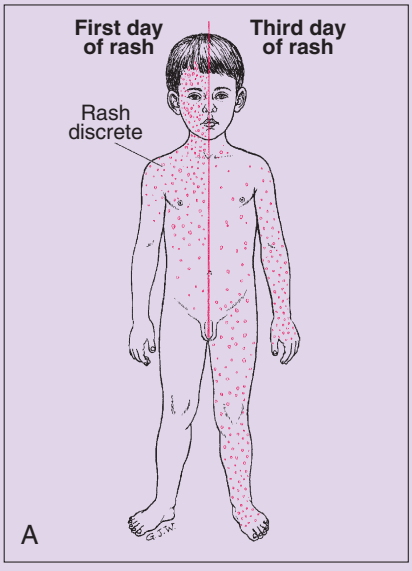

FIG 33-12 Rubella (German measles). **A,** Progression of rash. **B,** Clinical view. (*B* from Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

TABLE 33-2 COMMUNICABLE DISEASES OF CHILDHOOD—cont'd

DISEASE	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT AND COMPLICATIONS	NURSING CARE MANAGEMENT
Scarlet Fever* (Fig. 33-13) **Agent**—Group A β-hemolytic streptococci (GAS) **Source**—Usually from nasopharyngeal secretions of infected persons and carriers **Transmission**—Direct contact with infected person or droplet spread; indirectly by contact with contaminated articles or ingestion of contaminated milk or other food **Incubation period**—2-5 days, with range of 1-7 days **Period of communicability**—During incubation period and clinical illness, approximately 10 days; during first 2 wk of carrier phase, although may persist for months Severe cases now rare	**Prodromal stage**—Abrupt high fever, pulse increased out of proportion to fever, vomiting, headache, chills, malaise, abdominal pain, halitosis **Enanthema**—Tonsils enlarged, edematous, reddened, and covered with patches of exudates; in severe cases appearance resembles membrane seen in diphtheria; pharynx edematous and beefy red; during first 1-2 days tongue coated and papillae become red and swollen (white strawberry tongue); by fourth or fifth day white coat sloughs off, leaving prominent papillae (red strawberry tongue); palate covered with erythematous punctate lesions **Exanthema**—Rash appears within 12 hr after prodromal signs; red pinhead-size punctate lesions rapidly become generalized but are absent on face, which becomes flushed with striking circumoral pallor; rash more intense in folds of joints; by end of first week desquamation begins (fine, sandpaper-like on torso; sheetlike sloughing on palms and soles), which may be complete by 3 wk or longer	**Treatment of choice**—Full course of penicillin (or erythromycin in penicillin-sensitive children), or oral cephalosporin **Supportive measures**—Rest during febrile phase, analgesics for sore throat; antipruritics for rash if bothersome **Complications**—Peritonsillar and retropharyngeal abscess Sinusitis Otitis media Acute glomerulonephritis Acute rheumatic fever Polyarthritis (uncommon) Toxic shock syndrome Osteomyelitis	Institute Standard and Droplet Precautions until 24 hr after initiation of treatment. Ensure compliance with oral antibiotic therapy; intramuscular benzathine penicillin G [Bicillin] may be given if parents' reliability in giving oral drugs is questionable. Encourage rest during febrile phase; provide quiet activity during convalescent period. Relieve discomfort of sore throat with analgesics, gargles, lozenges, and antiseptic throat sprays. Encourage oral fluids during febrile phase; avoid irritating liquids (certain citrus juices) or rough foods (chips); when child is able to eat, begin with soft diet. Advise parents to consult practitioner if fever persists after beginning therapy. Discuss procedures for preventing spread of infection; discard toothbrush; avoid sharing drinking and eating utensils. Monitor for sequelae of GAS-acute rheumatic fever and acute glomerulonephritis.

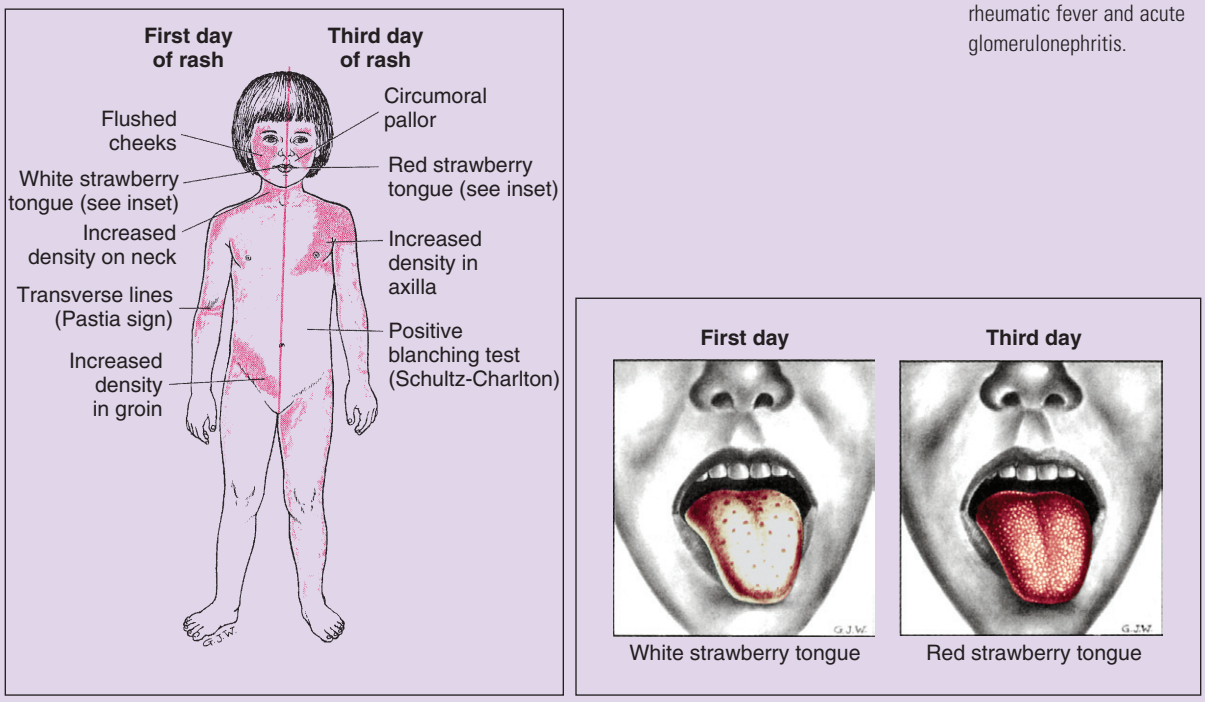

FIG 33-13 Scarlet fever.

*Commonly called *streptococcal pharyngitis;* with the exception of the characteristic rash, scarlet fever and streptococcal pharyngitis have the same epidemiology, features, symptoms, signs, sequelae, and treatment (AAP Committee on Infectious Diseases, 2012). Also note that GAS is a common cause of many infections in children, including impetigo, cellulitis, and necrotizing fasciitis.

and Leong, 2006). Fetal infection after maternal varicella, especially if infection occurs before the 20th week of gestation, may be fatal or result in congenital varicella syndrome. Varicella infection occurring in infants exposed to maternal varicella from a period 5 days before birth to 2 days after birth have an increased likelihood of becoming infected and should be treated with varicella-zoster immunoglobulin intravenous (IGIV) (AAP Committee on Infectious Diseases, 2012).

The use of varicella-zoster IGIV is recommended for children who are immunocompromised, who have no previous history of varicella, and who are likely to contract the disease and have complications as a result (AAP Committee on Infectious Diseases, 2012). The antiviral agents acyclovir or valacyclovir may be used to treat varicella infections in susceptible immunocompromised persons. It is effective in decreasing the number of lesions; shortening the duration of fever; and decreasing itching, lethargy, and anorexia.

Children with hemolytic disease such as sickle cell disease are at risk for aplastic anemia from EI. Human parvovirus B19 infects and lyses red blood cell (RBC) precursors, thus interrupting the production of RBCs. Therefore the virus may precipitate a severe aplastic crisis in patients who need increased RBC production to maintain normal RBC volumes. Thrombocytopenia and neutropenia may also occur as a result of human parvovirus B19 infection. Fetuses have a relatively high rate of RBC production and immature immune systems; they may develop severe anemia and hydrops as a result of maternal human parvovirus infection. Fetal death rates as a result of human parvovirus B19 have been estimated to be between 2% and 6% (AAP Committee on Infectious Diseases, 2012).

In the past decade the incidence of pertussis has increased, particularly in infants younger than 6 months old and children 10 to 14 years of age. Early clinical manifestations of pertussis in infants may include gagging, coughing, emesis, and apnea; the typical "whoop" associated with the disease is absent (Teng and Wang, 2011; Wood and McIntyre, 2008). In older children the disease may manifest as a common cold (see Table 33-2). It is now recommended that children 11 to 18 years old receive a booster pertussis vaccine (tetanus and acellular pertussis [Tdap]) to prevent the disease (see Immunizations, Chapter 31). Because pertussis is contagious, especially among close household members, identify it early and initiate treatment for the child and those who have been exposed. Azithromycin (for infants younger than 1 month old) and clarithromycin or azithromycin should be administered to infants and children with pertussis. Although the risk of contracting hypertrophic pyloric stenosis is increased in infants younger than 1 month old taking azithromycin, it remains the drug of choice for the treatment of pertussis in this age-group (AAP Committee on Infectious Diseases, 2012).

Prevention of complications from diseases such as diphtheria, pertussis, and scarlet fever requires compliance with antibiotic therapy. With oral preparations stress the need to complete the entire course of therapy.

Evidence suggests that vitamin A supplementation reduces both morbidity and mortality in measles and that all children with severe measles should receive vitamin A supplements. A single oral or parenteral dose of 200,000 IU for children at least 1 year old is recommended (use half that dose for children 6 to 12 months of age). The higher dose may be associated with vomiting and headache for a few hours. The dose should be repeated the next day and at 4 weeks for children with ophthalmologic evidence of vitamin A deficiency (AAP Committee on Infectious Diseases, 2012) (see also Table 33-2).

! NURSING ALERT

Although the risk of vitamin A toxicity from these doses (they are 100 to 200 times the recommended dietary allowance) is relatively low, nurses should instruct parents on safe storage of the drug. Ideally, vitamin A should be dispensed in the age-appropriate unit dose to prevent excessive administration and possible toxicity.

Provide Comfort

Many communicable diseases cause skin manifestations that are bothersome to children. The chief discomfort from most rashes is itching, and measures such as cool baths (usually without soap) and lotions (e.g., calamine) are helpful.

! NURSING ALERT

When lotions with active ingredients such as diphenhydramine in Caladryl are used, they should be applied sparingly, especially over open lesions, where excessive absorption can lead to drug toxicity. These lotions should be used with caution in children who are simultaneously receiving an oral antihistamine. Cooling the lotion in the refrigerator beforehand often makes it more soothing on the skin than at room temperature.

To avoid overheating, which increases itching, children should wear lightweight, loose, nonirritating clothing and keep out of the sun. If the child persists in scratching, keep the nails short and smooth or use mittens and clothes with long sleeves or legs. For severe itching antipruritic medication such as diphenhydramine (Benadryl) or hydroxyzine (Atarax) may be required, especially when the child has trouble sleeping because of itching. Loratadine, cetirizine, and fexofenadine do not cause drowsiness and may be preferred for urticaria during the day.

An elevated temperature is common, and both antipyretic medicine (acetaminophen or ibuprofen) and environmental manipulation are implemented (see Controlling Elevated Temperatures, Chapter 39). Acetaminophen is effective in lowering the fever but does not significantly reduce the symptoms of itching, anorexia, abdominal pain, fussiness, or vomiting.

A sore throat, another frequent symptom, is managed with lozenges, saline rinses (if the child is old enough to cooperate), and analgesics. Because most children are anorectic during an illness, bland foods and increased liquids are usually preferred. During the early stages of the disease children voluntarily curtail their activity; and, although bed rest is beneficial, it should not be imposed unless specifically indicated. During periods of irritability quiet activity (e.g., reading, music, television, video games, puzzles, coloring) helps distract children from the discomfort.

Support Child and Family

Most communicable diseases are benign, but they may produce considerable concern and anxiety for parents. Often the occurrence of a disease such as chickenpox is the first time the child is acutely uncomfortable. Parents need assistance to cope with manifestations of the illness such as intense itching. The family and child need reassurance that generally recovery is rapid. However, visible signs of the dermatosis may be present for some time after the child is well enough to resume usual activities.

CHILD MALTREATMENT

The broad term *child maltreatment* includes intentional physical abuse or neglect; emotional abuse or neglect; and sexual abuse of

children, usually by adults. It is one of the most significant social problems affecting children. In 2010 child protective service (CPS) agencies in the United States confirmed that an estimated 794,000 children were victims of child maltreatment. Of the confirmed cases approximately 17.6% suffered physical abuse, 9.2 % sexual abuse, 2.4% medical neglect, and 8.1 % psychologic maltreatment or emotional abuse. In 2010 there were an estimated 1560 child fatalities as a result of child abuse and neglect (U.S. Department of Health and Human Services, 2012). Children under 1 year of age had the highest rate of victimization (20.6 per 1000 children in the population of the same age), whereas children 1 to 3 years of age had rates of 11.9, 11.4, and 11.0 per 1000 children, respectively (U.S. Department of Health and Human Services, 2012). However, reported statistics only partially represent the actual incidence of child maltreatment because many cases are believed to be unreported.*

Child Neglect

Child neglect is the most common form of maltreatment. More than half of all reported cases are associated with deprivation of necessities, and 34% of deaths from maltreatment are in this group (U.S. Department of Health and Human Services, 2012). Neglect is generally defined as the failure of a parent or other person legally responsible for the child's welfare to provide for her or his basic needs and an adequate level of care.

Important contributing factors for child neglect are lack of knowledge of the child's needs, lack of resources, and caregiver substance abuse. For example, neglectful parents often demonstrate poor parenting skills. They may be unaware that an infant needs to be fed every 3 to 4 hours, may not know what to feed the child, and may have insufficient funds to buy food. The most serious lack of knowledge is failure to recognize emotional nurturing as an essential need of children (see also Failure to Thrive, Chapter 31).

Types of Neglect

Neglect takes many forms and can be classified broadly as physical or emotional maltreatment. Physical neglect involves the deprivation of necessities such as food, clothing, shelter, supervision, medical care, and education. Emotional neglect generally refers to failure to meet the child's needs for affection, attention, and emotional nurturance.

Neglect may also include lack of intervention for or fostering of maladaptive behavior such as delinquency or substance abuse. Emotional abuse or psychologic maltreatment, an even more difficult aspect of maltreatment to define, refers to the deliberate attempt to destroy or significantly impair a child's self-esteem or competence. Emotional abuse may take the form of rejecting, isolating, terrorizing, ignoring, corrupting, verbally assaulting, or overpressuring the child.

Physical Abuse

The deliberate infliction of physical injury on a child, usually by the child's caregiver, is termed *physical abuse.* Nonaccidental trauma is the term used to describe the injury resulting from the abuse. Legal definitions of physical abuse are found in state and federal statutes. The Child Abuse Prevention and Treatment Act of 1996 defines abuse as "any recent act or failure to act that results in imminent risk of serious harm, death, serious physical or emotional harm of a child (<18 years) by a parent or caregiver who is responsible for the child's welfare." Each state defines abuse according to its reporting laws. Minor physical injury is responsible for more reported cases of maltreatment than major physical injury, but major physical abuse causes more deaths. Despite the importance of the problem, a universally accepted definition of what constitutes minor and major physical abuse does not exist. Rather each state in the United States defines abuse according to its individual reporting laws.

Shaken Baby Syndrome/Traumatic Brain Injury

Shaken baby syndrome (SBS) is a serious form of child abuse caused by violent shaking of infants and is one form of abusive head trauma. Physicians commonly use more general terms, including *abusive head trauma, nonaccidental head injury, traumatic brain injury (TBI),* or *neuroinflicted brain injury;* these terms do not assume the mechanism of injury but rather describe the injury itself (AAP Committee on Child Abuse and Neglect, 2009; Chiesa and Duhaime, 2009; Squier, 2011). This violent shaking would be easily recognized by others as dangerous (AAP Committee on Child Abuse and Neglect, 2009) and is most often a result of the caregiver's frustration with crying. Every year in the United States an estimated 1200 to 1400 children are shaken, and 25% to 30% of these victims die as a result of their injuries. The rest have lifelong complications (Barr, 2012; Keenan, Runyan, Marshall, et al., 2004; National Center on Shaken Baby Syndrome, n.d.).* The peak incidence of SBS/TBI is in the third month of life; the majority of victims are male, and the perpetrators are most often related males in the victim's household (Barr, 2012).

It is important to understand what happens in SBS. Infants have a large head-to-body ratio, weak neck muscles, and a large amount of water in the brain. Violent shaking causes the brain to rotate within the skull, resulting in shearing forces that tear blood vessels and neurons. The characteristic injuries that occur are intracranial bleeding (subdural hematoma) and in approximately 85% of cases retinal hemorrhages, which are classic results of repetitive acceleration-deceleration head trauma (Levin, 2009). Injuries may also include fractures of the ribs and long bones; however, most often there are no signs of external injury. SBS is often not an isolated event. Victims can be seen with a variety of symptoms, from generalized flulike symptoms to unresponsiveness with impending death (Mraz, 2009). Many of the presenting symptoms such as vomiting, irritability, poor feeding, and listlessness are often mistaken for common infant and childhood ailments. In more severe forms presenting symptoms may include seizures, posturing, alterations in level of consciousness, apnea, bradycardia, or death. The long-term outcomes of SBS include seizure disorders; visual impairments, including blindness; developmental delays; hearing loss; cerebral palsy; and mild-to-profound mental, cognitive, or motor impairments (Walls, 2006). Nurses can take an active role in preventing SBS by teaching all caregivers about crying and techniques to cope with inconsolable crying (Altman, Canter, Patrick, et al., 2011; Carbaugh, 2004). Two studies report significant reductions in the incidence of SBS when programs aimed at educating parents about the nature of the infant's crying and associated infant behavior and preventing shaking as a form of dealing with the infant's crying behavior are presented to mothers and families in the immediate postpartum period (Barr, 2012). Barr (2012) notes that preventive programs are effective in the prevention of SBS. Nurses in the mother-baby unit should talk with parents about infant behavior, including crying and sleep patterns. Other caregivers should also be educated regarding infant crying behavior and consoling methods

*Additional information is available from the Children's Bureau, Administration for Children and Families, 370 L'Enfant Promenade SW, Washington, DC 20447, 800-422-4453, www.acf.hhs.gov.

*National Center on Shaken Baby Syndrome: www.dontshake.com.

aimed at preventing violent shaking (Barr, 2012). An educational tool for parents is the Period of PURPLE Crying* program, which presents material for parents about infant crying and resources to cope with infant crying.

! NURSING ALERT

Nurses should emphasize to parents and caregivers the danger of shaking infants. Education must include coping mechanisms for caring for infants with inconsolable crying.

CARE MANAGEMENT

Nursing care of the infant with SBS/TBI should immediately focus on recognizing the condition and attention given to the ABCs (airway, breathing, circulation), spinal cord immobilization, and prevention of hypoxemia by monitoring oxygen saturation. Because some infants demonstrate no outward signs and symptoms in the acute phase, the nurse should be alert for subtle signs such as alternating levels of consciousness, poor feeding, and decreased activity level. If SBS is suspected, the infant may be sent for a CT scan for diagnostic purposes. Additional nursing care should focus on preventing hypotension (monitor perfusion and BP), and fluids may be needed to maintain adequate vascular volume. ICP is monitored, and increased intracranial pressure (target of 15 mm Hg in infant; 18 mm Hg in child, and 20 mm Hg in adolescent) is prevented by avoiding suctioning unless absolutely necessary. Mannitol or 3% normal Saline IV is administered, the head of the bed is elevated 30 degrees, and sedative medication or neuromuscular blockade is given as warranted. Hypoglycemia should be avoided to maintain adequate brain function.

Depending on the infant's status, short-term and long-term care often includes administering enteral feedings if the child is unable to feed and H2 blockers to prevent stress ulcers and monitoring for signs of cerebral edema and seizure activity (see also Chapter 45, Head Injury). The care of the mother and other family members should not be forgotten. Often there is much blaming and increased emotional tension; law enforcement will likely be involved in an investigation, and this engenders additional family stress. The nurse supports the family by adopting a nonjudgmental attitude and focusing on the immediate medical needs of the child. A multidisciplinary team of health care workers may assist in caring for the needs of the family and in protecting the child and family from further physical and emotional harm.

Munchausen Syndrome by Proxy

Munchausen syndrome by proxy (MSBP), also known as *medical child abuse* or *factitious disorder by proxy,* is a rare but serious form of child abuse in which caregivers deliberately exaggerate or fabricate histories and symptoms or induce symptoms. It is a form of child maltreatment that may include physical, emotional, and psychologic abuse for the gratification of the caregiver. In most cases the perpetrator is the biologic mother with some degree of health care knowledge and training. Health care providers can become easily misled and unknowingly enable the perpetrator (Leider, Irving, Mauricio, et al., 2005). Because of the history of symptoms provided by the caregiver, the child endures painful and unnecessary medical testing and procedures. Common symptoms presented are seizures, nausea and vomiting, diarrhea, and altered mental status; they are usually witnessed only by the perpetrator.

Considerations when determining whether a child is a victim of MSBP include:

- Is the child's condition consistent with the reported history?
- Does diagnostic evidence support the reported history?
- Has anyone other than the caregiver witnessed the symptoms?
- Is treatment being provided primarily because of the caregiver's demands?

The resolution of symptoms after separation from the perpetrator confirms the diagnosis.

Factors Predisposing to Physical Abuse

The causes of child abuse are multifaceted. Child maltreatment occurs across all socioeconomic, religious, cultural, racial, and ethnic groups (Goldman, Salus, Wolcott, et al., 2003). Three risk factors are commonly identified in child abuse: parental characteristics, characteristics of the child, and environmental characteristics. However, no single factor or group of factors is predictive of abuse. Rather the interaction of these factors is thought to increase the risk of abuse occurring in a particular family.

Parental Characteristics. Some identified characteristics occur more frequently in parents who abuse their children and therefore are considered risk factors. Younger parents more often abuse their children. Single-parent families are at higher risk for abuse; in single-parent families that include an unrelated partner, the partner is sometimes the abuser, although a biologic parent is most commonly the perpetrator (U.S. Department of Health and Human Services, 2012).

Abusive families are often socially isolated and have few supportive relationships. They often have additional stressors such as low-income circumstances with little education. Parents with substance-abuse problems pose a greater risk for abuse and neglect because of a variety of factors. The additional stressors of substance abuse with the demands of normal care of children create situations in which abuse and neglect can occur because these parents have impaired judgment and may react with violence while under the influence of drugs or alcohol (Wells, 2009). With little or no available support system and concurrent stressors imposed by the child or environment, these parents are vulnerable to additional crises of any nature and may strike out at the child as a method of releasing their frustration and anxiety.

Other factors identified in abusive parents include low self-esteem and little knowledge of appropriate parenting skills. Parenting skills are learned behaviors, and parents who grew up with poor parental role models may have difficulty parenting their own children. Approximately one third of parents who were maltreated as children will subject their children to similar maltreatment (Gara, Allen, Herzog, et al., 2000).

Characteristics of the Child. The onus for child abuse is always on the abuser. However, children who are abused do have some common characteristics. Children from birth to 1 year of age are at highest risk for being abused (U.S. Department of Health and Human Services, 2012). Infants and small children require constant attention and must have all their needs met by others. This can result in parental or caregiver fatigue that results in striking out at the child with physical force, shaking the child, or ignoring his or her needs.

The physical and emotional demands placed on the parents or caregiver of an unwanted, brain-damaged, hyperactive, or physically disabled child may overwhelm them, resulting in abuse. Children with disabilities may not understand that abusive behaviors are not appropriate; thus they may not tell others or defend

*www.purplecrying.info/sections/index.php?sct=1&.

themselves. Premature infants may be at risk for maltreatment because of failure of parent-child bonding during early infancy, increased physical care needs, or irritability. One child may be singled out in an abusive family. Removing that child from the home often places the other siblings at risk for abuse. Therefore no child is safe if left in the abusive environment unless the parents can be helped to learn new parenting skills, meet the children's needs, and release their frustration through alternatives other than attacking their children.

Environmental Characteristics. The environment is a significant part of the potentially abusive situation. A typical environment is one of chronic stress, including problems of divorce, poverty, unemployment, poor housing, frequent relocation, alcoholism, and drug addiction. Increased exposure between children and parents such as that which occurs in crowded living conditions also increases the likelihood of abuse.

Although most reporting of abuse has been from lower socioeconomic populations as stated previously, child abuse is not a problem of any one societal group. Stresses imposed by poverty predispose lower socioeconomic families to abusive situations, and abuse in these groups is more likely to be reported. However, concealed crises may also be present in upper-class families. Families who have substitute caregivers such as day care providers and babysitters may also be at risk for child abuse, especially if the family has not fully evaluated the caregiver. Nurses need to be aware of all these factors to identify the less obvious examples of child abuse and neglect.

Sexual Abuse

Sexual abuse is one of the most devastating types of child maltreatment, and estimates indicate that it has increased significantly during the past decade (U.S. Department of Health and Human Services, 2012). Some of the apparent increase is because of increased awareness (Putnam, 2003).

As with all forms of child maltreatment, no universal definition for sexual abuse exists. Definitions cover a range of acts, including involvement of children in sexual acts they do not understand, to which they cannot give consent, or that violate social taboos (Finkel and DeJong, 2001). The Child Abuse and Prevention Act defines **sexual abuse** as "the use, persuasion, or coercion of any child to engage in sexually explicit conduct (or any simulation of such conduct) or producing any visual depiction of such conduct, or rape, molestation, prostitution, or incest with children."

Sexual abuse includes the following types of sexual maltreatment (see also Rape, Chapter 35):

- *Incest*—Any physical sexual activity between family members; blood relationship is not required (abusers can include stepparents, unrelated siblings, grandparents, uncles, and aunts); does not include sexual relations between legally sanctioned partners such as spouses
- *Molestation*—Vague term that includes "indecent liberties" such as touching, fondling, kissing, single or mutual masturbation, or oral-genital contact
- *Exhibitionism*—Indecent exposure, usually exposure of the genitalia by an adult man to children or women
- *Child pornography*—Arranging and photographing, in any media, sexual acts involving children, alone or with adults or animals, regardless of consent by the child's legal guardian; also may denote distribution of such material in any form with or without profit
- *Child prostitution*—Involving children in sex acts for profit and usually with changing partners
- *Pedophilia*—Literally means "love of child" and does not denote a type of sexual activity but rather the preference of an adult for prepubertal children as the means of achieving sexual excitement

Human trafficking often involves some form of coerced sexual activity and thus sexual abuse that may also often involve physical and mental abuse. Many victims of human trafficking are females under the age of 18 years who are forced to perform sexual acts for the monetary profit of the perpetrators. One form of sex trafficking called sex tourism involves adult men traveling to developing nations to have sex with young children (Sabella, 2011). Nurses may encounter victims of sex trafficking and subsequent sexual and physical abuse who are seeking medical care in outpatient and emergent health care settings for a plethora of health problems (STIs, bruises, wound infections, PTSD, suicidal ideation, and addiction). However, nurses may not be aware of the victim's plight unless he or she delves further into the person's history and background (Sabella, 2011).

Characteristics of Abusers and Victims

Anyone, including siblings and mothers, can be sexual abusers; but a typical abuser is a man whom the victim knows. Offenders come from all levels of society. Adults comprise 80% of sexual abuse offenders; the remaining 20% is composed of adolescents and preadolescents (Johnson, 2003). Many offenders hold full-time jobs, are active in community affairs, and may not have prior criminal records (Finkel and DeJong, 2001). Offenders often are employed (or volunteers) in positions such as teaching or coaching that bring them into contact with young girls and boys. Child sexual abuse may be generational unless discovered and stopped (Johnson, 2003). Offenders may commit many assaults before being caught.

Incestuous relationships between father or stepfather and daughter are generally prolonged, and the victims are usually reluctant to report the situation because of fear of retaliation and fear that they will not be believed. Typically incestuous relationships begin later than other forms of child abuse. The eldest daughter is usually abused, but in her absence another sister may be substituted. Sibling incest may also occur. Sexual abuse by relatives with a strong emotional bond with the victim such as a parent is often the most devastating to the child.

Boys are also victims of both intrafamilial and extrafamilial abuse. Compared with female victims, male victims are much less likely to report abuse, and they may suffer much greater emotional harm from incestuous relationships. Boys are likely to be subjected to anal penetration and oral-genital contact. They often have subtle physical findings and are abused by a father, stepfather, or mother's boyfriend.

Significant risk factors for child sexual abuse include parental unavailability, lack of emotional closeness and flexibility, social isolation, emotional deprivation, and communication difficulties. Most sexual abuse is committed by men and people known to the child, with family members constituting as many as two thirds of the perpetrators.

Initiation and Perpetuation of Sexual Abuse

The cycle of sexual abuse often starts insidiously unless it involves an isolated attack such as rape. Often offenders spend time with the victims to gain their trust before initiating any sexual contact. Most victims are then pressured into being an accessory to the sexual activity through various means (Box 33-1) and may be unaware that sexual activity is part of the offer. Children may not reveal the truth for fear that their parents would not believe them if they told, especially if the offender is a trusted member of the family. Some fear

BOX 33-1 METHODS USED TO PRESSURE CHILDREN INTO SEXUAL ACTIVITY

- The child is offered gifts or privileges.
- The adult misrepresents moral standards by telling the child that it is "okay to do."
- Isolated and emotionally and socially impoverished children are enticed by adults who meet their needs for warmth and human contact.
- The offender asks the child for help in finding a favorite pet or object with which the child can easily identify.
- The successful sex offender pressures the victim into secrecy regarding the activity by describing it as a "secret between us" that other people may take away if they find out.
- The offender plays on the child's fears, including fear of punishment by the offender, fear of repercussions if the child tells, and fear of abandonment or rejection by the family.

BOX 33-2 WARNING SIGNS OF ABUSE

- Physical evidence of abuse or neglect, including previous injuries
- Conflicting stories about the "accident" or injury from the parents or others
- Cause of injury blamed on sibling or other party
- An injury inconsistent with the history such as a concussion and broken arm from falling off a bed
- History inconsistent with child's developmental level such as a 6-month-old turning on the hot water
- A complaint other than the one associated with signs of abuse (e.g., a chief complaint of a cold when there is evidence of first- and second-degree burns)
- Inappropriate response of caregiver such as an exaggerated or absent emotional response, refusal to sign for additional tests or agree to necessary treatment, excessive delay in seeking treatment, or absence of parents for questioning
- Inappropriate response of child such as little or no response to pain, fear of being touched, excessive or lack of separation anxiety, indiscriminate friendliness to strangers
- Child's report of physical or sexual abuse
- Previous reports of abuse in the family
- Repeated visits to emergency facilities with injuries
- Parent or caregiver report of being gone and finding the child unresponsive, indicating absence during the supposed event that resulted in harm

that they will be blamed for the situation; and many young children with limited vocabulary have difficulty describing the activity when they do have the courage or opportunity to reveal the abuse.

Incest most frequently occurs between fathers and daughters, but it may also be between grandfather and granddaughter or brother and sister. Brother-sister incest has been found to be just as damaging as father-daughter abuse (Cyr, Wright, McDuff, et al., 2002). Victims may take years to disclose this abuse. However, not all incestuous relationships follow this pattern of silence. Reports of father-daughter incest during child custody conflicts have become more common and have raised serious concerns regarding the possibility of false accusation. Rather than tolerating or denying the child's sexual abuse, the other parent (usually the mother) is typically the chief accuser.

Nursing Care of the Maltreated Child

A critical responsibility of health professionals is identifying abusive situations as early as possible. Nurses who increase their knowledge of the different types of abuse and neglect and underlying causes enhance their ability to identify, intervene, and prevent children from maltreatment and neglect (Giardino and Giardino, 2003). The characteristics that may predispose members of some families to commit abuse can serve as a framework for assessing vulnerability but are never predictive of actual abuse. A careful, detailed history and interview combined with a thorough physical examination are the diagnostic tools needed to identify abuse. Nurses have a special role because they may be the first person to see the child and parent and are the consistent caregivers if the child is hospitalized (see Guidelines box).

In interviewing the child and family the nurse must be careful to avoid biasing the child's retelling of the events. Some experts suggest that health professionals limit the interview to the child's physical and mental health concerns and leave topics of the family's social, legal, or other problems to law enforcement or the CPS (Kellogg, 2005; McClain, Giardet, Lahoti, et al., 2000). If this is not possible, make an effort to coordinate the interview process so all pertinent health care professionals can be present for the interview.

Recognition of abuse or neglect necessitates a familiarity with both physical and behavioral signs that suggest maltreatment (Box 33-2). No one indicator can be used to diagnose maltreatment. It is a pattern or combination of indicators that should arouse suspicion and lead to further investigation. It is important to note that some situations such as bleeding disorders, osteogenesis imperfecta, or sudden infant death syndrome may be misinterpreted as abuse. In addition, some cultural practices such as cupping or coin rubbing (see Health Practices, Chapter 27), may mimic physical abuse. Unintentional injuries such as burns from metal buckles on car seats, bruising from seat belts, or spiral fractures from a twist and fall injury may also be wrongly diagnosed as abuse. Normal variants such as mongolian spots and congenital anomalies of genitalia can be mistaken for abuse.

GUIDELINES

Talking with Children Who Reveal Abuse

- Provide a private time and place to talk.
- Do not promise not to tell; tell them that you are required by law to report the abuse.
- Do not express shock or criticize their family.
- Use their vocabulary to discuss body parts.
- Avoid using any leading statements that can distort their report.
- Reassure them that they have done the right thing by telling.
- Tell them that the abuse is not their fault, that they are not bad or to blame.
- Determine their immediate need for safety.
- Let the child know what will happen when you report.

Caregiver-Child Interaction

The nurse can use the initial contact with the family to assess the interaction between the caregiver and the child. Observations of the caregivers should include emotional support for the child, attentiveness to his or her needs, and concern for his or her injury. Although caregivers and children may vary in responses to a stressful event, note an unusual caregiver-child relationship and factor this into the overall evaluation of the child.

Certain behavioral responses of the parents to their child and to the interviewer should alert the nurse to the possibility of maltreatment. Abusive parents may have difficulty showing concern for their child. They may be unable or unwilling to comfort the child. Abusers may blame the child for the injuries or belittle her or him for being clumsy or stupid. When interacting with health care workers, the parent may become hostile or uncooperative. During the child's hospitalization they may not participate in her or his care and may show little concern for her or his progress, eventual discharge, or need for follow-up care.

Abused children's responses to their parents or the injury may also support the suspicion of abuse. Although no one pattern is typical, extremes of behavior may be observed. Children may be unresponsive to the parent or excessively clinging and intolerant of separation. They may be overly attached to the abusive parent, possibly in the hope of preventing any upset that may precipitate anger and another attack. During care of the injury children may be passive and accepting of the discomfort or uncooperative and fearful of any physical contact. They may avoid eye contact. Some children maintain a wary watchfulness of all strangers; some shy away from strangers as if frightened; others are unusually affectionate and outgoing.

History and Interview

Child Physical Abuse. It is often difficult to distinguish child maltreatment from accidental injuries. Caregivers whose history of events may be deceptive or incomplete and children who are nonverbal may make the assessment more complex. A purposeful, skilled history and appropriate interview questions help the nurse ensure the right course of action. Knowledge of mechanism of injury and child development is essential. Cases of abuse are often detected when the child or caregiver history of events does not match with physical findings. Children who are verbal can often give a history of the injury. Separating the child from the caregiver may provide a more reliable history. It is important to ask nonleading, open-ended questions. The history should include a narrative of the injury from both caregiver and child (if verbal). Date, time, and location where the injury took place along with who was present at the time of the injury are essential questions. Family history for bleeding and bone disorders is important. Box 33-3 outlines areas of history that are of concern for potential abuse.

Neglect and Emotional Abuse. Each child may manifest different responses to neglect, depending on the situation and the child's developmental age. The goal of the interview is to determine whether the child is in a safe environment and whether the caregiver has the skills and resources to care for the child. It is often difficult to determine whether the circumstances constitute poor parenting skills or true neglect. Warning signals for behaviors for which to look are found in Box 33-2.

Sexual Abuse. An essential component to identifying sexual abuse is the interview. Several dynamics may impede the child's revelation of sexual abuse. Child sexual abuse is often perpetrated by someone known to the child, including family members. In some cases the child may have been sworn to secrecy. He or she may have been told that no one will believe the story or that the family would be harmed if he or she told someone about the abuse. Small children may imitate behaviors they have had perpetrated on themselves or have seen others do. The nurse must be able to recognize normal, age-related sexual curiosity and self-stimulating behaviors. Typically children do not act out specific details of the sexual act or perform intrusive acts on others unless they have sexual knowledge beyond their normal age-related development (Johnson, 2003).

Children's reports of sexual abuse may vary from contradictory stories to unwavering versions of the experience. Stories that sound contradictory may reflect the child's experiences in several instances of abuse. In addition, children who repeatedly tell identical facts may have been prompted to do so.

Increasing evidence suggests that the types of interrogation to which children are exposed after reports of sexual abuse shape their thinking. To avoid biasing the interaction, nurses must be skillful interviewers when questioning children who may be victims of abuse. Medical records should include verbatim statements made by the child and interviewer that reflect appropriate nonleading questions and statements (Hornor, 2001; Kellogg, 2005; McClain, Girardet, Lahoti, et al., 2000). The child may not be emotionally ready to discuss the abuse. Establishing rapport with the child is essential to gaining his or her trust. Interviews should not be rushed. Engaging the child in play activities while encouraging conversation may help her or him to discuss the abuse. It may take several interviews or psychologic counseling for the child to be forthcoming about the abuse. Information regarding the last sexual contact is important because it determines the need for a forensic evaluation. Children who have been sexually abused within the past 72 to 96 hours should be considered for forensic testing.

Unfortunately there is no typical profile of the victim, and the nurse must have a high index of suspicion to identify these children. Physical signs vary and may include any of those listed for sexual abuse. The victim may exhibit various behavioral manifestations, but none of these behaviors is diagnostic. When abused children exhibit these behaviors, the signs may be incorrectly attributed to the normal stresses of childhood, especially in older school-age children or adolescents. Even signs considered most predictive of sexual abuse such as certain genital findings, sexually inappropriate behavior for age, enactment of adult sexual activity, and intense focus on sexual activity (e.g., masturbation) do not always indicate that sexual abuse has occurred. Conversely abused children may not demonstrate more knowledge of sexual activity than nonabused children. However, one difference in the abused child's explanation of sexual activity may be unusual affective responses. For example, abused children may have an increased incidence of sleep disorders, temper tantrums, and depression.

! NURSING ALERT

When children report potentially sexually abusive experiences, their reports need to be taken seriously but also cautiously to avoid alarming the child or falsely accusing someone.

Physical Assessment

Child Physical Abuse. The goal of the physical assessment for child physical abuse is identification of all injuries. A systems approach ensures that the whole body is evaluated. In instances of severe abuse and injuries the assessment should begin with a rapid assessment of airway, breathing, circulation, and neurologic systems. A systematic head-to-toe examination follows. Attention to areas often overlooked such as the scalp, behind the ears, and the frenulum is essential. The child's exterior genital area and posterior surface should be examined completely.

Record the location and a detailed description of all injuries. Note the color, size, and location of all bruising. Burn documentation should include the location, pattern, demarcation lines, and presence of eschar or blisters. Diagrams of the injuries using a body

BOX 33-3 CLINICAL MANIFESTATIONS OF POTENTIAL CHILD MALTREATMENT

Physical Neglect

Suggestive Physical Findings

- Failure to thrive (growth failure)
- Signs of undernutrition such as thin extremities, abdominal distention, lack of subcutaneous fat
- Poor personal hygiene
- Unclean or inappropriate dress
- Evidence of poor health care such as delayed immunizations, untreated infections, frequent colds
- Frequent injuries from lack of supervision

Suggestive Behaviors

- Dull and inactive affect; excessively passive or sleepy
- Self-stimulatory behaviors such as finger sucking or rocking
- Begging or stealing food
- Absenteeism from school
- Substance abuse
- Vandalism or shoplifting

Emotional Abuse and Neglect

Suggestive Physical Findings

- Failure to thrive (growth failure)
- Eating or feeding disorder
- Enuresis
- Sleep disorder

Suggestive Behaviors

- Self-stimulatory behaviors such as biting, rocking, sucking
- During infancy lack of social smile and stranger anxiety
- Withdrawal from environment and people
- Unusual fearfulness
- Antisocial behavior such as destructiveness, stealing, cruelty to animals or people
- Extremes of behavior such as overcompliant and passive or aggressive and demanding
- Lags in emotional and intellectual development, especially language
- Suicide attempts or attempts to harm self

Physical Abuse

Suggestive Physical Findings

- Bruises and welts
  - On face, lips, mouth, back, buttocks, thighs, or areas of torso
  - Regular patterns descriptive of object used such as belt buckle, hand, wire hanger, chain, wooden spoon, squeeze or pinch marks
  - May be present in various stages of healing
- Burns
  - On soles of feet, palms of hands, back, or buttocks
  - Patterns descriptive of object used such as round cigar or cigarette burns; sharply demarcated areas from immersion in scalding water; rope burns on wrists or ankles from being bound; burns in the shape of an iron, radiator, or electric stove burner
  - Absence of "splash" marks and presence of symmetric burns
  - Stun gun injury: lesions circular, fairly uniform (up to 0.5 cm), and paired about 5 cm (1¾ in) apart
- Fractures and dislocations
  - Skull, nose, or facial structures
  - Injury denoting type of abuse such as spiral fracture or dislocation from twisting an extremity or whiplash from shaking child
  - Multiple new or old fractures in various stages of healing
- Lacerations and abrasions
  - On backs of arms, legs, torso, face, or external genitalia
  - Unusual symptoms such as abdominal swelling, pain, and vomiting from punching
  - Descriptive marks such as from human bites or pulling out of hair
- Chemical
  - Unexplained repeated poisoning, especially drug overdose
  - Unexplained sudden illness such as hypoglycemia from insulin administration

Suggestive Behaviors

- Wary of physical contact with adults
- Apparent fear of parents or going home
- Lying very still while surveying environment
- Inappropriate reaction to injury such as failure to cry from pain
- Lack of reaction to frightening events
- Apprehension when hearing other children cry
- Indiscriminate friendliness and displays of affection
- Superficial relationships
- Acting-out behavior such as aggression to seek attention
- Withdrawal behavior

Sexual Abuse

Suggestive Physical Findings

- Bruises, bleeding, lacerations, or irritation of external genitalia, anus, mouth, or throat
- Torn, stained, or bloody underclothing
- Pain on urination or pain, swelling, and itching of genital area
- Penile discharge
- Sexually transmitted infection, nonspecific vaginitis, or venereal warts
- Difficulty in walking or sitting
- Unusual odor in genital area
- Recurrent urinary tract infections
- Presence of sperm
- Pregnancy in young adolescent

Suggestive Behaviors

- Sudden emergence of sexually related problems, including excessive or public masturbation, age-inappropriate sexual play, promiscuity, or overtly seductive behavior
- Withdrawn behavior, excessive daydreaming
- Preoccupation with fantasies, especially in play
- Poor relationships with peers
- Sudden changes such as anxiety, loss or gain of weight, clinging behavior
- In incestuous relationships excessive anger at mother for not protecting daughter
- Regressive behavior such as bed-wetting or thumb-sucking
- Sudden onset of phobias or fears, particularly fears of dark, men, strangers, or particular settings or situations (e.g., undue fear of leaving house or staying at day care center or baby-sitter's house)
- Running away from home
- Substance abuse, particularly of alcohol or mood-elevating drugs
- Profound and rapid personality changes, especially extreme depression, hostility, and aggression (often accompanied by social withdrawal)
- Rapidly declining school performance
- Suicidal attempts or ideation

diagram form are helpful. If possible obtain photographs of the injuries with a measurement tool.

Not all forms of physical abuse have obvious signs. Intraabdominal organ injury from blunt trauma to the abdomen can occur without signs of external abdominal bruising. Nurses should consider intraabdominal injury in infants and children who have any other signs of abuse.

All evidence collected must adhere to strict guidelines for legal purposes; the chain of custody must be appropriately maintained with local law enforcement personnel. Documentation on the chain of custody form should include the names of people collecting and receiving evidence (e.g., photographs and deoxyribonucleic acid [DNA] samples), types of evidence collected and received, and date of receipt (Kaczor, Pierce, Makoroff, et al., 2006; Kellogg, 2005).

! NURSING ALERT

Incompatibility between the history and the injury is probably the most important criterion on which to base the decision to report suspected abuse.

Neglect and Emotional Abuse. Neglect from deprivation of necessities is easier to identify than emotional neglect or psychologic maltreatment because physical signs are usually evident. Assessment of the child's height, weight, nutritional status, hygiene, and age-appropriate interactions is important for the overall picture of potential neglect. Emotional maltreatment may be readily suspected, but it is difficult to substantiate. Physical signs are often nonspecific; and nurses must rely on behavioral indicators, which range from depression to acting-out behavior, to help identify a possibly abusive situation. Any persistent and unexplained change in the child's behavior is an important clue to possible emotional abuse.

Sexual Abuse. Identifying instances of sexual abuse is particularly difficult because often few if any obvious physical indications of the activity exist. Physical signs vary and may include any of those listed in Box 33-3 for sexual abuse. The goal of the physical examination is to document genital findings. In most cases the genital examination findings are normal, which does not mean that sexual abuse did not occur. Fondling or genital-to-genital contact without penetration may leave no physical findings. Forensic evidence obtained directly from a prepubertal victim's body diminishes greatly after 24 hours, with the best chance for evidence collection coming from bed linens or the child's underwear (Christian, Lavelle, DeJong, et al., 2000). The female genital examination should include a description of the vulva, hymen, and surrounding tissue. Abnormal findings of concern are injuries to the posterior vulva or the lower half of the hymenal ring or abrasions, bruising, or bleeding of the genital or anal tissue. It is often helpful to use a magnifying instrument (colposcope) to detect subtle injuries. There are many variants of normal findings for female genital anatomy; thus it is recommended that the examination be done by a practitioner experienced with these types of cases. Contrary to popular myth, the size of the hymenal opening does not predict the likelihood of sexual abuse (Christian and Rubin, 2002). For male victims swelling, abrasions, or bruising of the genital tissue raises concerns. Examine the anal area for symmetry, tone, fissures, or scars. Genital tissue heals very quickly and most often without scars. Therefore, unless the child is seen within a few days of injury, the genital tissue may appear normal. In addition, the vaginal and anal mucosa is elastic; therefore penetration without disruption of tissue is possible. This defies another myth that there is always evidence of female virginity. Consider the collection of specimens for determining the presence of sexually transmitted infections, which may have been contracted during the sexual contact.

CARE MANAGEMENT

Protect Child from Further Abuse. Initially identification of instances of suspected abuse or neglect is essential. The nurse may come in contact with abused children in an emergency department, practitioner's office, home, day care center, or school.

! NURSING ALERT

The priority is to remove the child from the abusive situation to prevent further injury.

All states and provinces in North America have laws for mandatory reporting of child maltreatment. Suspected child abuse is reported to the local authorities.* Referrals usually come to the state child welfare department and are assigned to a caseworker in an agency such as CPS. After a referral has been made, a caseworker is assigned to investigate the report. Based on the findings, the child is left in the home or removed temporarily.

A court proceeding may be necessary before the child can be placed outside the home or when parental rights are to be terminated. When the courts are involved, they usually require firsthand testimony by the referring parties. Nurses may be subpoenaed to appear in court, or their notes may be introduced as evidence in court hearings. Accurate and factual documentation is essential. Behaviors are described, not interpreted, and are recorded daily to establish a progress record (see Guidelines box). Conversations among the nurse, child, and parent are recorded verbatim as much as possible.

Support Child. Children suspected of being abused are often hospitalized for medical management of their injuries and to allow further assessment of their safety needs. The needs of these children are the same as those of any hospitalized child. The child should be treated as a child with the usual physical needs, developmental tasks, and play interests—not as a victim of abuse. The goal of the nurse-child relationship is to provide a role model for the parents in helping them relate positively and constructively to their child and to foster a therapeutic environment for the child in his or her reprieve from the abusing situation.

Support Family. The nurse also encourages the child's relationship with nonoffending parents. The nurse does not become a substitute parent but rather acts as a role model for parents in helping them relate positively and constructively to their child. When parental ignorance of childrearing practices has played a part in the abuse, the nurse can educate the parent regarding children's physical and emotional needs. Because of the parents' own childrearing, they may not be aware of nonviolent methods of discipline such as time-outs. They may also need help in dealing with their frustration so they do not vent anger on the child. Because these parents may be sensitive to criticism or resistant to authority

*Telephone numbers are usually listed under "Child Abuse" in the business white pages of the local directory or you can call the emergency child abuse hotline: 800-422-4453 (800-4-A-CHILD).

GUIDELINES

Recording Assessment Data in Suspected Abuse

History of Injury

- Date, time, and place of occurrence
- Sequence of events with recorded times
- Presence of witnesses, especially person caring for child at time of incident
- Time lapse between occurrence of injury and initiation of treatment
- Interview with child when appropriate, including verbal quotations and information from drawing or other play activities
- Interview with parent, witnesses, or other significant persons, including verbal quotations
- Description of parent-child interactions (verbal interactions, eye contact, touching, parental concern)
- Name, age, and condition of other children in home (if possible)

Physical Examination

- Location, size, shape, and color of bruises; approximate location, size, and shape on drawing of body outline
- Distinguishing characteristics such as a bruise in the shape of a hand; round burn (possibly caused by cigarette)
- Symmetry or asymmetry of injury; presence of other injuries
- Degree of pain; any bone tenderness
- Evidence of past injuries; general state of health and hygiene
- Developmental level of child; perform screening test (see Developmental Assessment, Chapter 28)

figures, teaching is implemented through demonstration and example rather than through lecturing. Praise any competent parenting abilities they demonstrate to promote their sense of parental adequacy.

Advise family members to encourage the child to resume normal activities and observe her or him for signs of distress. (See Posttraumatic Stress Disorder, Chapter 34.) Children express their feelings primarily through behavior. Parents should be alert for changes in behavior that indicate distress resulting from the incident such as remaining in the house, refusal to go to school, changes in sleeping patterns, and frequency of dreams and nightmares.

Referral to appropriate social service agencies is also essential. Many abusive parents live in poverty, and the daily stresses imposed by their circumstances are overwhelming. Seek resources for financial aid, improved housing, and child care. Self-help groups also provide important services. One such group is Parents Anonymous,* a group for parents who have abused or fear that they may abuse their child but only in terms of physical abuse, not sexual abuse.

Plan for Discharge. Discharge planning should begin as soon as the legal disposition for placement has been decided, which may be temporary foster home placement; return to the parents; or permanent termination of parental rights, which is the most drastic solution, but necessary in situations of life-threatening abuse. Whenever children are sent to a foster home or juvenile institution, they must be allowed an opportunity to express their feelings. No matter how severe the abuse, they usually mourn the loss of their parents. They need help to understand why they must not return home and that this new home is in no way a punishment. Whenever possible, foster parents are encouraged to visit in the hospital, and the nurse should take an active role in helping the new parents understand the child and his or her health care needs because studies have shown that the health care needs of children in foster care often go unmet (Mekonnen, Noonan, and Rubin, 2009).

Prevent Abuse. Prevention of child maltreatment has been an extremely difficult goal. However, nurses have played an important role in such programs. The Nurse-Family Partnership is one such program that has demonstrated evidence-based interventions resulting in the prevention of child maltreatment (Donelan-McCall, Eckenrode, and Olds, 2009).

Nurses in a variety of settings can implement similar activities. For example, nurses in prenatal clinics can prepare expectant families for adjustment to parenthood. Nursery and postpartum nurses can foster the attachment process by encouraging parents to hold and look at their infant and by teaching coping mechanisms for prolonged crying. Nurses in neonatal intensive care units can minimize the effects of separation by encouraging parents to visit and can help parents become comfortable caring for their child. Nurses in ambulatory settings can teach parents appropriate methods of bathing, feeding, toileting, disciplining, and preventing injuries while stressing the normal needs and developmental characteristics of children. Nurses must be sensitive to parental needs for attention, reassurance, and reinforcement and should refer parents to community services and self-help groups.

Unlike preventive efforts for neglect and physical abuse, which have been aimed at the potential offender, prevention of child sexual abuse has centered on education of children to protect themselves. Materials are available for parents that describe sexual abuse and its prevention.* Helpful games such as, "What if the babysitter wants to wrestle and hug but tells you to keep it a secret?" can be used to explore dangerous situations in advance and help children learn the importance of saying "no." They need reassurance that, no matter what the other person says or does, the parents want to know about it and will not punish them. Even if children participate in the activity before telling their parents, they must be reassured that it was not their fault. It is equally important to teach children safety in terms of potential risk situations. Several suggestions for parents regarding protecting and educating children against possible molestation are presented in the Family-Centered Care box. The nurse is frequently in a position to discuss the topic of abuse with parents and provide guidelines. In addition, parents need to be made aware that "nice" people, including friends and relatives, can be offenders; they should carefully observe how others act toward the child. A sudden change in the child's behavior and a response such as, "I don't like Uncle anymore" are clues to investigate the relationship. In the event of any doubt, prevent further solitary encounters between this person and the child. It is sometimes to the child's great misfortune that parents do not take certain comments seriously such as, "He hugs me too tight" or "I don't want to go with him." Casual parental statements such as, "He just loves you" or "You do whatever adults tell you to do" can place children in jeopardy. Health professionals must alert parents to such dangers and guide them toward an appreciation of the problem, providing concrete guidelines toward child education and protection.

FAMILY-CENTERED CARE

Preventing or Dealing with Sexual Abuse of Children

Sexual assault of children is much more common than most people realize. It may be preventable if children have proper preparation. *To provide protection and preparation:*

- Pay careful attention to who is around children. (Unwanted touch may come from someone liked and trusted.)
- Back up a child's right to say "no."
- Encourage communication by taking seriously what children *say.*
- Take a second look at signals of potential danger.
- Refuse to leave children in the company of those not trusted.
- Include information about sexual assault when teaching about safety.
- Provide specific definitions and examples of sexual assault.
- Remind children that even "nice" people sometimes do mean things.
- Urge children to tell about *anybody* who causes them to be uncomfortable.
- Prepare children to deal with bribes, threats, and possible physical force.
- Virtually eliminate secrets between children and parents.
- Teach children how to say "no," ask for help, and control who touches them and how.
- Model self-protective and limit-setting behavior for children.

Should it ever become necessary to help a child recover from a sexual assault:

- Listen carefully to understand children.
- Support the child for telling through praise, belief, sympathy, and lack of blame.
- Know local resources and choose help carefully.
- Provide opportunities to talk about the assault.
- Provide opportunities for entire family to go through recovery process.

Sexual assault affects everyone. To help deal with this social problem:

- Provide care and support to those who have been victimized.
- Recognize that offenders do not change without intervention.
- Organize neighborhood programs to support each other's efforts to protect children.
- Encourage schools to provide information about sexual assault as a problem of health and safety.
- Organize community groups to support educational-treatment and law-enforcement programs.

KEY POINTS

- The preschool years consist of the period from 3 to 5 years of age, a time that is considered critical for emotional and psychologic development.
- Biologic development in the preschool period is characterized by mature body systems and refinement in gross and fine motor behavior, as evidenced by activities such as running, riding a tricycle, and drawing.
- According to Erikson, acquiring a sense of initiative is the chief psychosocial task of the preschooler. Development of the superego occurs during this period as conscience begins to emerge.
- According to Piaget the preschool age is characterized by intuitive (or prelogical) thinking and a move toward logical thought processes through advanced, complex learning; language; and understanding of causality.
- The seeds of moral development are planted during the preschool period. According to Kohlberg, preschool children are in the stage of naive instrumental orientation, in which they are concerned with satisfying their own needs and less frequently the needs of others.
- Preschoolers often have difficulty discerning reality from fiction and believe that their thoughts are all powerful.
- Animism and magical thinking are hallmarks of preschool thinking.
- Eating habits are usually well established during the preschool years; therefore eating healthy and minimizing the intake of saturated fats and empty carbohydrate calories is an important part of educating for healthy living.
- Social development includes further separation-individuation; more sophisticated language; greater independence; and more complex, imaginative forms of play.
- Areas of special concern to parents during the preschool period are the preschool and kindergarten experience, sex education, fears, stress, and speech problems.
- In selecting an early-learning program, parents should inquire about daily activities, teacher qualifications, accreditation, student-staff ratio, safety, meals, fees, and health practices.
- Two rules that govern how parents answer questions about sex and other sensitive issues are to find out what the child knows and be honest.
- Fears constitute a great part of the preschool period; fear of objects or potential annihilation and parent-induced fears are common.
- Preschool aggression may result from frustration, modeling behavior, and reinforcement.
- Hesitancy or dysfluency in speech patterns is a normal characteristic of language development. Speech problems can occur when parents express excessive concern over this pattern.
- Health promotion continues to be directed toward proper nutrition, adequate sleep, proper dental care, and injury prevention.
- Child maltreatment may take the form of physical abuse or neglect, emotional abuse or neglect, or sexual abuse.
- Parental, child, and environmental characteristics are criteria that may predispose children to maltreatment.
- Identification of abuse entails securing evidence of maltreatment, taking a history pertaining to the incident, and assessing parental and child behaviors.
- The reported incidence of sexual abuse has increased in the past decade; common forms are incest, molestation, rape, exhibitionism, child pornography, child prostitution, and pedophilia.

CHAPTER

34

The School-Age Child and Family

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe the physical, cognitive, and moral changes that take place during the middle childhood years.
- Describe ways to help a child develop a sense of accomplishment.
- Demonstrate an understanding of the changing interpersonal relationships of school-age children.
- Discuss the role of the peer group in the socialization of the school-age child.
- Discuss the role of schools in the development and socialization of the school-age child.
- Outline an appropriate health teaching plan for the school-age child.
- Plan a sex education session for a group of school-age children.
- Identify the causes and discuss the preventive aspects of injury in middle childhood.

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

The segment of the life span that extends from age 6 years to approximately age 12 years has a variety of labels, each of which describes an important characteristic of the period. These middle years are most often referred to as school-age or the school years. This period begins with entrance into the school environment, which has a significant impact on development and relationships.

Physiologically, the middle years begin with the shedding of the first deciduous tooth and end at puberty with the acquisition of the final permanent teeth (with the exception of the wisdom teeth). Before 5 or 6 years of age, children have progressed from helpless infants to sturdy, complicated individuals with an ability to communicate, conceptualize in a limited way, and become involved in complex social and motor behaviors. Physical growth is also rapid during the preschool-age years. In contrast, the period of middle childhood, between the rapid growth of early childhood and the prepubescent growth spurt, is a time of gradual growth and development with more even progress in both physical and emotional aspects.

Biologic Development

During middle childhood, growth in height and weight assumes a slower but steady pace as compared with the earlier years. Between ages 6 and 12 years, children grow an average of 5 cm (2 inches) per year to gain 30 to 60 cm (1-2 feet) in height and almost double their weight, increasing 2 to 3 kg (4.5-6.5 pounds) per year. The average 6-year-old child is about 116 cm (45.7 inches) tall and weighs about 21 kg (46 pounds); the average 12-year-old child is about 150 cm (59 inches) tall and weighs approximately 40 kg (88 pounds). During this period, girls and boys differ little in size, although boys tend to be slightly taller and somewhat heavier than girls. Toward the end of the school-age years, both boys and girls begin to increase in size although most girls begin to surpass boys in both height and weight, to the acute discomfort of both girls and boys.

Proportional Changes

School-age children are more graceful than they were as preschoolers, and they are steadier on their feet. Their body proportions take on a slimmer look, with longer legs, varying body proportion, and a lower center of gravity. Posture improves over that of the preschool period to facilitate locomotion and efficiency in using the arms and

FIG 34-1 Middle childhood is the stage of development when deciduous teeth are shed.

trunk. These proportions make climbing, bicycle riding, and other activities easier. Fat gradually diminishes, and its distribution patterns change, contributing to the thinner appearance of children during the middle years.

Accompanying the skeletal lengthening and fat diminution is an increase in the percentage of body weight represented by muscle tissue. By the end of this age period, both boys and girls double their strength and physical capabilities and their steady and relatively consistent development of coordination increases their poise and skill. However, this increased strength can be misleading. Although strength increases, muscles are still functionally immature when compared with those of adolescents and they are more readily damaged by muscular injury caused by overuse.

The most pronounced changes that indicate increasing maturity in children are a decrease in head circumference in relation to standing height, a decrease in waist circumference in relation to height, and an increase in leg length in relation to height. These observations often provide a clue to a child's degree of physical maturity and have proved useful in predicting readiness for meeting the demands of school. There appears to be a correlation between physical indications of maturity and success in school.

Specific physiologic and anatomic characteristics are typical of children in middle childhood. Facial proportions change as the face grows faster in relation to the remainder of the cranium. The skull and brain grow very slowly during this period and increase little in size. Because all of the primary (deciduous) teeth are lost during this age span, middle childhood is sometimes known as the age of the loose tooth (Fig. 34-1). The early years of middle childhood, when the new secondary (permanent) teeth appear too large for the face, are known as the ugly duckling stage.

Maturation of Systems

Maturity of the gastrointestinal system is reflected in fewer stomach upsets; better maintenance of blood glucose levels; and an increased stomach capacity, which permits retention of food for longer periods. School-age children do not need to be fed as promptly or as frequently as preschool-age children. Caloric needs are less than they were in the preschool years.

Physical maturation is evident in other body tissues and organs. Bladder capacity, although differing widely among individual children, is generally greater in girls than in boys. The heart grows more slowly during the middle years and is smaller in relation to the rest of the body than at any other period of life. Heart and respiratory rates steadily decrease, and blood pressure increases from ages 6 to 12 years (see Appendix C).

The immune system becomes more competent in its ability to localize infections and to produce an antibody-antigen response. However, children have several infections in the first 1 to 2 years of school because of increased exposure to other children.

Bones continue to ossify throughout childhood but yield to pressure and muscle pulls more readily than with mature bones. Children need ample opportunity to move around, but they should observe caution in carrying heavy loads. For example, they should shift books or tote bags from one arm to the other. Backpacks distribute weight more evenly than tote bags.

Wider differences between children are observed at the end of middle childhood than at the beginning. These differences become increasingly apparent and, if they are extreme or unique, may create emotional problems. The associated characteristics of height and weight relationships, rapid or slow growth, and other important features of development should be explained to children and their families. Physical maturity is not necessarily correlated with emotional and social maturity. Seven-year-old children who look like 10-year-old children will, in fact, think and act like 7-year-old children. To expect behaviors appropriate for the older age is unrealistic and can be detrimental to their development of competence and self-esteem. Conversely, to treat 10-year-old children who look young physically as though they were younger is an equal disservice to them.

Prepubescence

Preadolescence is the period of approximately 2 years that begins at the end of middle childhood and ends with the thirteenth birthday. Because puberty signals the beginning of the development of secondary sex characteristics, prepubescence typically occurs during preadolescence.

Toward the end of middle childhood, the discrepancies in growth and maturation between boys and girls become apparent. On the average, there is a difference of approximately 2 years between girls and boys in the age of onset of pubescence. This is a period of rapid growth in height and weight, especially for girls.

There is no universal age at which children assume the characteristics of prepubescence. The first physiologic signs appear at about 9 years of age (particularly in girls) and are usually clearly evident in 11- to 12-year-old children. Although preadolescent children do not want to be different, variability in physical growth and physiologic changes among children of the same sex and between the two sexes is often striking at this time. This variability, especially in relation to the onset of secondary sexual characteristics, is of great concern to preadolescents. Either early or late appearance of these characteristics is a source of embarrassment and uneasiness to both sexes.

Preadolescence is a period of considerable overlapping of developmental characteristics of both middle childhood and early adolescence. However, several unique characteristics set this period apart from others. Generally, puberty begins at 10 years in girls and 12 years in boys, but it can be normal for either sex after the age of 8 years. Boys experience little visible sexual maturation during preadolescence.

Psychosocial Development

Developing a Sense of Industry (Erikson)

Freud described middle childhood as the latency period, a time of tranquility between the Oedipal phase of early childhood and the eroticism of adolescence. During this time, children experience

FIG 34-2 School-age children are motivated to complete tasks. **A,** Working alone. **B,** Working with others.

relationships with same-sex peers following the indifference of earlier years and preceding the heterosexual fascination that occurs for most boys and girls in puberty.

Successful mastery of Erikson's first three stages of psychosocial development is important in terms of development of a healthy personality. Successful completion of these stages requires a loving environment within a stable family unit. These experiences prepare the child to engage in experiences and relationships beyond the intimate family group.

A sense of industry or a stage of accomplishment is achieved somewhere between age 6 years and adolescence. School-age children are eager to develop skills and participate in meaningful and socially useful work. They acquire a sense of personal and interpersonal competence; receive the systematic instruction prescribed by their individual cultures; and develop the skills needed to become useful, contributing members of their social communities.

Interests expand in the middle years, and with a growing sense of independence, children want to engage in tasks that can be carried through to completion (Fig. 34-2). They gain satisfaction from independent behavior in exploring and manipulating their environment and from interaction with peers. Often the acquisition of skills provides a way to achieve success in social activities. Reinforcement in the form of grades, material rewards, additional privileges, and recognition provides encouragement and stimulation.

A sense of accomplishment also involves the ability to cooperate, to compete with others, and to cope effectively with people. Middle childhood is the time when children learn the value of doing things with others and the benefits derived from division of labor in the accomplishment of goals. Peer approval is a strong motivating power.

The danger inherent in this period of development is the occurrence of situations that might result in a sense of inferiority. Children with physical and mental limitations may be at a disadvantage in the acquisition of certain skills. When the reward structure is based on evidence of mastery, children who are incapable of developing these skills risk feeling inadequate and inferior. Even children without chronic disabilities may experience feelings of inadequacy in some areas. No child is able to do everything well, and children must learn that they will not be able to master every skill they attempt. All children, even children who usually have positive attitudes toward work and their own abilities, will feel some degree of inferiority when they encounter specific skills that they cannot master.

Children need and want real achievement. Children achieve a sense of industry when they have access to tasks that need to be done and they are able to complete the tasks well despite individual differences in their innate capacities and emotional development.

Cognitive Development (Piaget)

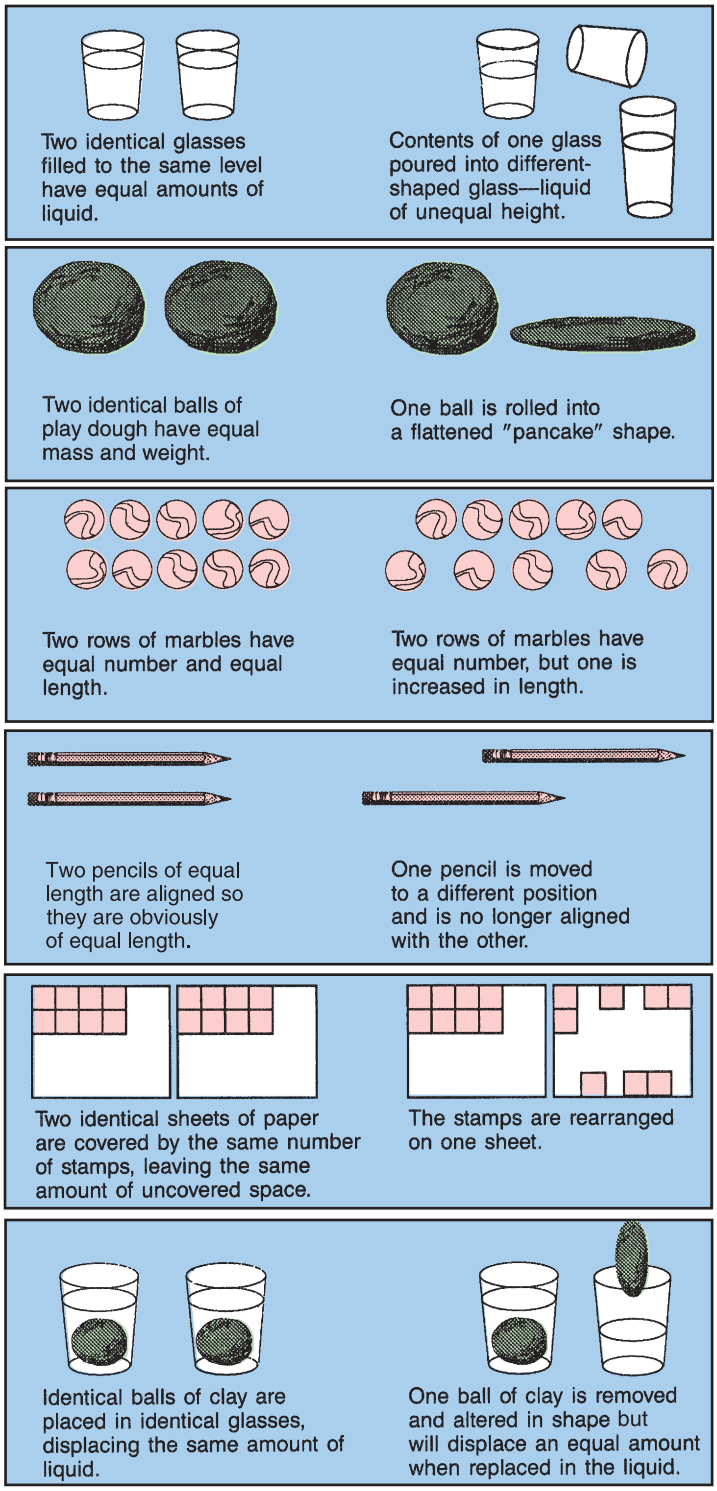
When children enter the school years, they begin to acquire the ability to relate a series of events to mental representations that can be expressed both verbally and symbolically. This is the stage Piaget describes as concrete operations, when children are able to use thought processes to experience events and actions. The rigid, egocentric view of the preschool years is replaced by mental processes that allow children to see things from another's point of view.

During this stage, children develop an understanding of relationships between things and ideas. They progress from making judgments based on what they see (perceptual thinking) to making judgments based on what they reason (conceptual thinking). They are able to master symbols and to use their memories of past experiences to evaluate and interpret the present.

One cognitive task of school-age children is mastering the concept of conservation (Fig. 34-3). At an early age (≈5-7 years), children grasp the concept of reversibility of numbers as a basis for simple mathematics problems (e.g., $2 + 4 = 6$ and $6 - 4 = 2$). They learn that simply altering their arrangement in space does not change certain properties of the environment, and they are able to resist perceptual cues that suggest alterations in the physical state of an object. For example, they recognize that changing the shape of a substance such as a lump of clay does not alter its total mass. They no longer perceive a tall, thin glass of water as containing a greater volume than a short, wide glass; they can distinguish between the weight of items regardless of their size. They recognize that size is not necessarily related to weight or volume. There is a developmental sequence in children's capacity to conserve matter. Conservation of mass usually is accomplished first, weight some time later, and volume last.

School-age children also develop classification skills. They can group and sort objects according to the attributes they share, place things in a sensible and logical order, and hold a concept in mind while making decisions based on that concept. Another characteristic of middle childhood is that children derive enjoyment from classifying and ordering their environment. They become occupied with collections of objects, such as stickers, shells, dolls, cars, cards, and stuffed animals. They may even begin to order friends and relationships (e.g., best friend, second-best friend).

They develop the ability to understand relational terms and concepts, such as bigger and smaller; darker and paler; heavier and lighter; to the right of and to the left of; and more than and less than.



Liquids: Conserving child recognizes that each glass contains the same amount of liquid. Usually attained at age 5 to 7 years.

Mass (continuous substance): Conserving child recognizes that each object contains the same amount of dough. Usually attained at age 5 to 7 years.
Weight: Conserving child recognizes that each object weighs the same. Usually attained at age 9 to 10 years.

Number: Conserving child recognizes that each row contains the same number of marbles. Usually attained at age 5 to 7 years.

Length: Conserving child recognizes that the two pencils are still of equal length. Usually attained at age 6 to 7 years.

Area: Conserving child recognizes that the amount of uncovered area remains the same on each sheet. Usually attained at age 9 to 10 years.

Volume (water displacement): Conserving child recognizes that water levels are the same, since only the shape of the clay has changed. Pieces of clay displace the same volume of liquid. Usually attained at age 9 to 12 years.

FIG 34-3 Common examples that demonstrate the child's ability to conserve (ages are only approximate).

They view family relationships in terms of reciprocal roles (e.g., to be a brother, one must have a sibling).

School-age children learn the alphabet and the world of symbols called *words,* which can be arranged in terms of structure and their relationship to the alphabet. They learn to tell time, to see the relationship of events in time (history) and places in space (geography), and to combine time and space relationships (geology and astronomy).

The ability to read is acquired during the school years and becomes the most significant and valuable tool for independent inquiry. Children's capacity to explore, imagine, and expand their knowledge is enhanced by reading.

Moral Development (Kohlberg)

As children move from egocentrism to more logical patterns of thought, they also move through stages in the development of conscience and moral standards. Young children do not believe that standards of behavior come from within themselves but, instead, that rules are established and set down by others. During the preschool years, children adopt and internalize the moral values of their parents. They learn standards for acceptable behavior, act according to these standards, and feel guilty when they violate them. Although children 6 or 7 years of age know the rules and behaviors expected of them, they do not understand the reasons behind them. Rewards and punishments guide their judgment; a "bad act" is one that breaks a rule or causes harm. Young children believe that what other people tell them to do is right and that what they themselves think is wrong. Consequently, children 6 or 7 years old may interpret accidents or misfortunes as punishment for "bad" acts.

Older school-age children are able to judge an act by the intentions that prompted it rather than just its consequences. Rules and judgments become less absolute and authoritarian and begin to be founded on the needs and desires of others. For older children, a rule violation is likely to be viewed in relation to the total context in which it appears. The situation, as well as the morality of the rule itself, influences reactions. Although younger children judge an act only according to whether it is right or wrong, older children take into account different points of view. They are able to understand and accept the concept of treating others as they would like to be treated.

Spiritual Development

Children at this age think in concrete terms but are avid learners and have a great desire to learn about their God. They picture God as human and use adjectives such as "loving" and "helping" to describe their deity. They are fascinated by the concepts of hell and heaven, with a developing conscience and concern about rules. They may fear going to hell for misbehavior. School-age children want and expect to be punished for misbehavior and, when given the option, tend to choose a punishment that "fits the crime." However, they may view illness or injury as a punishment for a real or imagined misdeed. The beliefs and ideals of family and religious persons are more influential than those of their peers in matters of faith.

School-age children begin to learn the difference between the natural and the supernatural but have difficulty understanding symbols. Consequently, religious concepts must be presented to them in concrete terms. Prayer or other religious rituals comfort them, and if these activities are a part of their daily lives, they can help them cope with threatening situations. Their petitions to their God in prayers tend to be for tangible rewards. Although younger children expect their prayers to be answered, as they get older, they begin to recognize that this does not always occur and they become less concerned when their prayers are not answered. They are able to discuss their feelings about their faith and how it relates to their lives (see Cultural Competence box).

Social Development

One of the most important socializing agents in the school-age years is the peer group. In addition to parents and schools, the peer group conveys a substantial amount of information to its members. Peer groups have a culture of their own with secrets, traditions, and codes of ethics that promote feelings of solidarity and detachment from adults. Through peer relationships, children learn how to deal with dominance and hostility, how to relate to persons in positions of leadership and authority, and how to explore ideas and the physical environment.

Peer-group identification is an important factor in gaining independence from parents. The aid and support of the group provide children with enough security to risk the moderate parental rejection brought about by small victories in the development of independence.

A child's concept of the appropriate gender role is also influenced by relationships with peers. During the early school years, few gender differences exist in the play experiences of children. Both girls and boys share games and other activities. However, in the later school years, the differences in the play of boys and girls becomes more marked.

CULTURAL COMPETENCE

Religious Orientation

Many schools and communities have a Judeo-Christian orientation toward prayer, holidays, and values. This may result in conflict and discomfort for children of other religious or ethnic groups. Sensitivity must be exercised so as not to offend and confuse children from other religious backgrounds, such as the Buddhist, Hindu, and Muslim faiths, and those with no religious backgrounds.

Social Relationships and Cooperation

Daily relationships with peers provide important social interactions for school-age children. For the first time, children join group activities with unrestrained enthusiasm and steady participation. Previous interactions were limited to short periods under considerable adult supervision. With increased skills and wider opportunities, children become involved with one or more peer groups in which they can gain status as respected members.

Valuable lessons are learned from daily interaction with age mates. First, children learn to appreciate the numerous and varied points of view that are represented in the peer group. As children interact with peers who see the world in ways that are somewhat different from their own, they become aware of the limits of their own point of view. Because age mates are peers and are not forced to accept each other's ideas as they are expected to accept those of adults, other children have a significant influence on decreasing the egocentric outlook of the child. Consequently, children learn to argue, persuade, bargain, cooperate, and compromise to maintain friendships.

Second, children become increasingly sensitive to the social norms and pressures of the peer group. The peer group establishes standards for acceptance and rejection, and children are often willing to modify their behavior to be accepted by the group. The need for peer approval becomes a powerful influence toward conformity. Children learn to dress, talk, and behave in a manner acceptable to the group. A variety of roles, such as class joker or class hero, may be assumed by individual children to gain approval from the group.

Third, the interaction among peers leads to the formation of intimate friendships between same-sex peers. The school-age period is the time when children have "best friends" with whom they share secrets, private jokes, and adventures; they come to one another's aid in times of trouble. In the course of these friendships, children also fight, threaten each other, break up, and reunite. These relationships, in which the child experiences love and closeness with a peer, may be important as a foundation for relationships in adulthood (Fig. 34-4).

FIG 34-4 School-age children enjoy engaging in activities with a "best friend." (© 2011 Photos.com, a division of Getty Images. All rights reserved.)

Clubs and Peer Groups. One of the outstanding characteristics of middle childhood is the formation of formalized groups, or clubs. A prominent feature of these groups is the rigid rules imposed on the members. There is exclusiveness in the selection of persons who have the privilege of joining. Acceptance in the group is often determined on a pass-fail basis according to social or behavioral criteria. Conformity is the core of the group structure. There are often secret codes, shared interests, and special modes of dress, and each child must abide by a standard of behavior established by the members. Conforming to the rules provides children with feelings of security and relieves them of the responsibility of making decisions. By merging their identities with those of their peers, children are able to move from the family group to an outside group as a step toward seeking further independence. Peer groups and clubs allow children to substitute conformity to a peer group for conformity to a family at a time when children are still too insecure to function independently.

During the early school years, groups are usually small and loosely organized, with changing membership and no formal structure. The clubs and groups usually do not display elements of cooperation and order that are seen in groups of older children. In general, girls' groups are less formalized than boys' are, and although there may be a mixture of both sexes in the early school years, the groups of later school years are composed predominantly of children of the same sex. Common interests are the basis around which the group is structured.

Peer-group identification and association are essential to a child's socialization. Poor relationships with peers and a lack of group identification can contribute to bullying. Bullying is any recurring activity that intends to cause harm, distress, or control toward another in which there is a perceived imbalance of power between the aggressor(s) and the victim (Lamb, Pepler, and Craig, 2009). Although bullying can occur in any setting, it most often occurs at school during unstructured times such as recess (Arseneault, Bowes, and Shakoor, 2010). Children who are targeted for bullying often have internalizing characteristics such as withdrawal, anxiety, depression, low self-esteem, and reduced assertiveness that may make them an easy target for bullying (Arseneault, Bowes, and Shakoor, 2010). Bullies are generally defiant toward adults, antisocial, and likely to break school rules. They have dominant personalities, may come from homes where parental involvement and nurturing are lacking, and may experience or witness violence or abuse at home (Bowes, Arseneault, Maughan, et al., 2009). Boys who bully tend to use physical force, referred to as *direct bullying,* but girls usually use indirect bullying methods, such as exclusion, gossip, or rumors (Arseneault, Bowes, and Shakoor, 2010). Cyberbullying is a new form of bullying and involves the use of cellular telephones, digital cameras, or social networking Internet sites to cause distress on an individual (American Academy of Pediatrics [AAP] Committee on Injury, Violence, and Poison Prevention, 2009).

The long-term consequences of bullying are significant. Chronic bullies seem to continue their behaviors into adulthood, negatively influencing their ability to develop and maintain relationships. Victims of bullying often experience psychologic distress such as worry, sadness, anxiety, depression, and nightmares and can have increased self-harm behaviors, social isolation, suicidal ideation, and violent behaviors (Arseneault, Bowes, and Shakoor, 2010). School personnel play an important role in implementing antibullying interventions in schools; however, research has recognized that involving the whole family in antibullying programs greatly increases success (Arseneault, Bowes, and Shakoor, 2010).

There are also dangers in peer-group attachments that are too strong. Peer pressures force some children to take risks or engage in behaviors that are against their better judgment. A child's membership in a gang is associated with marked increases in serious delinquent behavior (Fisher, Montgomery, and Gardner, 2008). Peer-group activities that result in unlawful or criminal gang violence are increasing in the United States. An integration of family-centered and school-based programs is needed to reduce the influences for children to become affiliated with gangs.

Relationships with Families

Although the peer group is influential and necessary for normal child development, parents are the primary influence in shaping their children's personalities, setting standards for behavior, and establishing value systems. Family values usually take precedence over peer value systems. Although children may appear to reject parental values while testing the new values of the peer group, ultimately they retain and incorporate into their own value systems the parental values they have found to be of worth.

In the middle school years, children want to spend more time in the company of peers and they often prefer peer-group activities to family activities. This can be disturbing to parents. Children become intolerant and critical of their parents, especially when their parents' ways deviate from those of the group. They discover that parents can be wrong, and they begin to question the knowledge and authority of their parents, who were previously considered to be all-knowing and all-powerful.

Although increased independence is the goal of middle childhood, children are not prepared to abandon all parental control. They need and want restrictions placed on their behavior, and they are not prepared to cope with all of the problems of their expanding environment. They feel more secure knowing there is an authority figure to implement controls and restrictions. Children may

complain loudly about restrictions and try to break down parental barriers, but they are uneasy if they succeed in doing so. They respect adults who prevent them from acting on every urge. Children view this behavior as an expression of love and concern for their welfare.

Children also need their parents to be adults, not friends. Sometimes parents, hurt by their children's rejection, attempt to maintain their love and gratitude by assuming the role of "pals." Children need the stable, secure strength provided by mature adults to whom they can turn during troubled relationships with peers or stressful changes in their world. With a secure base in a loving family, children are able to develop the self-confidence and maturity needed to break loose from the group and stand independently.

Play

Play takes on new dimensions that reflect a new stage of development in the school years. Play involves increased physical skill, intellectual ability, and fantasy. In addition, children develop a sense of belonging to a team or club by forming groups and cliques.

Rules and Rituals. The need for conformity in middle childhood is strongly manifested in the activities and games of school-age children. In the preschool years, children's games were either invented for them or played in the company of a friend or an adult. Now children begin to see the need for rules, and their games have fixed and unvarying rules that may be bizarre and extraordinarily rigid. Part of the enjoyment of the game is knowing the rules, because knowing means belonging. Conformity and ritual permeate their play and are also evident in their behavior and language. Childhood is full of chants and taunts, such as: "Eeeny, meeny, miney, mo," "Last one is a rotten egg," and "Step on a crack, break your mother's back." Children derive a sense of pleasure and power from such sayings, which have been handed down with few changes through generations.

Team Play. A more complex form of play that evolves from the need for peer interaction is team games and sports. A referee, umpire, or person of authority may be required so that the rules can be followed more accurately. Team play teaches children to modify or exchange personal goals for goals of the group; it also teaches them that division of labor is an effective strategy for attaining a goal. Children learn about competition and the importance of winning—an attribute highly valued in the United States.

Team play can also contribute to children's social, intellectual, and skill growth. Children work hard to develop the skills needed to become team members, to improve their contribution to the group, and to anticipate the consequences of their behavior for the group. Team play helps stimulate cognitive growth because children are called on to learn many complex rules, make judgments about those rules, plan strategies, and assess the strengths and weaknesses of members of their own team and members of the opposing team.

Quiet Games and Activities. Although play at this age is highly active, school-age children also enjoy quiet and solitary activities. The middle years are the time for collections, which constitute another ritual. Young school-age children's collections are an odd assortment of unrelated objects in messy, disorganized piles. Collections of later school years are more orderly, selective, and organized in scrapbooks, on shelves, or in boxes.

School-age children become fascinated with complex board, card, or computer games that they can play alone, with a best friend, or with a group. As in all games, adherence to the rules is fanatic. Disagreements over rules can cause much discussion and argument but are easily resolved by reading the rules of the game.

The newly acquired skill of reading becomes increasingly satisfying as school-age children expand their knowledge of the world through books (Fig. 34-5). School-age children never tire of stories and, as with preschool children, love to have stories read aloud. They also enjoy sewing, cooking, carpentry, gardening, and creative activities such as painting. Many creative skills such as music and art, as well as athletic skills such as swimming, karate, dancing, and skating, are learned during these years and continue to be enjoyed into adolescence and adulthood (Fig. 34-6).

Development of a Self-Concept

The term *self-concept* refers to a conscious awareness of self-perceptions, such as one's physical characteristics, abilities, values, self-ideals and expectancy, and idea of self in relation to others. It also includes one's body image, sexuality, and self-esteem. Although primary caregivers continue to exert influence on children's self-evaluation, the opinions of peers and teachers provide valuable input during middle childhood. With the emphasis on skill building and broadened social relationships, children are continually engaged in the process of self-evaluation.

Significant adults can often manage to unobtrusively manipulate the environment so that children experience success. Each small success increases a child's self-image. The more positive children feel about themselves, the more confident they will be in trying for success in the future. All children profit from feeling that they are in some way special to a significant adult. A positive self-concept makes

children feel likeable, worthwhile, and capable of significant contributions. These feelings lead to self-respect, self-confidence, and happiness. Negative feelings lead to self-doubt.

Development of a Body Image

School-age children have a relatively accurate and positive perception of their physical selves, but in general, they like their physical selves less as they grow older. The head appears to be the most important part of the school-age child's perceived image of self, with hair and eye color the characteristics used most frequently to describe the physical self.

Body image is influenced, but not solely determined, by significant others. The number of significant others who influence children's perception of themselves increases with age. Children are acutely aware of their own bodies, the bodies of their peers, and those of adults. They are also aware of deviations from the norm. Physical impairments, such as hearing or visual defects, ears that "stick out," or birthmarks, assume great importance. Increasing awareness of these differences, especially when accompanied by unkind comments and taunts from others, may cause a child to feel inferior and less desirable. This is especially true if the defect interferes with the child's ability to participate in games and activities.

Table 34-1 summarizes the major developmental achievements of the school-age years.

Coping with Concerns Related to Normal Growth and Development

School Experience

School serves as the agent for transmitting the values of society to each succeeding generation of children. School is also the setting for relationships with peers. After the family, schools are the second most important socializing agent in the lives of children.

Entrance into school causes a sharp break in the structure of the child's world. For many children, it is their first experience in conforming to a group pattern imposed by an adult who is not a parent and who has responsibility for too many children to be constantly aware of each child as an individual. Children want to go to school and usually adapt to the new conditions with little difficulty. Successful adjustment is related to the child's physical and emotional maturity and the parent's readiness to accept the separation associated with school entrance. Unfortunately, some parents express their unconscious attempts to delay the child's maturity by clinging behavior, particularly with their youngest child.

By the time they enter school, most children have a fairly realistic concept of what school involves. They receive information regarding the role of a student from parents, siblings, playmates, and the media. In addition, most children have had some experience with day care, preschool, or kindergarten. Middle-class children have fewer adjustments to make and less to learn about expected behavior because schools tend to reflect dominant middle-class customs and values. If the child has attended a preschool program, the focus of the preschool program also affects the child's adjustment. Some preschool programs provide custodial care only, but others emphasize emotional, social, and intellectual development.

Classmates have a significant impact on the socialization of children. School is the first time that most children become members of a large group of individuals their own age. Peer relationships become increasingly important and influential as children proceed through school. The specific influence exerted by the peer group depends on the background, interests, and abilities of the individual child.

Teachers. Children respond best to teachers who possess the characteristics of a warm, loving parent. Teachers in the early grades perform many of the activities formerly assumed by the parent, such as recognizing the child's personal needs (e.g., the need to go to the bathroom, need for help with clothing) and helping to develop their social behavior (e.g., manners).

Teachers, like parents, are concerned about the child's psychologic and emotional welfare. Although the functions of teachers and parents differ, both place constraints on behavior and both are in a position to enforce standards of conduct. However, the teacher's primary responsibility involves stimulating and guiding children's intellectual development, as opposed to providing for their physical welfare beyond the school setting.

TABLE 34-1 GROWTH AND DEVELOPMENT DURING THE SCHOOL-AGE YEARS

PHYSICAL AND MOTOR	MENTAL	ADAPTIVE	PERSONAL-SOCIAL
Age 6 Years			
Height and weight gain continues slowly	Develops concept of numbers	At table, uses knife to spread butter or jam on bread	Can share and cooperate better
Weight, 16-26.3 kg (35.5-58 pounds)	Can count 13 pennies	At play, cuts, folds, pastes paper; sews crudely if needle is threaded	Has great need for children of own age
Height, 106.7-122 cm (42-48 inches)	Knows whether it is morning or afternoon	Takes bath without supervision; performs bedtime activities alone	Will cheat to win
Central mandibular incisors erupt	Defines common objects such as fork and chair in terms of their use	Reads from memory; enjoys oral spelling game	Often engages in rough play
Loses first tooth	Obeys three commands in succession	Likes table games, checkers, simple card games	Often jealous of younger brother or sister
Gradual increase in dexterity	Knows right and left hands	Giggles a lot	Does what adults are seen doing
Active age; constant activity	Says which is pretty and which is ugly of a series of drawings of faces	Sometimes steals money or attractive items	May have occasional temper tantrums
Often returns to finger feeding	Describes the objects in a picture rather than simply enumerating them	Has difficulty owning up to misdeeds	Is a boaster
More aware of hand as a tool	Attends first grade	Tries out own abilities	Is more independent, probably an influence of school
Likes to draw, print, color			Has own way of doing things
Vision reaches maturity			Increases socialization

TABLE 34-1 GROWTH AND DEVELOPMENT DURING THE SCHOOL-AGE YEARS—cont'd

PHYSICAL AND MOTOR	MENTAL	ADAPTIVE	PERSONAL-SOCIAL
Age 7 Years			
Begins to grow at least 5 cm (2 inches) in height per year Weight, 17.7-30 kg (39-66.5 pounds) Height, 112-130 cm (44-51 inches) Maxillary central incisors and lateral mandibular incisors erupt More cautious in approaches to new performances Repeats performances to master them Jaw begins to expand to accommodate permanent teeth	Notices that certain items are missing from pictures Can copy a diamond Repeats three numbers backward Develops concept of time; reads ordinary clock or watch correctly to nearest quarter hour; uses clock for practical purposes Attends second grade More mechanical in reading; often does not stop at the end of a sentence; skips words such as "it," "the," and "he"	Uses table knife for cutting meat; may need help with tough or difficult pieces Brushes and combs hair acceptably without help Likes to help and have a choice Is less resistant and stubborn	Is becoming a real member of the family group Takes part in group play Boys prefer playing with boys; girls prefer playing with girls Spends a lot of time alone; does not require a lot of companionship
Ages 8 to 9 Years			
Continues to gain 5 cm (2 inches) in height per year Weight, 19.5-39.5 kg (43-87 pounds) Height, 117-142 cm (46-56 inches) Lateral incisors (maxillary) and mandibular cuspids erupt Movement fluid; often graceful and poised Always on the go; jumps, chases, skips Increased smoothness and speed in fine motor control; uses cursive writing Dresses self completely Likely to overdo; hard to quiet down after recess More limber; bones grow faster than ligaments	Gives similarities and differences between two things from memory Counts backward from 20 to 1; understands concept of reversibility Repeats days of the week and months in order; knows the date Describes common objects in detail, not merely their use Makes change out of a quarter Attends third and fourth grades Reads more; may plan to wake up early just to read Reads classic books but also enjoys comics More aware of time; can be relied on to get to school on time Can grasp concepts of parts and whole (fractions) Understands concepts of space, cause and effect, nesting (puzzles), conservation (permanence of mass and volume) Classifies objects by more than one quality; has collections Produces simple paintings or drawings	Makes use of common tools such as hammer, saw, screwdriver Uses household and sewing utensils Helps with routine household tasks such as dusting, sweeping Assumes responsibility for share of household chores Looks after all of own needs at table Buys useful articles; exercises some choice in making purchases Runs useful errands Likes pictorial magazines Likes school; wants to answer all the questions Is afraid of failing a grade; is ashamed of bad grades Is more critical of self Takes music and sport lessons	Is easy to get along with at home Likes the reward system Dramatizes Is more sociable Is better behaved Is interested in boy-girl relationships but will not admit it Goes about home and community freely, alone or with friends Likes to compete and play games Shows preference in friends and groups Plays mostly with groups of own sex but is beginning to mix Develops modesty Compares self with others Enjoys organizations, clubs, and group sports
Ages 10 to 12 Years			
Weight, 24.5-58 kg (54-128 pounds) Height, 127-162.5 cm (50-64 inches) Posture is more similar to an adult's; will overcome lordosis Remainder of teeth will erupt and tend toward full development (except wisdom teeth) **Girls**—Pubescent changes may begin to appear; body lines soften and round out **Boys**—Slow growth in height and rapid weight gain; may become obese in this period	Writes brief stories Attends fifth to seventh grades Writes occasional short letters to friends or relatives on own initiative Uses telephone for practical purposes Responds to magazine, radio, or other advertising Reads for practical information or own enjoyment—stories or library books of adventure or romance, animal stories	Makes useful tools or does easy repair work Cooks or sews in small way Raises pets Washes and dries own hair; is responsible for a thorough job of cleaning hair but may need reminding to do so Is sometimes left alone at home for an hour or so Is successful in looking after own needs or those of other children left in his or her care	Loves friends; talks about them constantly Chooses friends more selectively; may have a "best friend" Enjoys conversation Develops beginning interest in opposite sex Is more diplomatic Likes family; family really has meaning Likes mother and wants to please her in many ways Demonstrates affection Likes father, who is admired and may be idolized Respects parents

Teachers serve as models that children try to emulate. Children seek their teachers' approval and avoid their disapproval. The teacher is a significant person in the life of the early school-age child, and hero worship of a teacher may extend into late childhood and preadolescence. Teachers who make supportive statements that reassure or commend children, use accepting and clarifying statements that help children refine ideas and feelings, and provide assistance that aids children with their own problem solving contribute to the development of a positive self-concept in the school-age child.

Parents. Parents share responsibility for helping children achieve their maximal potential. Parents can supplement the school program in numerous ways (see Family-Centered Care box). Cultivating responsibility is the goal of parental assistance. Being responsible for schoolwork helps children learn to keep promises, meet deadlines, and succeed at their jobs as adults. Responsible children may occasionally ask for help (e.g., with a spelling list), but usually they prefer to think through their work by themselves. Excessive pressure or lack of encouragement from parents may inhibit the development of these desirable traits.

Latchkey Children

The term latchkey children is used to describe children who are left to care for themselves before or after school without the supervision of an adult. The large numbers of single-parent families and working mothers, together with the lack of available child care, have created a stress-provoking situation for many school-age children. Some of these children may have a chronic illness as well.

Inadequate adult supervision after school leaves children at greater risk for injury and delinquent behavior. In some instances, outside activities are curtailed and relationships with peers may be significantly diminished. Latchkey children may feel more lonely, isolated, and fearful than children who have someone to care for them. To cope with their fears and anxieties while alone, these children may devise strategies such as hiding, playing the television at a loud volume, or using pets for comfort.

Many communities and persons concerned about the welfare of latchkey children are trying to help these children and their parents deal with this potentially serious problem. Some communities and employers have implemented after-school programs or telephone "hotlines" that provide check-in and reassurance for children. Nurses should be aware of these community services and encourage parents to teach self-help skills to these children.

Limit Setting and Discipline

Many factors influence the amount and manner of discipline and limit setting imposed on school-age children. Some of these factors are the parents' psychosocial maturity, the parents' childhood and childrearing experiences, the children's temperament, the context of the children's misconduct, and the children's response to rewards and punishments. When children develop an ability to see a situation from another's point of view, they are also able to understand the effects of their reactions on others and themselves.

Discipline should take place in a positive, supportive environment with the use of strategies to instruct and guide desired behaviors and eliminate undesired behaviors (Knox, 2010). Reasoning is an effective technique for middle school–age children. With advancing cognitive skills, they are able to benefit from more complex disciplinary strategies. For example, withholding privileges, requiring compensation, imposing penalties, and contracting can be used with great success. Problem solving is the best approach to limit setting, and children themselves can be included in the process of determining appropriate disciplinary measures.

FAMILY-CENTERED CARE

Helping Children in School

General Guidelines

- Be supportive—provide companionship; share ideas and thoughts.
- Be positive—every child should experience some success each day.
- Share an interest in reading—use the library; discuss books they are reading.
- Support and encourage activity rather than passivity.
- Encourage originality—help children make their own projects from discarded articles or other available materials.
- Foster the development of hobbies and collections.
- Encourage children to wonder and reflect during free time.
- Encourage family experiences and trips to places of interest.
- Encourage questions—help children discover sources for information or places to explore and investigate.
- Stimulate creative thinking and problem solving—help children try out new solutions to problems without fear of making mistakes.
- Use rewards rather than punishment.

Specific Guidelines

- Meet the teacher at the beginning of school, and plan to visit the school to see what is taught and expected.
- Send the child to school every day. Teachers are concerned when parents make other plans for their children; it conveys the impression that school is unimportant.
- Demonstrate an interest in what the child is learning.
- Demonstrate an interest in content and growth more than in grades.
- Make it clear to the child that schoolwork is between the child and the teacher; the teacher and child should set goals for better school performance to allow the child to feel responsible for school successes and failures.
- Take advantage of situations that support and reinforce school learning.
- Share information with teachers that will help them understand the child better.
- Communicate with the teacher if there appears to be a problem; avoid waiting for a scheduled conference.
- Provide a quiet, well-lit area for study that is safe from interruption; do not allow television or radio.
- Avoid dictating a study time, but do enforce rules, such as no television until homework is done; accept the child's word that work is complete.
- Help with homework should focus on explaining the question, not giving the answer.
- Teach the child to break large tasks (e.g., a report) into smaller, manageable tasks spread over the allotted time rather than attempting the entire project the night before it is to be completed.
- Limit home tutoring to special circumstances, such as when the teacher requests parental assistance after a child's prolonged absence.
- Request special help for children with learning problems.
- Support the school staff by showing respect for both the school system and the teacher, at least in the child's presence.

Dishonest Behavior

During middle childhood, children may engage in what is considered to be antisocial behavior. Previously well-behaved children may engage in lying, stealing, and cheating. Such behaviors are disturbing and challenging to parents.

Lying can occur for a number of reasons. By the time children enter school, they still "tell stories," often exaggerating a story or situation as a means of impressing their family or friends. However, during middle childhood, children become able to distinguish between fact and fantasy. If children do not develop this characteristic, parents need to teach them what is real and what is make-believe.

Young children may lie to escape punishment or to get out of some difficulty even when their misbehavior is evident. Older children may lie to meet expectations set by others to which they have been unable to measure up. However, most children know that lying and cheating are wrong, and they are concerned when it is observed in their friends. They are quick to tell on others when they detect cheating.

Parents need to be reassured that all children lie occasionally and that sometimes children may have difficulty separating fantasy from reality. Parents should be helped to understand the importance of being truthful in their relationships with children.

Cheating is most common in young children 5 to 6 years of age. They find it difficult to lose at a game or contest, so they may cheat to win. They have not yet realized that this behavior is wrong, and they do it almost automatically. This behavior usually disappears as they mature. However, because children model observed behaviors, parents need to be aware of their own behavior. When parents set examples of honesty, children are more likely to conform to these standards.

As with other ethically related behavior, stealing is not unexpected in younger children. Between 5 and 8 years of age, children's sense of property rights is limited and they tend to take things simply because they are attracted to them or to take money for what it will buy. They are equally likely to give away something valuable that belongs to them. When young children are caught and punished, they are penitent—they "didn't mean to" and "promise to never do it again"—but they are likely to repeat the performance the following day. Often they not only steal but also lie about their behavior or attempt to justify it with excuses. It is seldom helpful to trap children into admission by asking directly if they committed the offense. Children do not take responsibility for these behaviors until the end of middle childhood. Stealing can be an indication that something is seriously wrong or lacking in the child's life. For example, children may steal to make up for love or another satisfaction that they feel is lacking. In most situations, it is wise not to attempt to attach a hidden or deep meaning to the stealing. An admonition, together with an appropriate and reasonable punishment, such as having the older child pay back the money or return the stolen items, takes care of most cases. Most children can be taught to respect the property rights of others with little difficulty despite numerous temptations and opportunities. If children's personal rights are respected, they are likely to respect the rights of others. Some children simply need more time to learn the rules regarding private property.

Stress and Fear

Children today experience significant amounts of stress, which can cause long-term adjustment and health problems. Stress in childhood comes from a variety of sources such as conflict within the family, interpersonal relationships, and poverty. The school environment and participation in multiple organized activities can be additional sources of stress. The demands from coaches and parents, in addition to school requirements and pressure from teachers to do well on proficiency testing, can cause unrealistic expectations on school-age children (Schredl, Biernelt, Roos, et al., 2008). In addition, with the increased exposure to sexuality and provocative clothing and behaviors, children of this age-group may feel pressured to have a girlfriend or boyfriend, which their maturity level cannot handle and which causes additional stress (McLeod and Knight, 2010).

The increasing violence in society has infiltrated into the school setting. In the present information age in which tragedy is broadcast daily in the media, children come to school knowing more about the latest world events than any previous generation of children. Many children know other children who have been killed or children who have brought weapons to school. School-age children can be victims of bullying, verbal insults, unwanted sexual remarks, damaged or stolen property, and physical abuse in the school environment (Fredland, 2008).

To help children cope with stress, parents, teachers, and health care providers need to frequently reassure children that they are safe, have honest and open communication, encourage children to express their feelings, and provide time for unstructured play (Washington, 2009). Adults must recognize signs that indicate a child is undergoing stress, identify the source of the stress promptly, and refer those children who need specialized treatment.

! NURSING ALERT

The nurse who observes the following signs of stress in a child should explore the situation further:

- Stomach pains or headache
- Changes in sleep patterns or nightmares
- Bed-wetting
- Changes in eating habits
- Aggressive or stubborn behavior
- Withdrawal or reluctance to participate
- Regression to earlier behaviors (e.g., thumb-sucking)
- Trouble concentrating or changes in academic performance

Children 7 to 12 years of age are capable of identifying their own physiologic responses to stress. Common physiologic signs of stress include tight muscles, hot or red in the face, jittery, fast heartbeat, breathing difficulties, headache, neck pain, and abdominal pain (Washington, 2009). Children should be taught to recognize these signs as indicators of stress and to use techniques to manage their stress. Children can learn relaxation techniques such as deep-breathing exercises, progressive relaxation of muscle groups, and positive imagery to immediately reduce stress (Kostenius and Ohrling, 2009). Encouraging them to "blow off steam" through physical activity reduces tension and anxiety. Children can be encouraged to observe effective coping strategies in others and adopt them for their own use (Kostenius and Ohrling, 2009). When an effective strategy has been developed for one situation, parents can show the child how to transfer the coping strategy or technique to other situations.

In addition to stress, school-age children experience a wide variety of fears, including fear of the dark, excessive worry about past behavior, self-consciousness, social withdrawal, and an excessive need for reassurance. These fears are considered normal for children this age. During the middle-school years, children become less fearful of body safety than they were as preschoolers but they still fear being hurt, being kidnapped, or having to undergo surgery. They also fear death and are fascinated by all the aspects of death and dying. The fears of noises, darkness, storms, and dogs lessen, but new fears related predominantly to school and family bother children during this time.

PROMOTING OPTIMAL HEALTH DURING THE SCHOOL YEARS

Nutrition

Although caloric needs are diminished in relation to body size during middle childhood, resources are being laid down at this time for the increased growth needs of adolescence. Parents and children need to be aware of the value of a balanced diet to promote growth because children usually eat what their family members eat. The quality of the child's diet depends on the family's pattern of eating.

Likes and dislikes established at an early age continue in middle childhood, although preferences for single foods subside and children develop a taste for a variety of foods. However, the easy availability of fast-food restaurants, the influence of the mass media, and the temptation of "junk food" make it easy for children to fill up on empty calories. Foods that do not promote growth, such as sugars, starches, and excess fats, are common in school-age children's diets. The easy availability of high-calorie foods, combined with the tendency toward more sedentary activities, has also contributed to an epidemic of childhood obesity.

Parents are unable to monitor what their children eat when they are away from home. A parent may pack a lunch for school but is unaware of how much is eaten, traded, sold, or thrown away. Nutrition education can and should be integrated in the curriculum throughout the school years. Important aspects of nutrition education include the U.S. Food and Drug Administration's MyPlate; elements of a wholesome diet; and how food products are grown, processed, and prepared. However, school cafeterias may not always provide healthy, nutritious meals. School nurses can take an active role in nutrition education by working with teachers to plan and implement units on nutrition instruction and by working with parents and children to give nutritional guidance.

Sleep and Rest

The amount of sleep and rest required during middle childhood is highly individualized. The amount of sleep depends on the child's age, activity level, and state of health. The growth rate slows in the school-age years, and less energy is expended in growth than during preceding years.

School-age children usually do not require naps, but they do need to sleep approximately 11 hours at age 5 years and 9 hours at age 12 years each night (Smaldone, Honig, and Byrne, 2007). Although fewer bedtime problems occur during these years, occasional difficulties are still associated with the bedtime ritual. Usually children 6 or 7 years old exhibit few bedtime problems, and encouraging quiet activity before bedtime, such as coloring or reading, facilitates the task of going to bed. However, most children in middle childhood must be reminded frequently to go to bed; 8- to 9-year-old children and 11-year-old children are particularly resistant. Often these children are unaware that they are tired; if they are allowed to remain up later than usual, they are fatigued the following day. Sometimes bedtime resistance can be resolved by allowing a later bedtime as the child gets older. Twelve-year-old children usually offer no resistance at bedtime; some even retire early to read a book or listen to music.

Exercise and Activity

The improved capabilities and adaptability of school-age children permit greater speed and effort in motor activities. Larger, stronger muscles permit longer and increasingly strenuous play without exhaustion. School-age children acquire the coordination, timing, and concentration that are required to participate in adult-type activities, but they may lack the strength, stamina, and control of adolescents and adults. They can engage in a greater amount of physical activity during the school years. However, parents, teachers, and coaches must remember that although children this age are large and appear strong, they may not be ready for strenuous competitive athletics.

All growing children need regular exercise and opportunities for satisfying experiences consistent with individual likes and dislikes. Appropriate activities during the school-age years include running, jumping rope, swimming, roller skating, ice skating, dancing, and bicycle riding. Positive reinforcement achieved by experiencing increasingly smooth, rhythmic, and efficient use of the body conditions the child toward regular physical activity. Exercise is essential for muscle development and tone, refinement of balance and coordination, increased strength and endurance, and stimulation of body functions and metabolic processes. Children need ample space to run, jump, skip, and climb in addition to safe indoor and outdoor facilities and equipment. Most children have abundant energy and need little encouragement to engage in physical activity. Children with disabling conditions or those who hesitate to become involved in active play (e.g., obese children) require special assessment and help so that activities appeal to them and are compatible with their limitations while also meeting their developmental needs.

Sports

Considerable controversy surrounds the trend toward early participation in competitive athletics and the amount and type of competitive sports that are appropriate for children in the elementary grades. The current view is that virtually every child is suited for some sport, and authorities do not discourage participation if children are matched to the type of sport appropriate to their abilities and to their physical and emotional constitution. School-age children enjoy competition (Fig. 34-7). However, teachers and coaches must understand the physical limitations of children this age and teach them the proper techniques and safety measures needed to avoid injuries. A safe and appropriate sport can be identified for even the most unskilled and uncompetitive child, including children with chronic illnesses and intellectual disability. Common activities for school-age children include baseball, soccer, gymnastics, and swimming. Equipment must be maintained in safe condition, and protective apparatus should be worn to prevent serious injury.

During the school-age years, girls have the same basic body structure as boys and have a similar response to systematic exercise training. However, at puberty, boys become larger and have more muscle mass, and at this stage, it is usually recommended that girls compete only against other girls. Before puberty, there is no essential difference in strength and size between girls and boys, making these precautions unnecessary.

Preadolescence is a time to teach fundamental motor skills; develop fitness in a practical, safe, and gradual manner; and promote healthy attitudes and values. Activities should include both practice sessions and unstructured play; the actual game or event should be managed in a manner that stresses mastery of the sport and enhancement of self-image rather than winning or pleasing others. All children should have an opportunity to participate, and special ceremonies should recognize all participants, not just individuals who excel in sports or athletics.

Acquisition of Skills

School-age children demonstrate increasing fine motor abilities and complex artistic skills. Handedness is well established by the beginning of the school years, and children make great strides in

FIG 34-7 The activities engaged in by school-age children vary according to interest and opportunity. **A,** Little League competitors. **B,** Playing tug-of-war.

writing and drawing during this period. It is a time of energetic and vibrant creative productivity. With the tools of language and reading, children create poems, stories, and plays. With more advanced fine motor skills, they are able to master an unlimited variety of handicrafts, such as ceramics, needlework, woodworking, and beadwork. They avidly pursue these skills in solitude, with a friend, or through organized groups such as boys' or girls' clubs or special interest groups that use crafts or other activities as a means to occupy, entertain, and educate children.

School-age children are capable of assuming responsibility for their own needs, although their distaste for soap and water and "dress" clothes is legendary. School-age children can and want to assume their share of household tasks, which usually are related to the male and female roles that have been defined by their culture. Many children also assume responsibility for tasks outside the home, such as baby-sitting, mowing lawns, or paper routes.

Dental Health

The first permanent (secondary) teeth erupt at about 6 years of age, beginning with the 6-year molar, which erupts posterior to the deciduous molars. Other permanent teeth appear in approximately the same order as eruption of the primary teeth (see Teething, Chapter 31) and follow shedding of the deciduous teeth (Fig. 34-8).

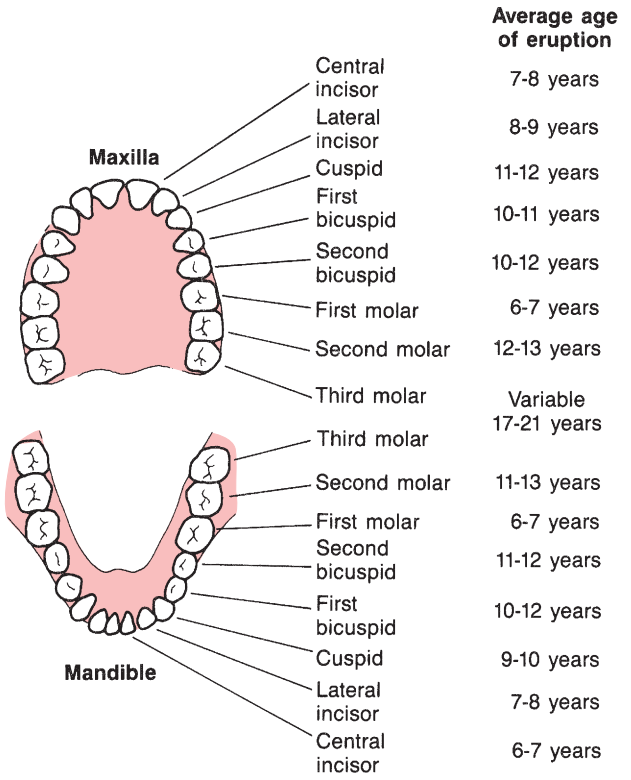

FIG 34-8 Sequence of eruption of the secondary teeth. (Data from Dean JA, Avery DR, McDonald RE: *McDonald and Avery dentistry for the child and adolescent*, ed 9, St Louis, 2011, Mosby.)

With the appearance of the second permanent (12-year) molar, most permanent teeth are present. Permanent dentition is more advanced in girls than in boys.

Because the permanent teeth erupt during the school-age years, dental hygiene and regular attention to dental caries are important parts of health supervision during this period (see Dental Health, Chapter 33). Correct brushing techniques should be taught or reinforced, and the role that fermentable carbohydrates play in production of dental caries should be emphasized. It is important to be alert to possible malocclusion problems that may result from irregular eruption of permanent teeth and that may impair function. Regular dental supervision and continued fluoride supplementation are integral parts of the health maintenance program.

The most effective means of preventing dental caries is proper oral hygiene. Children should be taught to perform their own dental care with the supervision and guidance of the parents. Parents should learn the correct brushing technique with their children, and they should monitor their child's efforts until the child can assume full responsibility.

Dental Problems

Limited or inadequate dental care results in the most common dental problems: dental caries, malocclusion, and periodontal disease. Trauma, especially tooth avulsion, is another important dental problem. All of these conditions benefit from early intervention to prevent tooth loss.

Dental caries (cavities) is the principal oral problem in children and adolescents. Reducing the incidence and consequences of dental caries is extremely important in childhood. If untreated, dental caries can result in total destruction of the involved teeth. The

prevalence rate of caries increases steadily across the life span; whereas 28% of children ages 2 to 5 years have caries, 59% of children 7 years of age have caries (Wagner and Oskouian, 2008).

Dental caries is a multifactorial disease involving susceptible teeth, cariogenic microflora, and an appropriate oral environment. The incidence of lesions and the likelihood of progressive invasion vary considerably and depend on a number of factors being present in the right combination. Because many children are exposed to health care but not dental care, oral inspection is an integral part of the physical assessment of every child. If there is any evidence of dental caries or other unhealthy dental state, the child should be referred for dental services. An alarming number of children do not receive regular dental supervision, and a significant number reach adulthood without dental examinations or treatment by a dentist.

Periodontal disease, an inflammatory and degenerative condition involving the gums and tissues supporting the teeth, often begins in childhood and accounts for a significant amount of tooth loss in adulthood. The more common periodontal problems are gingivitis (simple inflammation of the gums) and periodontitis (inflammation of the gums and loss of connective tissue and bone in the supporting structures of the teeth). Gingivitis, the most prevalent periodontal disease, is a reversible inflammatory disease that can begin in early childhood and is most often associated with the buildup of plaque on the teeth. Management is directed toward prevention by conscientious brushing and flossing, including the use of fluoride. Children should see a dentist at any signs of inflammation or irritation.

Malocclusion occurs when teeth of the upper and lower dental arches do not approximate in the proper relationships. As a result, the physiologic function of chewing is less effective and the cosmetic effect is displeasing. Teeth that are uneven, crowded, or overlapping are unable to meet their counterparts in the opposite jaw in the appropriate relationships and may be predisposed to disease in later years.

Orthodontic treatment is most successful when it is started in the late school-age or early teenage years after the last primary teeth have been shed and before growth ceases. However, referral should be made as soon as malocclusion is evident because some deformities can be corrected at an earlier age.

Dental injury may occur in childhood and includes fractures of varying degrees of severity, chipping, dislocation, or avulsion. All tooth injuries require prompt treatment by a competent dentist to prevent permanent displacement or loss. Delayed examination and diagnosis of tooth damage can result in infection or pulp involvement. Because it can affect the remaining teeth, replacement of the lost tooth is needed to maintain normal alignment and position of the other teeth.

A tooth that is avulsed (exarticulated, or "knocked out") should be replanted by the child, parent, or nurse and stabilized as soon as possible so the blood supply to the tooth can be reestablished and the tooth kept alive (see Emergency box). A tooth that is replanted promptly has a good survival rate. Avulsed primary teeth are usually not reimplanted.

As with all injuries to the mouth, an avulsed tooth causes a large amount of bleeding, which is frightening to children and their families; therefore the nurse or anyone faced with dental trauma should be prepared to provide support and reassurance during the dental trauma.

EMERGENCY

Avulsed Permanent Tooth

- Recover tooth.
- Hold tooth by crown; avoid touching root area.
- If tooth is dirty, rinse it gently under running water or saline; be certain to insert stopper in sink or basin (to avoid tooth loss).

To Reimplant the Tooth

- Insert tooth into socket; be certain that the lip side (or convex surface) is facing front.
- Have child maintain tooth in place by slowly biting down on a piece of gauze.
- Transport child to dentist immediately.
- Avoid sudden stops or sharp turns to prevent dislodging tooth.

If Reluctant to Reimplant the Tooth

- Place avulsed tooth in suitable medium for transport:
  - Cold milk
  - Saliva—under child's or parent's tongue
- If child is holding tooth in the mouth, avoid sudden stops to prevent swallowing tooth.
- DO NOT FORGET TO TAKE THE TOOTH.

Sex Education

Many children experience some form of sex play during or before preadolescence as a response to normal curiosity, not as a result of love or sexual urges. Children are experimentalists by nature, and sex play is incidental and transitory. Any adverse emotional consequences or guilt feelings depend on how the behavior is managed by the parents if it is discovered or whether children view their actions as wrong in the eyes of significant persons, particularly the parents.

The child's attitude toward sex is acquired indirectly at an early age. Initial curiosity about differences in body structure between boys and girls and between children and adults arises in the preschool years. Middle childhood is an ideal time for formal sex education, and many authorities believe that the topic is best presented from a life span approach. Information about sexual maturation and the process of reproduction minimizes children's uncertainty, embarrassment, and feelings of isolation that often accompany puberty.

An important component of ongoing sex education is effective communication with parents. If parents either repress the child's sexual curiosity or avoid dealing with it, the sexual information that the child receives may be acquired almost entirely from peers. When peers are the primary source of sexual information, it is transmitted and exchanged in secret conversation and contains a large amount of misinformation.

Nurse's Role in Sex Education

No matter where nurses practice, they can provide information on human sexuality to both parents and children. To discuss the topic adequately, nurses must have an understanding of the physiologic aspects of sexuality; knowledge of the cultural and societal values; and an awareness of their own attitudes, feelings, and biases about sexuality.

When presenting sexual information to school-age children, nurses should treat sex as a normal part of growth and development. Questions should be answered honestly, matter of factly, and to the same extent as questions about other topics. Answers should be at the child's level of understanding. There may be times when boys and girls should be taught content separately.

Children need help to differentiate sex and sexuality. Exercises on clarifying values, identifying role models, engaging in problem-solving skills, and practicing responsibility are important to prepare children for early adolescence and puberty. In addition, children need explanations of sexual information that is provided via the media or jokes. Information concerning pregnancy, contraceptives, and sexually transmitted diseases, including those caused by human immunodeficiency virus and human papillomavirus, should be presented in simple, accurate terms.

Preadolescents need precise and concrete information that will answer questions such as, "What if I start my period in the middle of class?" or "How can I keep people from telling I have an erection?" It is important to tell children what they want to know and what they can expect to happen as they become mature sexually.

During encounters with parents, nurses can be open and available for questions and discussion. They can set an example by the language they use in discussing body parts and their function and by the way in which they deal with problems that have emotional overtones, such as exploratory sex play and masturbation. Parents need help to understand normal behaviors and to view sexual curiosity in their children as a part of the developmental process. Assessing the parents' level of knowledge and understanding of sexuality provides cues to their need for supplemental information that will prepare them for the increasingly complex explanations they will need to provide as their children grow older.

School Health

Child health maintenance is ultimately the responsibility of the parents; however, the public schools and health departments in the United States have contributed to the improvement of child health by providing a healthful school environment, health services, and health education that emphasize sound health practices. Most of these functions constitute major components of community health services and involve large amounts of public funds and large numbers of health care professionals, including nurses.

A school health program is involved in ongoing health maintenance through assessment, screening, and referral activities. Routine health services provided by most schools include health appraisal, emergency care, safety education, communicable disease control, counseling, and follow-up care. Health education of school-age children is directed toward providing knowledge of health and influencing habits, attitudes, and conduct in relation to health and injury prevention.

Traditionally, school nurses were viewed as the individuals who detected diseases in the school, applied bandages, and cared for students who were ill or injured. Although these functions remain important parts of the school nurse's job, the role has expanded considerably. Today, school nurses manage and coordinate all the care required by regular students and students with special health care needs. In many settings, school health services have enlarged into family health centers that meet the needs of not only school-age children but also their families and the community. In these settings, school nurse practitioners provide health care that includes assessment of physical, psychomedical, psychoeducational, behavioral, and learning problems, as well as comprehensive well-child care (AAP, 2008).

The passage of the Education for All Handicapped Children Act and its amendments (Public Laws 94-142 and 99-457) mandated the integration of children with chronic illnesses and disabilities into the least restrictive environments, including regular classrooms whenever possible. School nurses are responsible for the medical and nursing needs of these children while they are in the school setting. School nurses develop, implement, and evaluate individualized health care plans for these children. Not all schools have a school nurse, and the use of unlicensed assistive personnel (UAP) is needed in some cases. After appropriate training and supervision, UAP can provide standardized routine health care to students. Delegation and supervision of UAP require skillful nursing assessment, effective communication, and professional judgment (AAP Council on School Health, 2009).

Injury Prevention

Because school-age children have developed more refined muscular coordination and control and can apply their cognitive capacities to their behavior, the number of injuries in middle childhood is diminished compared with the number in early childhood. The most common cause of severe injury and death in school-age children is motor vehicle accidents—either as a pedestrian or passenger (Centers for Disease Control and Prevention [CDC], 2010). It is important that nurses continue to emphasize three automobile safety measures that have been found to reduce the severity of injuries: effective car restraint systems, door-lock mechanisms, and appropriate passenger seating locations in the motor vehicle (Table 34-2). The rear vehicle seat is the safest place for children younger than 13 years, and booster seats should be used until 8 years of age (CDC, 2010).

School-age children's desire for riding bicycles increases the risk for injury on streets. Other serious injuries include accidents on skateboards, roller skates, in-line skates, scooters, and other sports equipment. All-terrain vehicles (ATVs) are popular with children

TABLE 34-2 INJURY PREVENTION DURING THE SCHOOL-AGE YEARS

DEVELOPMENTAL ABILITIES RELATED TO RISK FOR INJURY	INJURY PREVENTION
Motor Vehicle Accidents	
Is increasingly involved in activities away from home	Educate child regarding proper use of seat belts while a passenger in a vehicle.
Is excited by speed and motion	Maintain discipline while a passenger in a vehicle (e.g., keep arms inside, do not lean against doors, do not interfere with driver).
Is easily distracted by environment	Remind parents and children that no one should ride in the bed of a pickup truck.
Can be reasoned with	Emphasize safe pedestrian behavior.
	Insist on child wearing safety apparel (e.g., helmet) when applicable, such as riding bicycle, motorcycle, moped, or all-terrain vehicle (see Family-Centered Care box, p. 1001).

Continued

TABLE 34-2 INJURY PREVENTION DURING THE SCHOOL-AGE YEARS—cont'd

DEVELOPMENTAL ABILITIES RELATED TO RISK FOR INJURY	INJURY PREVENTION
Drowning	
Is apt to overdo	Teach child to swim.
May work hard to perfect a skill	Teach basic rules of water safety.
Has cautious, but not fearful, gross motor actions	Select safe and supervised places to swim.
	Check sufficient water depth for diving.
Likes swimming	Swim with a companion.
	Use an approved flotation device.
	Advocate for legislation requiring fencing around pools.
	Learn cardiopulmonary resuscitation.
Burns	
Has increasing independence	Make certain home has smoke detectors.
Is adventurous	Set water heaters to 48.9° C (120° F) to avoid scald burns.
Enjoys trying new things	Instruct child in behavior in areas involving contact with potential burn hazards (e.g., gasoline, matches, bonfires or barbecues, lighter fluid, firecrackers, cigarette lighters, cooking utensils, chemistry sets).
	Instruct child to avoid climbing or flying kite around high-tension wires.
	Instruct child in proper behavior in the event of fire (e.g., fire drills at home and school).
	Teach child safe cooking (use low heat; avoid any frying; be careful of steam burns, scalds, or exploding foods, especially from microwaving).
Poisoning	
Adheres to group rules	Educate child regarding hazards of taking nonprescription drugs and chemicals, including aspirin and alcohol.
May be easily influenced by peers	Teach child to say "no" if offered illegal or dangerous drugs or alcohol.
Has strong allegiance to friends	Keep potentially dangerous products in properly labeled receptacles, preferably out of reach.
Bodily Damage	
Has increased physical skills	Help provide facilities for supervised activities.
Needs strenuous physical activity	Encourage playing in safe places.
Is interested in acquiring new skills and perfecting attained skills	Keep firearms safely locked up except under adult supervision.
	Teach proper care of, use of, and respect for devices with potential danger (e.g., power tools, firecrackers).
Is daring and adventurous, especially with peers	Teach children not to tease or surprise dogs, invade their territory, take dogs' toys, or interfere with dogs' feeding.
Frequently plays in hazardous places	Stress eye, ear, or mouth protection when using potentially hazardous objects or devices or when engaging in potentially hazardous sports.
Confidence often exceeds physical capacity	
Desires group loyalty and has strong need for friends' approval	Teach safety regarding use of corrective devices (glasses); if child wears contact lenses, monitor duration of wear to prevent corneal damage.
Delights in physical activity	Stress careful selection, use, and maintenance of sports and recreation equipment, such as skateboards and in-line skates (see Family-Centered Care box, p. 1001).
Takes risks	
Is likely to overdo	Emphasize proper conditioning, safe practices, and use of safety equipment for sports or recreational activities.
Growth in height exceeds muscular growth and coordination	Caution against engaging in hazardous sports, such as those involving trampolines.
	Use safety glass and decals on large glassed areas, such as sliding glass doors.
	Use window guards to prevent falls.
	Teach name, address, and phone number and emphasize that child should ask for help from appropriate people (e.g., cashier, security guard, police) if lost; have identification on child (e.g., sewn in clothes, inside shoe).
	Teach stranger safety: Avoid clothing displaying the child's name or family name in public places. Caution child to never go with a stranger. Have child tell parents if anyone makes child feel uncomfortable in any way.
	Always listen to child's concerns regarding others' behavior.
	Teach child to say "no" when confronted by uncomfortable situations.

FIG 34-9 The right size bike is important; the child should be able to sit on the bike and place the balls of both feet on the ground. The foot should comfortably reach and manipulate the pedal in the down position. Wearing a protective helmet is mandatory. The helmet should be positioned so it sits low on the forehead and parallel to the ground when the head is held upright. It should not rock back and forth or shift from side to side. The strap should fasten securely under the chin.

but are unstable, difficult to handle, and responsible for a large number of childhood injuries. Several national organizations have developed policy and position statements to discourage the use of ATVs in any child younger than 16 years (American Pediatric Surgical Association, 2009).

Most injuries occur in or near the home or school. The most effective means of prevention is education of the child and family regarding the hazards of risk taking and the improper use of equipment. Safety helmets, protective eye and mouth shields, and protective padding are strongly recommended for children engaging in active sports even though they may not be required equipment. Falls from bicycles are the cause of a significant number of head injuries in school-age children, and the most important aspect of bicycle safety is to encourage children to wear protective helmets (Fig. 34-9) (Okun and Adam, 2008). Family-Centered Care boxes provide guidelines for bicycle, skateboard, and in-line skate safety and guidance during the school years.

Physically active school-age children are also highly susceptible to cuts and abrasions, and the incidence of childhood fractures, strains, and sprains is high. Trampoline injuries are highest in children ages 5 through 14 years and account for numerous fractures, sprains, and head injuries. Trampolines in the home environment, routine physical education classes, or outdoor playgrounds are not recommended for children of any age (Eberl, Schalamon, Singer, et al., 2009).

SCHOOL-AGE DISORDERS WITH BEHAVIORAL COMPONENTS

Attention Deficit Hyperactivity Disorder and Learning Disability

Attention deficit hyperactivity disorder (ADHD) refers to developmentally inappropriate degrees of inattention, impulsiveness, and

FAMILY-CENTERED CARE

Bicycle Safety

- Always wear a properly fitted bicycle helmet that is approved by the U.S. Consumer Product Safety Commission (CPSC); encourage parents to look for the CPSC approval sticker on the inside liner of the helmet.
- Replace a helmet every 5 years or sooner if manufacturer recommends it. **Never use a damaged or outgrown helmet.**
- Ride bicycles with traffic and away from parked cars.
- Ride single file.
- Walk bicycles through busy intersections only at crosswalks.
- Give hand signals well in advance of turning or stopping.
- Keep as close to the curb as practical.
- Watch for drain grates, potholes, soft shoulders, loose dirt, and gravel.
- Keep both hands on handlebars except with signaling.
- Never ride double on a bicycle.
- Do not carry packages that interfere with vision or control; do not drag objects behind a bike.
- Watch for and yield to pedestrians.
- Watch for cars backing up or pulling out of driveways; be especially careful at intersections.
- Look left, right, and then left before turning into traffic or roadway.
- Never hitch a ride on a truck or other vehicle.
- Learn rules of the road and respect for traffic officers.
- Obey all local ordinances.
- Wear shoes that fit securely while riding.
- Wear light colors at night and attach fluorescent material to clothing and bicycle.
- Equip the bicycle with proper lights and reflectors.
- Be certain the bicycle is the correct size for rider (see Fig. 34-9).
- Have the bicycle inspected to ensure good mechanical condition.
- Children riding as passengers must wear appropriate-size helmets and sit in specially designed protective seats.

Adapted from American Academy of Pediatrics Committee on Injury and Poison Prevention: Bicycle helmets, *Pediatrics* 122(2):450, 2008.

FAMILY-CENTERED CARE

Skateboard, In-Line Skate, and Scooter Safety

- Children younger than 5 years should not use skateboards or in-line skates because they are not developmentally prepared to protect themselves from injury. Children ages 6 to 10 years should use these only with close adult supervision.
- Children younger than 8 years should ride scooters only with close adult supervision.
- Children who ride skateboards, in-line skates, or scooters should wear helmets and other protective equipment, especially on their knees, wrists, and elbows, to prevent injury.
- Skateboards, in-line skates, and scooters should never be used near traffic or in streets. Their use should be prohibited at night. Activities that bring skateboards together (e.g., "catching a ride") are especially dangerous.
- Some types of use, such as riding homemade ramps on hard surfaces, may be particularly hazardous.

Data from Brudvik C: Injuries caused by small wheel devices, *Prev Sci* 7:313-320, 2006.

FAMILY-CENTERED CARE

Guidance During School Years

Age 6 Years

- Prepare parents to expect strong food preferences and frequent refusal of specific food items.
- Prepare parents to expect an increasingly ravenous appetite.
- Prepare parents for emotionality as child experiences erratic mood changes.
- Help parents anticipate continued susceptibility to illness.
- Teach injury prevention and safety, especially bicycle safety.
- Encourage parents to respect child's need for privacy and to provide a separate bedroom for child, if possible.
- Prepare parents for child's increasing interests outside the home.
- Help parents understand the need to encourage child's interactions with peers.

Ages 7 to 10 Years

- Prepare parents to expect improvement in health with fewer illnesses, but warn them that allergies may increase or become apparent.
- Prepare parents to expect an increase in minor injuries.
- Emphasize caution in selecting and maintaining sports equipment, and reemphasize safety.
- Prepare parents to expect increased involvement with peers and interest in activities outside the home.
- Emphasize the need to encourage independence while maintaining limit setting and discipline.
- Prepare mothers to expect more demands at 8 years.
- Prepare fathers to expect increasing admiration at 10 years; encourage father-child activities.
- Prepare parents for prepubescent changes in girls.

Ages 11 to 12 Years

- Help parents prepare child for body changes of pubescence.
- Prepare parents to expect a growth spurt in girls.
- Make certain child's sex education is adequate with accurate information.
- Prepare parents to expect energetic but stormy behavior at 11 years, becoming more even-tempered at 12 years.
- Encourage parents to support child's desire to "grow up" but to allow regressive behavior when needed.
- Prepare parents to expect an increase in child's masturbation.
- Instruct parents that the amount of rest the child needs may increase.
- Help parents educate child regarding experimentation with potentially harmful activities.

Health Guidance

- Help parents understand the importance of regular health and dental care for the child.
- Encourage parents to teach and model sound health practices, including diet, rest, activity, and exercise.
- Stress the need to encourage children to engage in appropriate physical activities.
- Emphasize providing a safe physical and emotional environment.
- Encourage parents to teach and model safety practices.

hyperactivity. To be diagnosed as ADHD, the symptoms must have been present between 4 and 18 years of age and must be present in more than one major setting (AAP, Clinical Practice Guideline, 2011). In addition, the persistence of developmentally inappropriate and marked inattention must not be a symptom of another disorder (American Psychiatric Association [APA], 2000). A **learning disability (LD)** refers to a heterogeneous group of disorders manifested by significant difficulties in the acquisition and use of listening, speaking, reading, writing, reasoning, or mathematic skills.

BOX 34-1 CHARACTERISTICS OF ATTENTION DEFICIT HYPERACTIVITY DISORDER

Inattention

Appears careless in schoolwork and activities at home, easily distracted by external stimuli, forgetful in daily activities, avoids or dislikes engaging in tasks that require sustained mental effort

Hyperactivity

Fidgety, squirms in seat, restless, has difficulty in playing quietly or engaging in quiet-time games or activities, talks excessively

Impulsivity

Has poor impulse control, has difficulty waiting for turn or waiting in line, interrupts others' conversations

Modified from American Psychiatric Association: *Diagnostic and statistical manual of mental disorders,* ed 4, text rev (DSM-IV TR), Washington, DC, 2000, Author.

Learning disabilities and ADHD affect every aspect of a child's life but are most obvious in the classroom. Early identification of affected children is important because the characteristics of these disorders significantly interfere with the normal course of emotional and psychologic development. Many children develop maladaptive behavior patterns that impede psychosocial adjustment while they try to cope with cognitive dysfunction. Their behavior evokes negative responses from others, and repeated exposure to negative feedback adversely affects their self-concept. The characteristics of ADHD affect the child's written and adaptive skills, social status, and self-esteem (Cunningham and Jensen, 2011; Myers, Eisenhauer, and Ryan, 2003).

Diagnostic Evaluation

The behaviors exhibited by children with ADHD are not unusual. The difference lies in the quality of motor activity and the developmentally inappropriate inattention, impulsivity, and hyperactivity displayed by children with ADHD. The manifestations may be numerous or few and mild or severe, and they vary with the child's developmental level. Any given child will not have every manifestation characteristic of the syndrome, and the degree of severity is highly variable. Mild manifestations of symptoms may not be apparent in some educational and family environments, but severe symptoms will be recognizable in most environments. Every child with ADHD is different from all other children with ADHD. The clinical manifestations of ADHD are outlined in Box 34-1.

Most behavioral manifestations of ADHD are apparent at an early age, but the LDs may not become evident until the child enters school. The disorder is unpredictable; it may remit spontaneously at any age, and the number of years that a child will require treatment is unknown.

A major clinical manifestation is distractibility. The stimuli may come from external sources or internal sources. Children often demonstrate immaturity relative to chronologic age. Selective attention is often seen, in which the child has difficulty attending to "nonpreferred" tasks such as completing chores or finishing homework. The child may not consider the consequences of behavior, may take excessive physical risks (often beginning early in life), and may demonstrate inappropriate social skills.

Children with ADHD demonstrate one of three subtypes (APA, 2000):

1. Combined type—Six (or more) symptoms of inattention and six (or more) symptoms of hyperactivity-impulsivity that persist for at least 6 months. Most children and adolescents with ADHD have the combined type.
2. Predominantly inattentive type—Six (or more) symptoms of inattention (but fewer than six symptoms of hyperactivity-impulsivity) that persist for at least 6 months.
3. Predominantly hyperactive-impulsive type—Six (or more) symptoms of hyperactivity-impulsivity (but fewer than six symptoms of inattention) that persist for at least 6 months. Inattention may often still be a significant clinical feature in such cases.

A diagnosis of ADHD is established based on characteristics in the APA's (2000) *Diagnostic and Statistical Manual of Mental Disorders* (*DSM-IV-TR*) and a thorough evaluation of the child. It is important to emphasize the need for a complete and thorough multidisciplinary evaluation that incorporates the efforts of the pediatrician (often a developmental pediatrician or pediatric neurologist), psychologist, pediatric nurse, classroom teacher, reading and math specialist, special education teacher, possibly a speech therapist, and the child's parents. The clinicians and professionals must first determine whether the child's behavior is age appropriate or truly problematic.

A history (both medical and developmental) and a description of the child's behavior should be obtained from as many observers of the child as possible (especially the parents and teachers), along with the health care professionals involved. Descriptions of the child's behavior in home and school situations should be included. In obtaining descriptive material, the interviewer must question the observers carefully because some persons, especially parents, may be so concerned with gross behaviors that they overlook less distressing but equally important symptoms. For example, parents may report a "colicky" infant, a child who began to run soon after walking, a toddler who was compelled to touch everything in sight, and a child who resisted sleep until exhausted. A pregnancy and birth history may provide clues to a situation that might have produced an episode of hypoxia.

A physical examination, including vision and hearing screening and a detailed neurologic evaluation, will help rule out any severe neurologic disorders. Psychologic testing, especially projective tests, is valuable in identifying visual-perceptual difficulties, problems with spatial organization, and other phenomena that suggest cortical or diencephalic involvement; it also helps to identify the child's intelligence and achievement levels.

Behavioral checklists and adaptive scales are also helpful in measuring social adaptive functioning in children with ADHD. Psychiatric disorders, medical problems, and traumatic experiences are ruled out, including lead poisoning, seizures, partial hearing loss, psychosis, and the witnessing of sexual activity or violence.

Therapeutic Management

Management of the child with ADHD usually involves multiple approaches that include family education and counseling, medication, proper classroom placement, environmental manipulation, and behavioral therapy or psychotherapy. Interventions for children with LD are primarily educational.

Pharmacologic Therapy. The most commonly used medications for AHDH are the psychostimulants methylphenidate hydrochloride (Ritalin) and dextroamphetamine sulfate (Dexedrine). The majority of patients with ADHD are treated with the psychostimulant methylphenidate (AAP, Clinical Practice Guideline, 2011). Psychostimulants cause an increase in dopamine and norepinephrine levels, which leads to stimulation of the inhibitory system of the central nervous system (CNS). Children are given a small dosage initially, and the dosage is gradually increased until the desired response is achieved. Children who receive stimulants should be monitored carefully for the development of tics during initial treatment, and stimulants should be avoided in children who have a history of ticlike behaviors, a family history of Tourette syndrome (TS), or ADHD combined with TS.

The stimulant dextroamphetamine may be used in children younger than 6 years of age to treat ADHD, but evidence of its safety and efficacy in young children and adolescents has been questioned. Lisdexamfetamine (Vyvanse) reportedly has less substance abuse potential that dextroamphetamine; it is metabolized to dextroamphetamine only after ingestion and thus may be more suitable for children and adolescents who may abuse dextroamphetamine (AAP, Clinical Practice Guideline, 2011). Other medications include the mixed amphetamine salts (Adderall), which are available in extended release form. In some cases a nonstimulant may be added to the medication regimen along with a stimulant to achieve optimal therapeutic effects. Many of the stimulant drugs are available in short-acting and long-acting form to better meet the child's need for therapeutic management. An additional consideration in the administration of medications is the child's ability to swallow pills; some come in capsule form and can be sprinkled on applesauce (Ryan-Krause, 2011).

Other nonstimulant medications recommended by the AAP Clinical Practice Guideline (2011) include the selective norepinephrine reuptake inhibitor atomoxetine (Strattera), and the selective alpha adrenergic agonists guanfacine (Tenex, Intuniv) and clonidine. Guanfacine and clonidine are available in extended-release form but are reported to have limited evidence of efficacy and safety in preschool children with ADHD (AAP, Clinical Practice Guideline, 2011).

It is important to remember that, except for atomoxetine, these medications are not prescribed based on the child's weight but rather on resolution of the symptoms; therefore it is important to follow the child closely and evaluate for therapeutic effects and potential side effects. With all of these medications, regularly scheduled reevaluation of the child is essential to determine medication effectiveness, detect and evaluate any side effects, monitor development and health status (especially growth and blood pressure), and assess family interaction (see Critical Thinking Case Study). Children taking stimulant drugs for ADHD should undergo an extensive physical examination and history, including a family history of cardiac disease or cardiac problems. Currently, electrocardiography screening is recommended only for children taking stimulant drugs for ADHD who have a close member with a history of cardiac arrhythmia or structural heart defect (Perrin, Friedman, Knilans, et al., 2008). Medication therapy alone is not adequate to manage the child's symptoms, and other treatment modalities such as behavioral therapy should also be used for successful treatment.

Behavioral Therapy. Behavioral therapy focuses on the prevention of undesired behavior. The nurse should help families identify new appropriate contingencies and reward systems to meet the child's developing needs. They may also receive instruction in effective parenting skills, such as delivering positive reinforcement, rewarding small increments of desired behaviors, and providing age-appropriate consequences (e.g., time-out, response cost). The use of organizational charts for completing self-care activities and the use of a word processor instead of manually writing assignments

CRITICAL THINKING CASE STUDY

Attention Deficit Hyperactivity Disorder

Johnnie, age 8 years, is a third grader who was recently diagnosed with ADHD. He has been taking methylphenidate (Ritalin) for about 1 month. In the short time that Johnnie has been taking this medication, his math teacher has noticed an improvement in his performance in math class. He is receiving a grade of B instead of his previous grades of D on most math quizzes. The math teacher has also noted that Johnnie is socializing more with his classmates and now has a "best friend" in math class. Johnnie usually receives his methylphenidate from the school nurse before lunch. Yesterday Johnnie's mother told the school nurse that he has not eaten his lunch for the past week and is not hungry.

What important issues regarding Johnnie's medication should the nurse consider in her discussions with Johnnie's mother?

Questions

1. Evidence—Is there sufficient evidence to draw conclusions about Johnnie's medication from his behavior?
2. Assumptions—Describe some underlying assumptions about the following:
   a. Pharmacologic action of methylphenidate in ADHD
   b. Side effects of methylphenidate
   c. Management of side effects

ADHD, Attention deficit hyperactivity disorder.

are emphasized. Through collaborative teamwork, parents learn techniques to help the child become more successful at home and in school.

Counseling or therapy can be helpful for children who demonstrate signs of anxiety or depression. Therapy can help children develop healthier self-esteem and practice problem-solving strategies. Adolescents may benefit from group work that focuses on social skill development. Parents of children with ADHD can face a lot of stress, and therapy may be indicated for parents and other family members.

Multimodal Treatment. The results of several studies suggest that multimodal treatment that involves the use of pharmacotherapy and behavioral intervention as well as close follow-up and feedback from school personnel is more effective than intensive behavioral treatment alone (Selekman, 2010).

Environmental Manipulation. Encourage families to learn how to modify the environment to allow the child to be more successful. Consistency is especially important for children with ADHD. Consistency between families and teachers in terms of reinforcing the same goals is essential. Fostering improved organizational skills requires a more highly structured environment than most children need. Children should be encouraged to make more appropriate choices and to take responsibility for their actions.

Other helpful interventions include teaching parents how to make organizational charts (e.g., listing all activities that must be performed before leaving for school) and how to decrease distractions in the environment while the child is completing homework (e.g., turning off the television, having a consistent study area equipped with needed supplies), as well as helping parents understand ways to model positive behaviors and problem solving. The focus is on strategies to help the child succeed and cope with deficits while emphasizing strengths.

Appropriate Classroom Placement. Children with ADHD need an orderly, predictable, and consistent classroom environment with clear and consistent rules. Homework and classroom assignments may need to be reduced, and more time may need to be allotted for tests to allow the child to complete the task. Verbal instructions should be accompanied by visual references such as written instructions on the blackboard. Schedules may need to be arranged so that academic subjects are taught in the morning when the child is experiencing the effects of the morning dose of medication. Low-interest and high-interest classroom activities should be intermingled to maintain the child's attention and interest. Regular and frequent breaks in activity are helpful because sitting in one place for an extended time may be difficult. Computers are helpful for children who have difficulty with writing **(dysgraphia)** and fine motor skills; in such children, handwriting will *not* improve. They need to find alternatives to physical competition that requires coordination of movement.

If the child has an LD, special training activities may be accomplished in self-contained classes limited to six to eight children, in special resource rooms with equipment and teaching teams, by mobile consultants who move from room to room to provide assistance to teachers and children, and in special first-grade programs in which high-risk children receive special attention to prevent or reduce the need for services as they progress. The purpose of programs for children with LDs is to assist them toward more successful achievement, personal adjustment, and retention in the regular classroom. Selekman (2010) lists additional behavioral, educational, and environmental strategies for children and adolescents with ADHD.

Growth and Development. Children with ADHD who are taking stimulant medications need to be assessed for the achievement of appropriate growth and development milestones at least every 6 months (Pliszka and AACAP Work Group on Quality Issues, 2007; Selekman, 2010). The side effects of these drugs often include appetite suppression, nausea, and vomiting; suppression of growth acceleration and sleep disturbances have also been recorded in children taking stimulant drugs (Selekman, 2010).

Prognosis. With appropriate intervention, ADHD is relatively stable through early adolescence for most children. Some children experience decreased symptoms during late adolescence and adulthood, but a significant number of these children carry their symptoms into adulthood. The goal for children with LDs is to help them identify their areas of weakness and learn to compensate for them.

CARE MANAGEMENT

Nurses, especially school nurses, are active participants in all aspects of the management of children with ADHD and LDs. Nurses in the community work with families and school personnel on a long-term basis to help plan and implement therapeutic regimens and to evaluate the effectiveness of therapy. They coordinate services and serve as a liaison between health and education professionals directly involved in the child's therapy program. School nurses understand the child's special needs and work with teachers (see Family-Centered Care box). Nurses in any setting (community, school, hospital, practitioner's office) provide support and guidance to children and families during the difficult period of the child's growing up with a disabling condition.

Management begins with an explanation to the parents and the child about the diagnosis, including the nature of the problem and the practitioner's concept of the underlying CNS basis for the

FAMILY-CENTERED CARE

A Child's Perception of Taking Ritalin at School

I feel embarrassed by having to leave class early to go take my medication. The other kids always ask where I'm going and why. It would be better if we could leave class at the same time as everyone else, go take the medication, and then just be a little late to the next class. Students don't ask why people are late for class, only why they leave early. It also bothers me when kids tell other kids, "Go take a pill" and other mean things just because someone is acting up.

What could nurses and teachers do to help? Most kids do not understand why other kids have to take medication. I think it would help if a nurse or teacher talked with the other kids and explained why some children take the medication and how ADHD affects people. That way there would be more understanding among all the kids.

—Marissa White, age 16 years

ADHD, Attention deficit hyperactivity disorder.

disorder. Most parents are confused and feel some measure of guilt. To some parents, a diagnosis of ADHD is confirmation of the fear that their child has some irreversible, serious disease; to others, it is a relief. All parents need the opportunity to vent their feelings and suspicions. A common complaint of parents is that health care professionals do not listen to what they have to say about their children. The health care professional should focus on building self-esteem by encouraging the family to focus on developing the child's strengths (e.g., sports, hobbies, and talents) rather than just the weaknesses (Jellinek, 2008).

Parents need to be informed of the possible side effects of medications. The psychostimulants have similar side effects that include weight loss, abdominal pain, headaches, decreased appetite, sleeplessness, increased crying and irritability, nervous stimulation, and cardiovascular stimulation. The use of caffeine decreases the efficacy of these drugs, and insulin requirements may also be altered. If decreased appetite is a concern, helpful interventions include giving the psychostimulants with or after meals rather than before, encouraging consumption of nutritious snacks in the evening when the effects of the medication are decreasing, and serving frequent small meals with healthy "on-the-go" snacks. Sleeplessness is reduced by administering the medication early in the day.

Children and adolescents with ADHD are at increased risk for accidents and unintentional injuries because of their impulsivity and decreased judgment of dangerous activities. Therefore measures should be taken to protect such children from personal injury (Selekman, 2010).

Children taking tricyclic antidepressants display a dramatic increase in the incidence of dental caries. The marked anticholinergic action of the drugs increases saliva viscosity and produces a dry mouth. Emphasis on rigorous dental hygiene, conscientious home fluoride treatments, regular visits to the dentist, limited intake of refined carbohydrates, and use of artificial saliva is an important nursing function. The child should drink plenty of fluids and be well hydrated.

Parents often express concern that their children will become addicted to the psychostimulants or antidepressant drugs. Both types of drugs have the potential for abuse, and all children taking these drugs should be monitored closely for psychologic dependence, tolerance, depression, and other adverse behavior changes or idiosyncratic effects. Most children with ADHD are not interested in abusing their drugs because the effect of the drugs in these children is opposite that produced in normal individuals. However, caution parents to keep these drugs safely stored away from young children who may inadvertently ingest them and adolescents who may abuse them.

Parents need information about the prognosis and an understanding of the treatment plan. The greater their understanding of the disorder and its effects, the more likely they will be to carry out the recommended program of therapy. It is important that they understand that the therapy is not necessarily a panacea and that it will extend over a long period. This has particular significance for changes they need to make in environmental management. Reading material to help the child and family can be obtained from a variety of sources.

Posttraumatic Stress Disorder

Posttraumatic stress disorder (PTSD) refers to the development of characteristic symptoms after exposure to an extremely traumatic experience or catastrophic event. The traumatic experience is typically life threatening to oneself or a significant other and may involve grotesque mutilation or death, serious injury, or physical coercion (e.g., an assault, a natural disaster, sexual abuse, witnessing violence). It is important to note that PTSD is not limited to children who have lived in "war-torn" countries. Events such as automobile, school, or recreational accidents and bullying have also been identified as causes of PTSD. The characteristic symptoms are persistent re-experiencing of the traumatic event, avoidance of stimuli associated with the event or trauma, numbing of general responsiveness, and increased arousal.

Acute PTSD is diagnosed if symptoms are present after the first month but before the third month after the initial traumatic event. Acute stress disorder may also occur with acute PTSD. Chronic PTSD is diagnosed if the symptoms persist beyond 3 months (Cohen and AACAP Work Group on Quality Issues, 2010).

The response to the event takes place in three stages. The initial response involves intense arousal, which usually lasts for a few minutes to 1 or 2 hours. The stress hormones are at the maximum as the individual prepares for "fight or flight." A prolonged arousal phase may indicate psychosis.

The second phase, which lasts approximately 2 weeks, is one in which defense mechanisms are mobilized. It is a period of calm in which the event appears to have produced no impression. The child feels numb, and stress hormone secretion is absent. Defense mechanisms are less adaptive to specific situations and may not be what the situation demands. Denial that anything is wrong is a commonly observed defense mechanism.

The third phase is one of coping and consciously directed inquiry, which normally extends over 2 to 3 months. The victims want to know what happened and appear to be getting worse when actually they are getting better. Numerous psychologic symptoms such as depression, repetitive phenomena, phobic symptoms, anxiety, and conversion reactions may be present. Children often display repetitive actions. They play out the situation over and over again in an attempt to come to terms with their fear. Flashbacks are common. This phase can be self-perpetuating, and a prolonged reaction can develop into an obsession with the traumatic event. Some traumatic effects remain indefinitely.

Trauma-focused psychotherapy is considered first-line therapy, and selective serotonin reuptake inhibitor (SSRI) drugs may be considered on an individual basis. Rebirthing therapies or restrictive treatments that bind or withhold water or food are not recommended (Cohen and AACAP Work Group on Quality Issues, 2010).

A practice parameter for the assessment and management of PTSD in children and adolescents is published elsewhere (Cohen and AACAP Work Group on Quality Issues, 2010).

CARE MANAGEMENT

Children need to deal with all traumatic events. Their reactions depend heavily on their social environment and the way in which their caregiving adults react to the event. In the second phase of PTSD, the appropriateness of the defense mechanism must be assessed, and children must be assisted in the application of their defense. Children who do not engage in some catharsis or who have a prolonged defense phase need referral for special psychologic help.

Coping is a learned response, and children in the third phase of PTSD can be helped to deal with their fear. Children usually are willing to accept reasoning. Those who are assisted in their catharsis and are allowed expression will survive without serious lasting effects. They should be encouraged to play out the stress and to discuss their feelings about the event. If they are unable to do this, they may become obsessed with the traumatic event and require professional help. Conversion reactions are common obsessive behaviors in children with PTSD.

Children need professional help if any of the phases of PTSD are prolonged. Boys tend to have a prolonged defense phase more often than girls. Occasionally the event will be unrecognized, and the affected child will engage in what is considered to be unusual behavior. Children exhibiting any sudden change in behavior need to be assessed for a traumatic event. When the change in behavior is traced to a traumatic event, treatment can be implemented.

Nurses in settings such as the emergency department, pediatric intensive care unit, and neonatal intensive care unit should also recognize that parents of children who experience a traumatic acute trauma, life-threatening illness, or chronic illness may also experience symptoms of PTSD. PTSD may occur more often in mothers than in fathers, but some evidence indicates that fathers may have delayed symptoms (Mowery, 2011). Appropriate nursing interventions include allowing parents to discuss their feelings about the incident or threat (to themselves or their children), encouraging support from other parents in similar situations, avoiding interjecting one's own experience or feelings, and evaluating the child's reaction to the parents' symptoms (Mowery, 2011).

School Phobia

Children (other than beginning students) who resist going to school or who demonstrate extreme reluctance to attend school for a sustained period as a result of severe anxiety or fear of school-related experiences are said to have school phobia. The terms *school refusal and school avoidance* are also used to describe this behavior. School phobia occurs in children of all ages but is more common in children 10 years of age and older. School avoidance behaviors occur in both boys and girls and in children from all socioeconomic levels.

Anxiety that often verges on panic is a constant manifestation, and children can develop symptoms as a protective mechanism to keep them from facing the situation that distresses them. Physical symptoms are prominent and may affect any part of the body and include anorexia, nausea, vomiting, diarrhea, dizziness, headache, leg pains, and abdominal pains. Children may even develop a low-grade fever. A striking feature of school phobia is the prompt subsiding of symptoms when it is evident that the child can remain at home. Another significant observation is an absence of symptoms on weekends and holidays unless they are related to other places such as Sunday school or parties. Occasional mild reluctance to attend school is common among schoolchildren, but if the fear continues for longer than a few days, it must be considered a serious problem.

The onset of school phobia is usually sudden and precipitated by a school-related incident. By taking a careful history, nurses find out whether a poor attendance record is caused by trivial reasons.

CARE MANAGEMENT

Treatment for school phobia depends on the cause. The primary goal is to return the child to school. The longer a child is permitted to stay out of school, the more difficult it is for him or her to reenter. Parents must be convinced gently but firmly that an immediate return to school is essential and that it is their responsibility to insist on school attendance.

A school reentry protocol may be necessary for the child with severe symptoms. In reentry programs, the child role-plays routines that are involved in getting ready for school and occur at school. Relaxation techniques are also used. The child usually goes to school initially for a half day and then progresses to a full day. Often the school nurse is asked to provide support to the parents and the teacher during the reentry process. If the problem persists, professional help is recommended.

Bullying

Bullying is a form of aggression in which a person asserts power over another who is considered weaker through social, emotional, and physical means. The consequences of bullying include depression, long-term psychopathology, suicidality, psychosomatic symptoms, and psychoses. Bullying involves aggression in which the behavior is intended to harm or embarrass the victim; it occurs repeatedly over time, and there is an imbalance of power, with the bully exerting dominance over the victim (Liu and Graves, 2011). The behavior may be carried out by one person or several people who isolate the victim for purposes of harming and embarrassing through an imbalance of power. Bullying may be perceived by some as a normal social developmental step in childhood, and in some cases the bully may perceive the behavior as being fun rather than harmful. Some may view bullying with a "boys will be boys" attitude and ignore the behavior. Research has shown that bullying occurs more often in boys, but girls may also be involved in what is called *relational bullying*—a more subtle and indirect form of bullying. Bullying is more common in middle school than in high school (Liu and Graves, 2011).

Because most bullying occurs in and around the school, there has been more emphasis on recognizing and dealing with the behaviors in schools.* Interventions should include recognizing the behavior in both the bully and the victim, protecting the victim, and stopping the behavior altogether. To be effective, behavioral changes from the bully and social changes in the school environment with the assistance of parents and adults in the school should occur. The school nurse and community nurse are likely to come in contact with victims and bullies alike; the practitioner may also be involved in caring for the physical and emotional health of the victim. School and community-lead programs to heighten awareness of the consequences of bullying are reported to have been ineffective in stopping bullying; however, further studies are needed (Liu and Graves, 2011).

*Resources on bullying include the following: www.eyesonbullying.org; and stopbullyingnow.hrsa.gov/kids/.

Conversion Reaction

A conversion reaction (also known as hysteria, hysterical conversion reaction, and childhood hysteria) is a sudden-onset psychophysiologic disorder that can usually be traced to a precipitating environmental event. The disorder is observed with equal frequency in both sexes in childhood, but affected girls outnumber affected boys during adolescence. Manifestations of conversion reaction involve primarily the voluntary musculature and special senses and include abdominal pain, fainting, pseudoseizures, paralysis, headaches, and visual field restriction. Once considered rare in childhood, this disorder occurs more frequently than has generally been acknowledged. The most commonly observed symptom is seizure activity that can be differentiated from symptoms of neurogenic origin by formal tests, the most useful of which are normal electroencephalogram findings.

Many children with conversion reaction experienced a major family crisis before the onset of symptoms, such as the loss of a parent or other significant person through death, divorce, or moving. Children with conversion reaction characteristically come from families with communication problems or have a parent with depression or hypochondriasis.

Educating the child and family about the cause of emotional stresses or feelings and alternative approaches to coping with stress may alleviate the child's symptoms. If deep personality problems are evident, psychiatric consultation is indicated. Nursing care is similar to that for the child with recurrent abdominal pain.

Childhood Depression

Depression in childhood is often difficult to detect because children may be unable to express their feelings and tend to act out their problems and concerns. Some states of depression are temporary, such as acute depression precipitated by a traumatic event. The event might include a period of hospitalization, the loss of a parent through death or separation, or the loss of a significant relationship with something (a pet), a person (a friend, significant other, or family member), or a place (move from a familiar home, neighborhood, or city). Children with depression may demonstrate a variety of behaviors. Most responses in children are not sustained and can be modified with social and family support.

More serious and less common are the depressive responses to more chronic stress and loss. These are often observed in children with chronic illness or disability. There is no apparent precipitating event, but there is often a history of frequent disruptions in important relationships. A history of depressive illness in one or both parents during the child's lifetime is also common. Manifestations in the child are similar to those observed in acute reactions, but they occur more frequently and extend over a longer period.

CARE MANAGEMENT

Depressed children are managed by a health care team that is specially trained in the care of children with mental disorders. Treatment is highly individualized and undertaken in the least restrictive environment. Suicidal children are admitted to the hospital for protection if the family is unable to provide constant monitoring. Pharmacotherapy may involve TCAs or SSRIs such as fluoxetine, trazodone (Desyrel), sertraline, and paroxetine (Paxil), as well as bupropion (Wellbutrin) and venlafaxine (Effexor). There have been reports that antidepressant medications may cause increased suicidal thinking and behaviors in pediatric patients. This prompted the U.S. Food and Drug Administration (FDA) to require black box drug labeling detailing the potential suicide-related risks for pediatric patient. This warning was updated, and it was noted that the risk of suicide was highest among adolescents and young adults ages 18 to 24 years. Some data suggest that the suicide rate among adolescents taking therapeutic doses of SSRIs was lower than among those who were not being treated with antidepressant medication (Gibbons, Hur, Bhaumik, et al., 2006). However, the issue remains controversial because study results are mixed, and further studies are needed (Walter and DeMaso, 2011). Patients taking SSRIs should be followed closely (once a week) for the first 4 weeks of therapy before a dose increase is made. After 4 weeks it is recommended that follow-up occur biweekly and that children and adolescents with a risk for suicidality be referred for specialized treatment (Walter and DeMaso, 2011).

Nurses should be aware that depression is a problem that can be easily overlooked in children and can interrupt normal growth and development. Recognizing depression and suicidal tendencies in depressed adolescents and making appropriate referrals are important nursing functions. Identification of a depressed child requires a careful history (health, growth and development, social and family health), interviews with the child, and observations by the nurse, parents, and teachers. If antidepressants are prescribed, the child and family need to know that antidepressants must be at a therapeutic level for 2 to 4 weeks to achieve a beneficial effect. The child and family also need to monitor the child for side effects of the specific drug prescribed and any interactions with other drugs.

Childhood Schizophrenia

Childhood schizophrenia is a term that refers to severe deviations in ego functioning and is generally reserved for psychotic disorders that appear in children younger than 15 years of age. Childhood schizophrenia is a rare illness among children in the general population; among children with mental illness, only about 2 in every 1000 have childhood schizophrenia.

Childhood schizophrenia is characterized by symptoms that last for at least 6 months and seriously interfere with the child's functioning in school, at home, or in other social situations. The basic disturbance is a lack of contact with reality and the subsequent development of a world of the child's own. Other areas of development that may be impaired include cognition, perception, emotion, language, and physical motor control. The most common manifestations involve language disturbances, impaired interpersonal relationships, and inappropriate affect (outward expression of emotion). Treatment involves management of the symptoms, prevention of relapse, and social and occupational rehabilitation. Antipsychotic drugs that may be used include haloperidol, clozapine, chlorpromazine, olanzapine, quetiapine fumarate, and risperidone. Family interventions and family therapy often result in improvements in psychotic symptoms, thought disorders, and social functioning among children with schizophrenia.

CARE MANAGEMENT

Nursing care of children with psychotic disorders is a highly specialized area. Nurses should be alert to the possibility that schizophrenia can occur in children and refer children to a psychiatrist for evaluation if they consistently demonstrate abnormal behavior. In addition, nurses need to teach family members of children taking antipsychotic medications to observe for possible side effects. Common side effects include dizziness, drowsiness, tachycardia, hypotension, and extrapyramidal effects such as abnormal movements and seizures.

KEY POINTS

- Middle childhood, also known as the *school years,* is the period of life that extends from 6 to 12 years of age.
- Although growth is slower in middle childhood than in previous years, there is a steady gain in height and weight, with maturation of body systems; primary teeth are lost and replaced by permanent teeth.
- A major task during the middle school years is developing a sense of industry or accomplishment (Erikson).
- Piaget's period of concrete operations refers to the school-age period when children are able to use their thought processes to experience events and actions and make judgments based on reasoning.
- The child develops a conscience and is able to understand and adhere to rules and standards set by others.
- Entertaining different points of view, becoming sensitive to social norms, and forming peer friendships are important features of social development during the school years.
- Cooperative play, team activities, and the acquisition of skills are prime elements of play during the school years; rules and rituals assume greater importance.
- Parental concerns during middle childhood include lying, cheating, stealing, and school achievement.
- The availability of junk foods, irregular family meals, and schedules of working parents often interfere with optimal nutrition.
- Dental care is important during this time; potential dental problems include caries, periodontal disease, malocclusion, and dental injury.
- Increased socialization and media exposure make the school years an ideal time for sex education.
- School health programs ideally include health appraisal, emergency care, safety education, communicable disease control, counseling, guidance, and health education with adjustment to individual student needs.
- Injury prevention is directed toward safety education, provision of safe play areas and equipment, and well-supervised sports activities.

CHAPTER

35

The Adolescent and Family

David Wilson

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe the physical changes that occur at puberty.
- Discuss the reactions of the adolescent to physical changes that take place at puberty.
- Demonstrate an understanding of the processes by which the adolescent develops a sense of identity.
- Discuss the significance of the changing interpersonal relationships and the role of the peer group during adolescence.
- Outline a health teaching plan for adolescents.
- Identify the causes and discuss the preventive aspects of injuries during adolescence.
- Demonstrate an understanding of common disorders of the male and female reproductive systems.
- Demonstrate an understanding of health problems related to adolescent sexuality.
- Outline a care plan for the child or adolescent with an eating disorder.
- Discuss the manifestations and nursing management of selected emotional and/or behavioral problems.

PROMOTING OPTIMAL GROWTH AND DEVELOPMENT

Adolescence is a period of transition between childhood and adulthood—a time of rapid physical, cognitive, social, and emotional maturing as the boy prepares for manhood and the girl prepares for womanhood. The precise boundaries of adolescence are difficult to define, but this period is customarily viewed as beginning with the gradual appearance of secondary sex characteristics at about 11 or 12 years of age and ending with cessation of body growth at 18 to 20 years.

Several terms are used to refer to this stage of growth and development. *Puberty* refers to the maturational, hormonal, and growth process that occurs when the reproductive organs begin to function and the secondary sex characteristics develop. This process is sometimes divided into three stages: *prepubescence,* the period of about 2 years immediately before puberty when the child is developing preliminary physical changes that herald sexual maturity; *puberty,* the point at which sexual maturity is achieved, marked by the first menstrual flow in girls but by less obvious indications in boys; and *postpubescence,* a 1- to 2-year period following puberty during which skeletal growth is completed and reproductive functions become fairly well established. *Adolescence,* which literally means "to grow into maturity," is generally regarded as the psychologic, social, and maturational process initiated by the pubertal changes. It involves three distinct subphases: *early adolescence* (ages 11 to 14), *middle adolescence* (ages 15 to 17), and *late adolescence* (ages 18 to 20). The term *teenage years* is used synonymously with *adolescence* to describe ages 13 through 19.

Biologic Development

The physical changes of puberty are primarily the result of hormonal activity under the influence of the central nervous system, although all aspects of physiologic functioning are mutually interacting. The obvious physical changes are noted in increased physical growth and in the appearance and development of secondary sex characteristics; less obvious are physiologic alterations and neurogonadal maturity, accompanied by the ability to procreate. Physical distinction between the sexes is made on the basis of distinguishing characteristics. Primary sex characteristics are the external and internal organs that carry out the reproductive functions (e.g., ovaries, uterus, breasts, penis). *Secondary sex characteristics* are the changes that occur throughout the body as a result of hormonal changes (e.g., voice alterations, development of facial and pubertal hair, fat deposits) but that play no direct part in reproduction.

Hormonal Changes of Puberty

The events of puberty are caused by hormonal influences and controlled by the anterior pituitary (adenohypophysis) in response to a stimulus from the hypothalamus. Stimulation of the gonads has a dual function: (1) production and release of gametes—production of sperm in the male and maturation and release of ova in the female; and (2) secretion of sex-appropriate hormones—estrogen and progesterone from the ovaries (female) and testosterone from the testes (male).

The ovaries, testes, and adrenals secrete sex hormones. These hormones are produced in varying amounts by both sexes throughout the life span. The adrenal cortex is responsible for the small amounts secreted before the pubescent years, but the sex hormone production that accompanies maturation of the gonads is responsible for the biologic changes observed during puberty.

Estrogen, the feminizing hormone, is found in low quantities during childhood. This hormone is secreted in slowly increasing amounts until about age 11 years. In males, this gradual increase continues through maturation. In females, the onset of estrogen production in the ovary causes a pronounced increase that continues until about 3 years after the onset of menstruation, at which time it reaches a maximum level that continues throughout the reproductive life of the female.

Androgens, the masculinizing hormones, are also secreted in small and gradually increasing amounts up to about 7 to 9 years of age, at which time there is a more rapid increase in both sexes, especially boys, until about age 15 years. These hormones appear to be responsible for most of the rapid growth changes of early adolescence. With the onset of testicular function, the level of androgens (principally *testosterone*) in males increases over that in females and continues to increase until a maximum level is attained at maturity.

Sexual Maturation

The visible evidence of sexual maturation is achieved in an orderly sequence, and the state of maturity can be estimated on the basis of the appearance of these external manifestations. The age at which these changes are observed and the time required to progress from one stage to another may vary among children. The time from the appearance of breast buds to full maturity may be 1½ to 6 years for adolescent girls. It may take 2 to 5 years for male genitalia to reach adult size. The stages of development of secondary sex characteristics and genital development have been defined as a guide for estimating sexual maturity and are referred to as the *Tanner stages* (Box 35-1). The usual sequence of appearance of maturational changes is presented in Box 35-2.

Sexual Maturation in Girls. In most girls, the initial indication of puberty is the appearance of breast buds, an event known as *thelarche,* which occurs between 8 and 13 years of age (Fig. 35-1). This is followed in approximately 2 to 6 months by growth of pubic hair on the mons pubis, known as *adrenarche* (Fig. 35-2). In a minority of normally developing girls, however, pubic hair may precede breast development. The average age of thelarche for Caucasian girls is 10 years, with a range of 8 to 12¾ years; for African-American girls, the average age of thelarche is earlier, around 9 years, with a range of 7 to 11 years (Herman-Giddens, 2006). The average age of thelarche for Hispanic girls falls somewhere between the other two groups.

The initial appearance of menstruation, or menarche, occurs about 2 years after the appearance of the first pubescent changes, approximately 9 months after attainment of peak height velocity, and 3 months after attainment of peak weight velocity. There is evidence that girls are developing secondary sex characteristics at a younger age with differences noted between Caucasian and African-American girls. The explanation for this is not yet clear but appears to be influenced by being overweight as well as environmental influences. The normal age range of menarche is usually 10½ to 15 years, with the average age being 12 years, 4 months for North American girls (Wu, Mendola, and Buck, 2002). Ovulation and regular menstrual periods usually occur 6 to 14 months after menarche. Girls may be considered to have pubertal delay if breast development has not occurred by age 13 years or if menarche has not occurred within 4 years of the onset of breast development.

Sexual Maturation in Boys. The first pubescent changes in boys are testicular enlargement accompanied by thinning, reddening, and increased looseness of the scrotum (Fig. 35-3). These events usually occur between 9½ and 14 years of age. Early puberty is also characterized by the initial appearance of pubic hair. Penile enlargement begins, and testicular enlargement and pubic hair growth continue throughout midpuberty. During this period, there is also increasing muscularity, early voice changes, and development of early facial hair. Temporary breast enlargement and tenderness, *gynecomastia,* are common during midpuberty, occurring in up to one third of boys. The spurts in height and weight occur concurrently toward the end of midpuberty. For most boys, breast enlargement disappears within 2 years. By late puberty, there is a definite

BOX 35-1 TANNER STAGES

The Tanner stages were developed by Dr. J.M. Tanner and colleagues. Tanner stages describe the stages of pubertal growth and are numbered from stage 1 (immature) to stage 5 (mature) for both males and females. In girls and young women, the Tanner stages describe pubertal development based on breast size and the shape and distribution of pubic hair. In boys and young men, the Tanner stages describe pubertal development based on the size and shape of the penis and scrotum and the shape and distribution of pubic hair.

Data from Tanner JM: *Growth of adolescents,* Oxford, 1962, Blackwell Scientific Publications.

BOX 35-2 USUAL SEQUENCE OF MATURATIONAL CHANGES

Girls

- Breast changes
- Rapid increase in height and weight
- Growth of pubic hair
- Appearance of axillary hair
- Menstruation (usually begins 2 years after first signs noted above)
- Abrupt deceleration of linear growth

Boys

- Enlargement of testicles
- Growth of pubic hair, axillary hair, hair on upper lip, hair on face and elsewhere on body (facial hair usually appears about 2 years after appearance of pubic hair)
- Rapid increase in height
- Changes in the larynx and consequently the voice (usually take place along with growth of penis)
- Nocturnal emissions
- Abrupt deceleration of linear growth

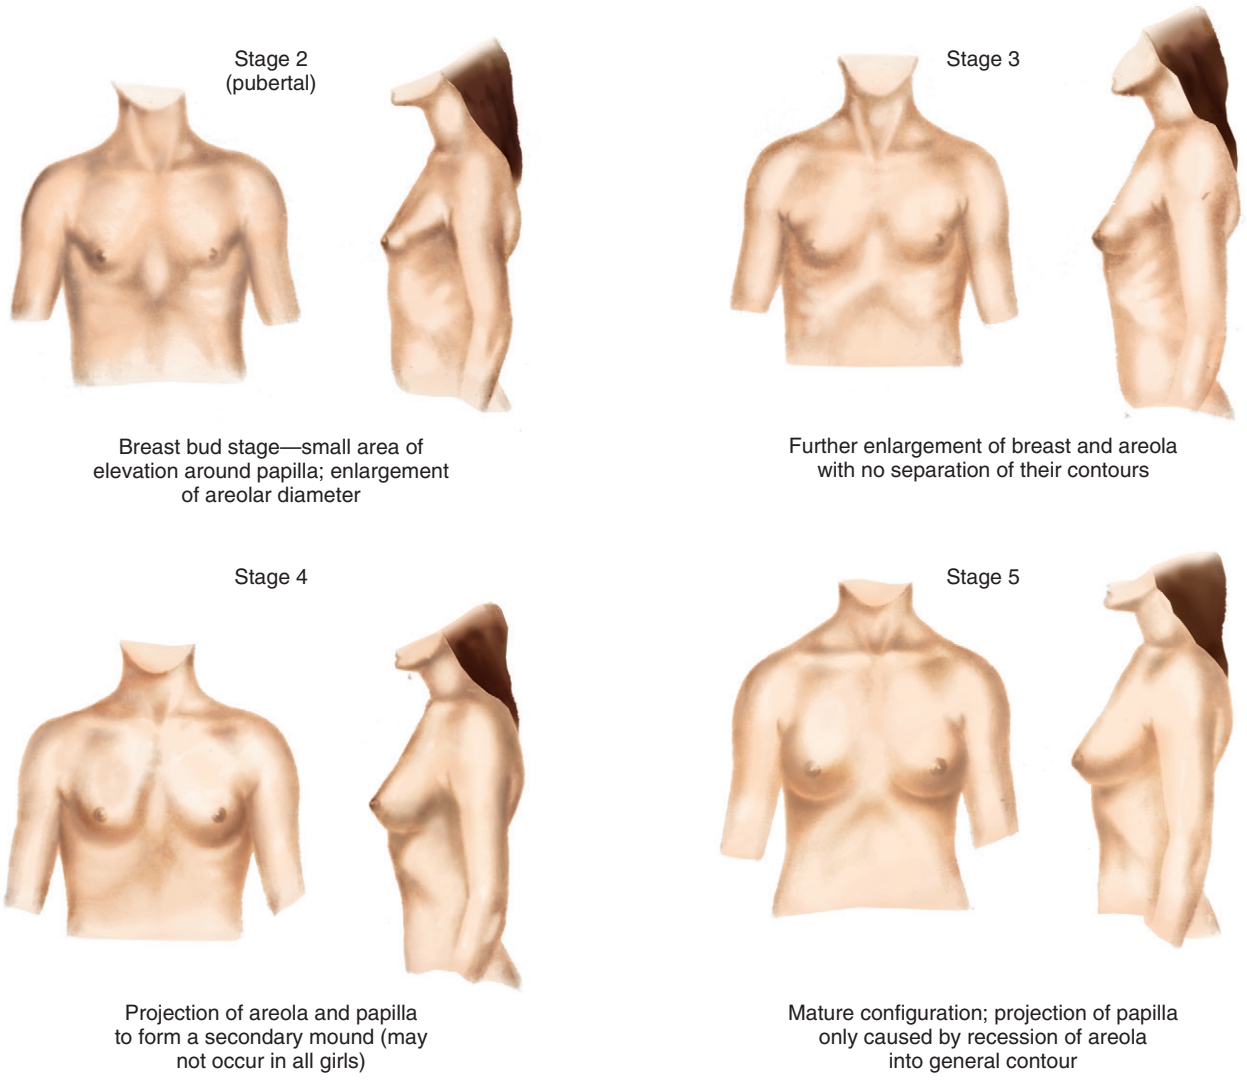

FIG 35-1 Development of the breast in girls—average age span: 8 to 13 years. Stage 1 (prepubertal, elevation of papilla only) is not shown. (Adapted from Daniel WA, Paulshock BZ: A physician's guide to sexual maturity, *Patient Care* 13:122–124, 1979; Marshall WA, Tanner JM: Variations in pattern of pubertal changes in girls, *Arch Dis Child* 44:291, 1969.)

increase in the length and width of the penis, testicular enlargement continues, and first ejaculation occurs. Axillary hair develops, and facial hair extends to cover the anterior neck. Final voice changes occur secondary to the growth of the larynx. Concerns about *pubertal delay* should be considered for boys who exhibit no enlargement of the testes or scrotal changes by 13½ to 14 years of age or if genital growth is not complete 4 years after the testicles begin to enlarge.

Physical Growth

A constant phenomenon associated with sexual maturation is a dramatic increase in growth. The final 20% to 25% of height is achieved during puberty, and most of this growth occurs during a 24- to 36-month period—the adolescent growth spurt. This accelerated growth occurs in all children but, as in other areas of development, is highly variable in age of onset, duration, and extent. The growth spurt begins earlier in girls, usually between ages 9½ and 14½ years; on average, it begins between ages 10½ and 16 years in boys. During this period, the average boy gains 10 to 30 cm (4-12 inches) in height and 7 to 30 kg (15.5-66 pounds) in weight. The average girl, in whom the growth spurt is slower and less extensive, gains 5 to 20 cm (2-8 inches) in height and 7 to 25 kg (15.5-55 pounds) in weight. Growth in height typically ceases 2 to 2½ years after menarche in girls and at age 18 to 20 years in boys.

This increase in size is acquired in a characteristic sequence. Growth in length of the extremities and neck precedes growth in other areas, and because these parts are the first to reach adult length, the hands and feet appear larger than normal during adolescence. Increases in hip and chest breadth take place in a few months, followed several months later by an increase in shoulder width. These changes are followed by increases in length of the trunk and depth of the chest. This sequence of changes is responsible for the characteristic long-legged, gawky appearance of early adolescent children.

Sex Differences in General Growth Patterns. Sex differences in general growth and distribution patterns are apparent in skeletal growth, muscle mass, adipose tissue, and skin. Skeletal

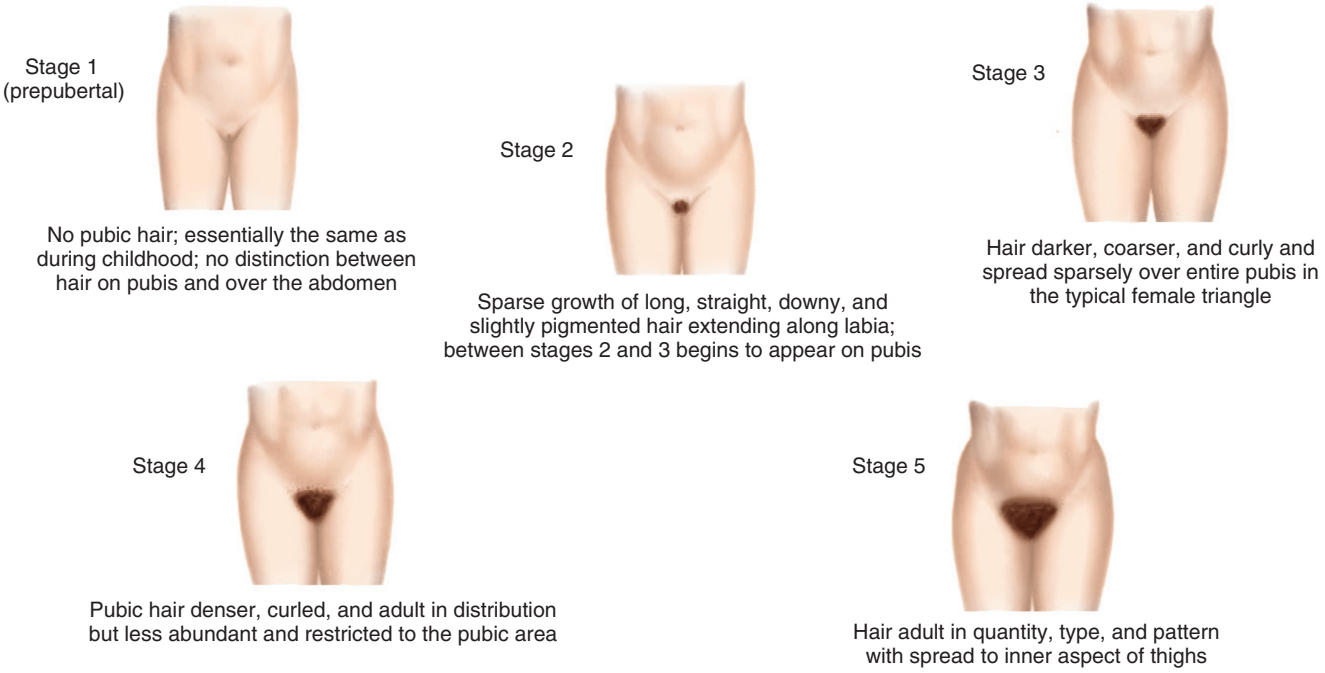

FIG 35-2 Growth in pubic hair in girls—average age span for stages 2 through 5: 11 to 14 years. (Adapted from Daniel WA, Paulshock BZ: A physician's guide to sexual maturity, *Patient Care* 13:122–124, 1979; Marshall WA, Tanner JM: Variations in pattern of pubertal changes in girls, *Arch Dis Child* 44:291, 1969.)

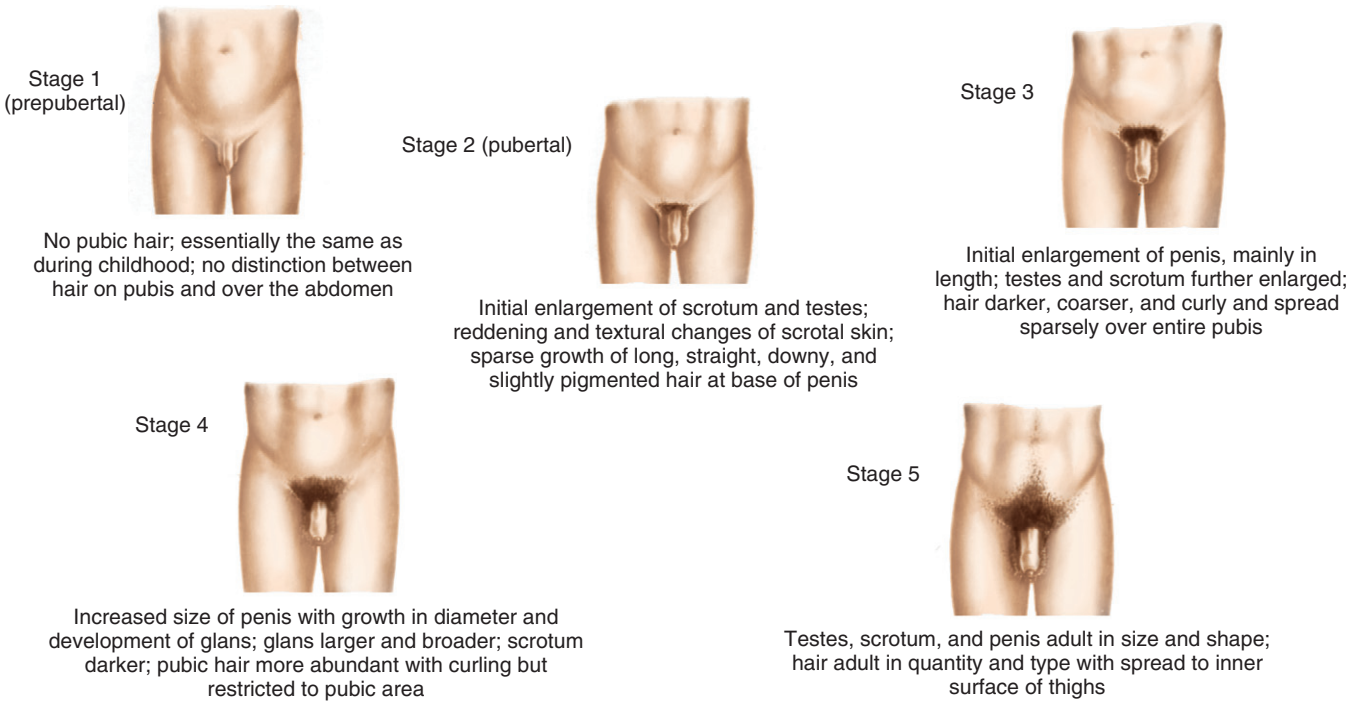

FIG 35-3 Developmental stages of secondary sex characteristics and genital development in boys—average age span: 12½ to 16 years. (Adapted from Daniel WA, Paulshock BZ: A physician's guide to sexual maturity, *Patient Care* 13:122–124, 1979; Marshall WA, Tanner JM: Variations in pattern of pubertal changes in girls, *Arch Dis Child* 44:291, 1969.)

growth differences between boys and girls are apparently a function of hormonal effects at puberty and are evident primarily in limb length. The earlier cessation of growth in girls is caused by epiphyseal unity under the potent effect of estrogen secretion, and the hormonal effect on female bone growth is much stronger than the similar effect of testosterone in boys. In boys, the prolonged growth period before puberty and the less rapid epiphyseal closure are reflected in their greater overall height and longer arms and legs. Other skeletal differences are increased shoulder width in boys and broader hip development in girls.

Hypertrophy of the laryngeal mucosa and enlargement of the larynx and vocal cords occur in both boys and girls to produce voice changes. Girls' voices become slightly deeper and considerably fuller, but the effect in boys is striking. The change in the voice of adolescent boys occurs between Tanner stages 3 and 4, with the voice often shifting uncontrollably from deep to high tones in the middle of a sentence.

Growth of lean body mass, principally muscle, which tends to occur after the bone growth spurt, takes place steadily during adolescence. Lean body mass is both quantitatively and qualitatively greater in boys than in girls at comparable stages of pubertal development. Muscle development, under the influence of androgenic hormones, increases steadily. Muscles become remarkably well developed in boys, whereas in girls, muscle mass increase is proportionate to general tissue growth.

Nonlean body mass, primarily fat, is also increased but follows a less orderly pattern. There may be a transient increase in subcutaneous fat just before the skeletal growth spurt, especially in boys. This is followed 1 to 2 years later by a modest to marked decrease, which is again more notable in boys. Later, variable amounts of fat are deposited to fill out and contour the mature physique in patterns characteristic of the adolescent's gender, particularly in the regions over the thighs, hips, and buttocks and around the breast tissue. It should be noted, however, that pediatric obesity has increased in the United States, and it is believed that obesity can change the timing of puberty. Girls with thelarche as the first sign of puberty have earlier menarche and greater body fat and body mass index (BMI) at menarche than girls with adrenarche as the first pubertal sign. Kaplowitz (2008) points out that there is evidence of a causal relationship between obesity and onset of early puberty in girls rather than earlier puberty causing an increase in body fat; no correlations between body fat and earlier puberty in boys have been reported.

Hormonal influences during puberty cause acceleration in growth and maturation of the skin and its structural appendages. Sebaceous glands become extremely active at this time, especially those on the genitalia and in the "flush areas" of the body (i.e., face, neck, shoulders, upper back, and chest). This increased activity and the structural nature of the glands are extremely important in the pathogenesis of a common problem of puberty: acne (see Chapter 47). The eccrine sweat glands, present almost everywhere on the human skin, become fully functional and respond to emotional and thermal stimulation. Heavy sweating appears to be more pronounced in boys than in girls. The apocrine sweat glands, nonfunctional in childhood, reach secretory capacity during puberty. Unlike the eccrine sweat glands, the apocrine glands are limited in distribution and grow in conjunction with hair follicles in the axillae, around the areola of the breast, around the umbilicus, on the external auditory canal, and in the genital and anal regions. Apocrine glands secrete a thick substance as a result of emotional stimulation that, when acted on by surface bacteria, becomes highly odoriferous.

Body hair assumes very characteristic distribution patterns and changes texture during puberty. Under the influence of gonadal and adrenal androgens, hair coarsens, darkens, and lengthens at sites related to secondary sex characteristics. Pubic and axillary hair appear in both sexes, although pubic hair is more extensive in males than in females. Beard, mustache, and body hair on the chest, upward along the linea alba, and sometimes on other areas (e.g., back and shoulders) appears in males and is androgen dependent. Extremity hair appears in varying amounts in both males and females but is also more prolific in the male.

Physiologic Changes

A number of physiologic functions are altered in response to some of the pubertal changes. The size and strength of the heart, blood volume, and systolic blood pressure increase, whereas the pulse rate and basal heat production decrease (see Appendix C). Blood volume, which has increased steadily during childhood, reaches a higher value in boys than in girls, a fact that may be related to the increased muscle mass in pubertal boys. Adult values are reached for all formed elements of the blood. Respiratory rate and basal metabolic rate, decreasing steadily throughout childhood, reach the adult rate in adolescence. Respiratory volume and vital capacity are increased and to a far greater extent in males than in females. During this period, physiologic responses to exercise change drastically: performance improves, especially in boys, and the body is able to make the physiologic adjustments needed for normal functioning after exercise is completed. These capabilities are a result of the increased size and strength of muscles and the increased level of cardiac, respiratory, and metabolic functioning.

Psychosocial Development

Developing a Sense of Identity (Erikson)

Traditional psychosocial theory holds that the developmental crisis of adolescence leads to the formation of a sense of identity (Erikson, 1963). Throughout childhood, individuals have been going through the process of identification as they concentrate on various parts of the body at specific times. During infancy, children identify themselves as being separate from the mother; during early childhood, they establish a gender-role identification with the appropriate-sex parent; and in later childhood, they establish who they are in relation to others. In adolescence, they come to see themselves as distinct individuals, somehow unique and separate from every other individual.

Adolescence begins with the onset of puberty and extends to relative physical and emotional stability at or near graduation from high school. During this time, the adolescent is faced with the crisis of *group identity versus alienation.* In the period that follows, the individual strives to attain autonomy from the family and develop a sense of *personal identity* as opposed to *role diffusion.* A sense of group identity appears to be essential to the development of a sense of personal identity. Young adolescents must resolve questions concerning relationships with a peer group before they are able to resolve questions about who they are in relation to family and society.

Group Identity. During the early stage of adolescence, pressure to belong to a group is intensified. Adolescents find it essential to have a group to which they feel they can belong and that provides them with status. Belonging to a crowd helps adolescents establish the differences between themselves and their parents. They dress as the group dresses and wear makeup and hairstyles according to group criteria, all of which are different from those of the parental generation. Language, music, and dancing reflect a culture that is

exclusive to the adolescent. When adults begin to emulate these fashions and interests, the style changes immediately. The evidence of adolescent conformity to the peer group and nonconformity to the adult group provides teenagers with a frame of reference in which they can display their own self-assertion while they reject the identity of their parents' generation. To be different is to be unaccepted and alienated from the group.

Individual Identity. The quest for personal identity is part of the ongoing identification process. As adolescents establish identity within a group, they also attempt to incorporate multiple body changes into a concept of the self. Body awareness is part of self-awareness. In their search for identity, adolescents consider the relationships that have developed between themselves and others in the past, as well as the directions they hope to take in the future.

Significant others hold expectations for the adolescent's behavior. Often these expectations or demands are persistent enough to result in certain decisions that might be made differently or not at all if the individual could be solely responsible for identity formation. It is all too easy to slip into the roles that are expected by these external influences without incorporating personal goals or questioning these decisions. Thus individuals may become what parents or others wish them to be, based on these premature decisions. Adolescents might form a negative identity when society or their culture provides them with a self-image that is contrary to the values of the community. Labels such as "loser," "punk," "troublemaker," or "failure" are applied to certain adolescents, who then accept and live up to these labels with behaviors that validate and strengthen them.

The process of evolving a personal identity is time-consuming and fraught with periods of confusion, depression, and discouragement. Determining an identity and a place in the world is a critical and perilous feature of adolescence (see Critical Thinking Case Study). However, as the pieces gradually shift and settle into place, a positive identity eventually emerges. Role diffusion results when the individual is unable to formulate a satisfactory identity from the multiplicity of aspirations, roles, and identifications.

Sex-Role Identity. Adolescence is the time for consolidation of a sex-role identity. During early adolescence, the peer group begins to communicate expectations regarding heterosexual relationships, and as development progresses, adolescents encounter expectations for mature sex-role behavior from both peers and adults. Expectations vary from culture to culture, among geographic areas, and among socioeconomic groups.

Emotionality. Adolescents vacillate in their emotional states between considerable maturity and childlike behavior. One minute they are exuberant and enthusiastic; the next minute they are depressed and withdrawn. Unpredictable but essentially normal mood swings are common during this time. As the tension is relieved, emotion is brought under control and individuals retreat to review what has happened, to attempt to master their anger, and to increase their ability to control their emotions and gain from the new experience. Because of these mood swings, adolescents are frequently labeled as unstable, inconsistent, and unpredictable. Little things can cause an emotional upheaval and, depending on the teenager's interpretation, can mean a great deal.

Teenagers are better able to control their emotions in later adolescence. They can approach problems more calmly and rationally, and although they are still subject to periods of sadness, their feelings are less vulnerable and they begin to demonstrate more mature emotions. Whereas early adolescents react immediately and emotionally, older adolescents can control their emotions until socially acceptable times and places for expression present themselves. They are still subject to heightened emotion, and when it is expressed, their behavior reflects feelings of insecurity, tension, and indecision.

Cognitive Development (Piaget)

Cognitive thinking culminates with the capacity for *abstract thinking.* This stage, the period of *formal operations,* is Piaget's fourth and last stage. Adolescents are no longer restricted to the real and actual, which was typical of the period of concrete thought; now they are also concerned with the possible. They now think beyond the present. Without having to center attention on the immediate situation, they can imagine a sequence of events that might occur, such as college and occupational possibilities; how things might change in the future, such as relationships with parents; and the consequences of their actions, such as dropping out of high school. At this time, their thoughts can be influenced by logical principles rather than just their own perceptions and experiences. They become increasingly capable of scientific reasoning and formal logic.

Adolescents are capable of mentally manipulating more than two categories of variables at the same time. For example, they can consider the relationship between speed, distance, and time in planning a trip. They can detect logical consistency or inconsistency in a set of statements and evaluate a system or set of values in a more analytic manner. For instance, they question the parent who insists on honesty in the teenager but at the same time cheats on an income tax report or expense account.

In adolescence, young people begin to think about both their own thinking and the thinking of others. They wonder what opinion others have of them, and they are able to imagine the thoughts of others. With this capacity comes the ability to differentiate between others' thoughts and their own and to interpret the thoughts of others more accurately. They are able to understand that few concepts are absolute or independent of other influencing factors. As they become aware that other cultures and communities have different norms and standards from their own, it becomes easier for them to accept members of these other cultures, and the decision to behave in their own culture in an accepted manner becomes a more conscious commitment.

CRITICAL THINKING CASE STUDY

Discussing the Future

Jeremy, age 17, will be graduating from high school in the spring. His mother, a single parent, tells you that she is concerned because graduation is quickly approaching and Jeremy has made no plans for what he will do with his life after graduation. Whenever Jeremy mentions the topic, his mother tells him "This is what you must do" and begins to outline the steps he must take. Jeremy just walks away. She asks, "What should I do?" What advice should you give Jeremy's mother?

1. Evidence—Is there sufficient evidence to draw any conclusions about what advice the nurse should give Jeremy's mother?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Adolescents and the search for personal identity
   b. The influence of others on the adolescent's search for personal identity
   c. Ways to communicate with adolescents
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

Moral Development (Kohlberg)

Although younger children merely accept the decisions or point of view of adults, adolescents, to gain autonomy from adults, must substitute their own set of morals and values. When old principles are challenged but new independent values have not yet emerged to take their place, young people search for a moral code that preserves their personal integrity and guides their behavior, especially in the face of strong pressure to violate the old beliefs. Their decisions involving moral dilemmas must be based on an *internalized set of moral principles* that provides them with the resources to evaluate the demands of the situation and to plan actions that are consistent with their ideals.

Late adolescence is characterized by serious questioning of existing moral values and their relevance to society and the individual. Adolescents can easily take the role of another. They understand duty and obligation based on reciprocal rights of others, as well as the concept of justice that is founded on making amends for misdeeds and repairing or replacing what has been spoiled by wrongdoing. However, they seriously question established moral codes, often as a result of observing that some adults verbally ascribe to a code but do not adhere to it.

Spiritual Development

As adolescents move toward independence from parents and other authorities, some begin to question the values and ideals of their families. Others adhere to these values as a stable element in their lives as they struggle with the conflicts of this turbulent period. Adolescents need to work out these conflicts for themselves, but they also need support from authority figures or peers for their resolution.

Adolescents are capable of understanding abstract concepts and of interpreting analogies and symbols. They are able to empathize, philosophize, and think logically. Most teens search for ideals and speculate about illogical statements and conflicting ideologies. Their tendency toward introspection and emotional intensity often makes it difficult for others to know what they are thinking. They tend to keep their thoughts private, fearing that no one will understand these feelings that they perceive to be unique and special. However, they may reveal deep spiritual concerns. They need support and encouragement in their struggle for understanding and the freedom to question without censure.

Generally, the stated importance of participation in organized religion declines somewhat during the adolescent years. More high school students than post–secondary school young people attend religious services regularly, and, not surprisingly, the younger the adolescents, the more likely they are to view religion as being important to them. Among older adolescents, the importance of organized religion declines more among college students than among those not in college. Late adolescence appears to be a time when individuals reexamine and reevaluate many of the beliefs and values of their childhood. Consistent with developmental changes in value autonomy, the religious beliefs of young people are likely to become more personalized and less bound to the traditional religious practices they may have been exposed to when they were younger. As adolescents mature and form an identity, they may either reject their family's traditional beliefs or they may decide to conform to those beliefs (Neuman, 2011).

Neuman (2011) suggests that adolescents, who are searching for an identity and personal growth, may perceive God as one who accepts them and confirms their self-identity. Religious beliefs in adolescence are also strongly influenced by interpersonal relationships with peers as well as adults in their environment.

Greater levels of religiosity and spirituality are associated with fewer high risk behaviors and more health-promoting behaviors, especially for youth living in environments lacking positive influences (Regnerus and Glen, 2003). Nurses play an important role for teens by providing an opportunity to discuss issues regarding spirituality.

Social Development

To achieve full maturity, adolescents must free themselves from family domination and define an identity independent of parental authority. However, this process is fraught with ambivalence on the part of both teenagers and their parents. Adolescents want to grow up and be free of parental restraints, but they are fearful as they try to comprehend the responsibilities that are linked with independence. Feelings of immortality and exemption from the consequences of risk-taking behavior, although viewed as negative, can serve an important developmental function at this time. These feelings give adolescents the courage to separate from their parents and become independent. Part of this emancipation involves developing social relationships outside the family that help adolescents identify their role in society. Adolescence is a time of intense sociability and often a time of equally intense loneliness. Acceptance by peers, a few close friends, and the secure love of a supportive family are requisites for interpersonal maturation.

Relationships with Parents

During adolescence, the parent-child relationship changes from one of protection-dependency to one of *mutual affection and equality.* The process of achieving independence often involves turmoil and ambiguity as both parent and adolescent learn to play new roles and work toward this end while, at the same time, resolving the often painful series of rifts essential to establishing the ultimate relationship.

Most behavior observed in the adolescent is related to the struggle for independence and the external restrictions and checks and balances that are placed on this spontaneous maturation process. On the one hand, adolescents are accepted as maturing preadults. They are allowed privileges heretofore denied, and they are provided with increasing responsibilities. On the other hand, because of their unpredictability and insecurity in evaluating situations and making sound judgments, they must conform to regulations and restrictions set by adults. This state of affairs is particularly exemplified by the struggle between parents and adolescents concerning curfews and the use of social media.

As teenagers assert their rights for grown-up privileges, they frequently create tensions within the home. They resist parental control, and conflicts can arise from almost any situation or any subject. Favorite topics of dispute include whether or not the adolescent has his or her own cell phone, Internet and cell phone use, manners, dress, chores and duties, homework, disrespectful behavior, friendships, dating and relationships, money, automobiles, alcohol and other substance abuse, and time schedules. Present in these areas of conflict is the overriding argument that "everyone else has one" or is allowed the desired item or privilege and the ever-present assertions that "You don't understand me or trust me" and "You always treat me like a child." Spoken or unspoken, parents' reactions consist of "Is this all the thanks I get for what I have done for you?"

Adolescents' earliest attempts to achieve emancipation from parental controls are manifested in a period of rejection of the parents. They absent themselves from home and family activities and spend increasing time with the peer group. They confide less in

FAMILY-CENTERED CARE

Communication with Adolescents: The Art of Listening

Conflicts between parents and their adolescents are often a result of a natural characteristic of parenthood: the desire to protect one's offspring from harm or from simply doing something "stupid" or embarrassing or something they may later regret. Teenagers sometimes "bounce" their thoughts and ideas off adults. At times they really want some feedback; at other times they simply want to elicit a reaction.

I found it easy to listen openly, thoughtfully, and without interrupting when my teenagers' friends discussed troublesome topics. However, one day, when one of my own teenagers had a similar conversation with me, the parent part kicked in. I felt responsible and spoke my piece on the spot. This brought communication to a halt and resulted in defensiveness. It was a long time before my child tried to talk to me about anything controversial again. The next time one of my teenagers started a similar conversation, I decided to try to trick myself.

Throughout the entire conversation, I told myself over and over again to act as if this were not my teenager but, rather, someone else's child. I found this actually worked quite well, and I was able to listen without interrupting. I continued to use the system, sometimes with more success than at other times.

–Mother of Four

their parents, but parents continue to play an important role in their personal and health-related decision making.

With advancing adolescence, teenagers become more competent and with this competence comes a need for more autonomy. Although they may be psychologically prepared for independence, they are often thwarted in their efforts by lack of money or other parental barriers. Conflict arises in relation to the teenagers' outside activities and the elements of privacy and trust. Parental monitoring remains important throughout adolescence and may have a direct influence on adolescent sexual and substance-use behavior. Parents should be guided toward an authoritative style of parenting in which authority is used to *guide* the adolescent while allowing developmentally appropriate levels of freedom and providing clear, consistent messages regarding expectations. Consistency in guidance and establishing ground rules is extremely important for adolescents even though they may fiercely reject the parents' wishes. Authoritative style of parenting has been shown to have both immediate and long-term protective effects toward adolescent risk reduction (DeVore and Ginsburg, 2005). However, to gain the trust of adolescents, parents must respect their adolescent's privacy and show an honest and sincere interest in what the adolescent believes and feels (see Family-Centered Care box).

Relationships with Peers

Although parents remain the primary influence in their lives, for the majority of teenagers, peers assume a more significant role in adolescence than they did during childhood. The peer group serves as a strong support to teenagers, individually and collectively, providing them with a sense of belonging and a feeling of strength and power. The peer group forms the transitional world between dependence and autonomy.

Peer Group. Adolescents are usually social, gregarious, and group minded. Thus the peer group has an intense influence on adolescents' self-evaluation and behavior. To gain acceptance by a group, younger teenagers tend to conform completely in such things as mode of dress, hairstyle, taste in music, and vocabulary. Teenagers use the peer group as a standard measure of what is normal.

FIG 35-4 Teenagers like to gather in small groups. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

The school is psychologically important to adolescents as a focus of social life. Teenagers usually distribute themselves into a relatively predictable social hierarchy. They know to which groups they and others belong. A sense of school connectedness has been found to predict decreased risk-taking behaviors in adolescents (Bond, Butler, Thomas, et al., 2007). School connectedness is correlated with caring teachers and the absence of prejudice or discrimination from peers. A sense of school connectedness is less dependent on class size, attendance, academic preparation, and parental involvement (Maes and Lievens, 2003).

Within the larger groups are smaller, distinct, and rather exclusive crowds or cliques of selected close friends who are emotionally attached to each other. The selection is based on common tastes, interests, and background. Although cliques may become formalized, most remain informal and small. However, each has an identifying feature that proclaims its difference from others and its solidarity within itself, in much the same manner as the adolescent generation as a whole sets itself apart from the adult generation. Cliques are usually made up of one gender, and girls tend to be more cliquish than boys and to have a greater need for close friendships (Fig. 35-4). Within the intimacy of the group, adolescents gain support in learning about themselves, consideration for the feelings of others, and increased ego development and self-reliance.

To *belong* is of utmost importance; thus adolescents behave in a way that will ensure their establishment in a group. Adolescents are highly susceptible to social approval, acceptance, and demands. To be ignored or criticized by peers creates feelings of inferiority, inadequacy, and incompetence.

Best Friends. Personal friendships of the one-on-one variety usually develop between same-sex adolescents. This relationship is closer and more stable than it is in middle childhood, and it is important in the quest for identity. A best friend is the best audience on whom to try out possible roles and identities that an adolescent wants to test. Best friends may try a role together, each supporting the other. Each cares about what the other thinks and feels. Because a sense of intimacy grows within a permanent relationship, the stability of this same-sex friendship is an important link in the progress toward an intimate relationship in young adulthood.

Interests and Activities

Adolescents spend a large amount of time engaging in leisure-time activities. As teenagers progress through the developmental stages of

FIG 35-5 The cell phone allows adolescents to talk for hours with peers. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

adolescence, these leisure-time activities move from being family centered to being peer centered. In addition to providing teenagers with fun and enjoyment, leisure-time activities assist in the development of social, physical, and cognitive skills. Leisure-time activities also allow teenagers the opportunity to learn to set priorities and structure their time (Fig. 35-5).

The role of social media and advanced technology are nowhere more prominent than in the lives of today's adolescents. The widespread availability of the Internet and access to social networking websites such as FaceBook, chatrooms, free e-mail, blogs, and Twitter have created "virtual" communities and ways for young people to interact with others; web cameras even allow those interactions to include real-time video communication. Cellular telephones offer more mobile opportunities to talk on the phone, send text messages or instant messaging, send photos, or use video phone capabilities.

Internet chatrooms and social networking sites have created a more public arena for trying out identities and developing interpersonal skills with a wider network of people, occasionally with anonymity. This can create opportunities for young people who have a limited access to friends (because of rural location, shyness, or rare chronic conditions) to interact with people like themselves. However, most adolescents appear to be using the online social environment to interact with the same peers they spend their day with at school.

Text messaging and instant messaging via cell phones has become a common activity and can sometimes be disruptive during school. In addition, both the online and text environment can create opportunities for **cyberbullying,** in which teens engage in insults, harassment, and publicly humiliating statements online or on cell phones. There is increased danger of adolescents coming in contact and sharing personal information with sexual predators who pose as adolescents in an attempt to make personal contact with underage victims or engage them in sexting (sending sexually explicit or suggestive pictures or messages online) (Dowdell, Burgess, and Flores, 2011). Adolescent sexting, rather than being an innocent anonymous activity, has been linked to risky sexual behaviors in a few studies (Rice, Rhoades, Winetrobe, et al., 2012; Temple, Paul, van den Berg, et al., 2012).

Today, many adolescents must learn to juggle their time between school, activities, and job responsibilities. Adolescent work experiences provide many benefits, including time management, teamwork skills, and increased income. However, many jobs available to teenagers do not provide opportunities to apply the skills they learn in school, and jobs often have high demands for quick work with low rewards. Few apprentice opportunities are available for teenagers in the United States. It is generally recommended that adolescents limit their work to no more than 20 hours per week during the school year.

Adolescent Sexuality

Sexual activity is common by the late teen years, but only 13% of teens have ever had vaginal intercourse by age 15 years. The average age of sexual initiation is about age 17 years. The top three reasons teenagers report for waiting to have sex include religious or moral beliefs, desire to postpone motherhood, and "haven't found the right person yet" (Abma, Martinez, and Copen, 2010).

Adolescence represents a critical time in the development of sexuality. Hormonal, physical, cognitive, and social changes that occur during adolescence all have an impact on sexual development. Of all the developmental changes that affect adolescent sexuality, none is more obvious than the impact of puberty. Adolescents must come to terms with hormonal influences, physiologic manifestations such as menstruation and ejaculation, and physical changes such as breast and genital development. All of these changes have a profound impact on the way teenagers perceive their bodies (i.e., body image). In addition to transitions in body image, increasing levels of pubertal hormones contribute to increased levels of sexual motivation among both boys and girls.

Changes in sexual motivations and feelings, happening at the same time as shifts in cognitive skills, contribute to painful conjectures ("Is what I'm feeling normal?"), self-conscious concern ("Am I good-looking enough?"), and hypothetical thinking ("What if she wants to have sex?"). The emergence of formal operational thinking also increases adolescents' decision-making capabilities concerning sexual issues. As they mature, teenagers become better able to think through potential risks and benefits of sexual behaviors before they engage in any behavior. Older adolescents may also be able to conceptualize more long-term consequences of present behaviors. One of the important tasks of adolescence is to incorporate sexuality successfully into close, intimate relationships. This task is made possible by the advanced cognitive abilities that emerge over the course of adolescence.

Part of adolescent **identity formation** involves the development of sexual identity. As they begin to integrate changes involved with puberty, young adolescents also develop emotional and social identities separate from their families'. For young adolescents, the process of sexual identity development usually involves forming close friendships with same-sex peers, with whom they may experiment sexually, often to satisfy curiosity. Sexual activity among young teenagers varies by gender. Masturbation provides an opportunity for sexual self-exploration; participation in this behavior is influenced by learned cultural attitudes and sex-role expectations.

Many teenagers begin to make a shift from relationships with same-sex peers to intimate relationships with members of the opposite sex during middle adolescence (Fig. 35-6). Opposite-sex relationships typically begin with peer activities involving both boys and girls. Pairing off as couples becomes more common as middle adolescence progresses. The type and degree of seriousness of partner relationships vary. Initial relationships are usually noncommittal, extremely mobile, and seldom characterized by any deep romantic

FIG 35-6 Relationships with peers of the opposite sex are an important part of adolescence. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

attachments. Sexual activity becomes more common during middle adolescence. The relationship between love and sexual expression is brought into focus during middle adolescence. Most young people oppose exploitation, pressure, or force in sex as well as sex solely for the sake of physical enjoyment without a personal relationship. Adolescents find it hard to believe that sex can exist without love; therefore they view each relationship as real love.

An integrated sexual identity often emerges during late adolescence as individuals incorporate sexual experiences, feelings, and knowledge. For most, this identity is consistent with their own physical and mental capacities and with societal limits and expectations. Most older adolescents identify themselves as being predominantly heterosexual; about 3% of males and 8% of females identify themselves as bisexual or homosexual (Mosher, Chandra, and Jones, 2005). Whatever their sexual orientation, most older teenagers possess the capacity to have intimate relationships that satisfy the emotional and sexual needs of both partners.

Sexual orientation is an important aspect of sexual identity. **Sexual orientation** is defined as a pattern of sexual arousal or romantic attraction toward persons of the opposite gender (heterosexual), of the same gender (homosexual, often called *gay* or *lesbian*), or of both genders (bisexual). Sexual orientation encompasses several dimensions, including attraction, fantasy, actual sexual behavior, and self-labeling or group affiliation. In individuals, the direction and intensity of each dimension are not necessarily consistent with any of the others. For example, individuals may be attracted most strongly to their same gender, fantasize about both genders, have sexual activity only with the opposite gender, and identify as gay or lesbian. Other individuals may engage in same-gender sexual behavior and fantasize about both genders but identify as heterosexual. As with all aspects of sexual identity, the dimensions of sexual orientation are influenced by cultural meaning and expectation, by gender, by peer groups, and by other environmental contexts.

Adolescence is the period during which individuals commonly begin to identify their sexual orientation as part of their developing sexual identity. However, this identification process can be profoundly influenced by cultural beliefs and values, by societal and family pressures, or by a lack of similar peers. The majority of adolescents eventually report an orientation toward exclusively heterosexual relationships. For adolescents whose orientation encompasses any same-sex dimensions, the identity process during adolescence can be complicated, especially when community norms disapprove of orientations other than heterosexual. Adolescents who have witnessed harassment or violence directed at gay, lesbian, and bisexual people, for example, may be reluctant to self-identify even when their attractions and behaviors are exclusively same-sex or bisexual.

The development of sexual orientation as part of sexual identity includes several developmental milestones during late childhood and throughout adolescence. These milestones do not necessarily occur in the same order for everyone, nor are they completed in the same amount of time. They include:

1. The realization of romantic or erotic attraction to people of one (or both) genders
2. Erotic daydreaming about one or both genders
3. Romantic partners or dates without sexual activity
4. Sexual activity with people of the preferred gender or genders (also, for some teens, sexual activity with a nonpreferred gender, out of curiosity or through social pressure)
5. Self-identification of the orientation that best fits one's current circumstances and understanding
6. Publicly self-identifying that orientation, usually to intimate friends and family first and then the wider social group
7. An intimate, committed sexual relationship with a person of the gender appropriate to one's orientation

There is no evidence that gay, lesbian, or bisexual adults are more or less likely to create long-term, stable relationships than are heterosexual couples. It should be noted that bisexual adolescents and adults do not generally engage in sexual relationships with both genders concurrently; self-identification as bisexual usually refers to the ability to be attracted to either gender but does not imply that such a person requires partners of both genders or that one must be equally attracted to and have sexual experience with both genders to be bisexual.

Although the order of these milestones varies greatly among adolescents, adolescents who identify as gay, lesbian, or bisexual tend to publicly self-identify later than heterosexual peers. Without positive gay, lesbian, or bisexual role models or a supportive peer group, sexual-minority teens can feel isolated and they may not share their orientation with anyone for fear of rejection or violence (see Critical Thinking Case Study). A comparison of bisexual youth and heterosexual youth found that bisexual adolescents, especially girls, reported lower levels of connection to family and school than did heterosexual adolescents. Nurses should be alert to these lower levels of protective relationships for bisexual youth because it may lead to poor health outcomes (Saewyc, Homma, Skay, et al., 2009).

Development of Self-Concept and Body Image

The sudden growth that takes place in early adolescence creates feelings of confusion for adolescents. They have lost the security of a familiar body and feel uncomfortable with their altered body. Consequently, they may try to either hide their body or advertise it or they may alternate between the two extremes. Teenagers are acutely aware of their appearance as they begin to acquire images of

CRITICAL THINKING CASE STUDY

Discussing Sexual Orientation with Adolescents

John, a 17-year-old adolescent, comes into the school-based clinic and tells the nurse practitioner that he thinks he is homosexual. What is the most appropriate response for the nurse practitioner?

1. Evidence—Is there sufficient evidence to draw any conclusions about John's sexual orientation at this time?
2. Assumptions—Describe an underlying assumption about each of the following issues:
   a. Sexual orientation in adolescents
   b. Society's reaction to homosexuality
   c. Health care professionals and sexuality
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

themselves as adults, but they see discrepancies between their ideal and actual skills and abilities.

Adolescents are continually comparing themselves with their peers and making judgments about their own normality based on these observations. Pubertal children feel most comfortable when they are just like their friends and age-mates. Perceived defects or deviations from the group average are threatening to their idealized image. Any blemish is likely to be magnified out of proportion, and any delay of the visible evidence of maturity is cause for worry. Unfortunately, this is also the time when the hormonal effect of the sebaceous glands produces acne, which creates problems for some adolescents. To the adolescent, even the most insignificant pimple may be viewed as a gross disfigurement. The diagnosis of chronic disease or a permanent physical disability has special significance during adolescence and creates additional stresses for both adolescents with the condition and health care providers.

Experts have determined that the body image established during adolescence is the one that individuals retain throughout life. Much of adolescents' search for identity takes place before a mirror as they try to read from the reflected features just who they are and what they look like to other people. Adolescents practice facial expressions and postures, try out hair arrangements, worry about a pimple, and in other ways attempt to assess the best means to achieve a maximum effect—to reveal the "true self."

The self-concept becomes more differentiated as adolescents acquire a more complex picture of themselves, one that takes situational factors into account. The self-concept gradually becomes more individualized and more distinct from the concepts of others. Although younger teenagers describe themselves in terms of similarities with peers, as adolescence advances, young people describe themselves in terms of their special characteristics.

Responses to Puberty

The response to the physical changes of pubertal growth and development is manifested differently depending on the stage of development. During early adolescence, young adolescents become preoccupied with the rapid changes in their body and are interested in the anatomy, physiology, and function of their sexual organs. Boys must also confront the sexual feelings and tensions that accompany puberty, and the appearance of nocturnal emissions may be puzzling, troublesome, or embarrassing. Unless the boy has been prepared in advance, he may find it difficult to discuss his feelings with his parents and may turn to his friends for information and guidance. Many girls also find the rapid changes in their body to be sources of concern. Some girls perceive the increase in weight and associated fat deposition as evidence of obesity and may indulge in fad diets. Although many girls look forward to menstruation and take this event in stride, others may find the first menstrual period a distressing and frightening event. All teenagers, regardless of gender, are concerned with the question "Am I normal?" To answer this question, they compare their body with those of their peers and with images in the media. This leads to a great deal of uncertainty about their appearance and attractiveness.

If an adolescent does not enter puberty at the same time as his or her peers, considerable inner conflict may occur. Early-maturing girls and boys have higher rates of sexual risk-taking behaviors, delinquency, and substance abuse than their on-time peers (Costello, Sung, Worthman, et al., 2007; Lynne, Graber, Nichols, et al., 2007). Early puberty onset in females who are offspring of adolescent mothers may also be a significant factor in teenage pregnancies (De Genna, Larkby, and Cornelius, 2011). Nurses who work with adolescents must provide teaching and health care interventions that are appropriate for the adolescent's chronologic and cognitive development rather than the stage of physical maturation.

As growth and development proceed through middle adolescence, the rapid body changes diminish and the adolescent has time to try to make the body more attractive. Adolescents strive to achieve the perfect body within their own cultural norms. The "right" clothes and hairstyle become very important. By late adolescence, the heightened concern with body image has ended and is replaced by a general comfort with the body.

The changes that occur during the early, middle, and late phases of adolescence are summarized in Table 35-1.

PROMOTING OPTIMAL HEALTH DURING ADOLESCENCE

The major causes of morbidity and mortality in adolescence are not diseases but, instead, health-damaging behaviors. New sources of morbidity in adolescence include injury, depression, violence, sexually transmitted infections (STIs), and pregnancy; obesity may begin in childhood or adolescence, but the health consequences are more evident in early and middle adulthood. Health promotion for this age-group consists mainly of teaching and guidance to avoid risk-taking activities and health-damaging behaviors. Adolescence provides an opportunity for teenagers to incorporate healthy lifestyle behaviors that will benefit them not only during the teenage years but also throughout the life span.

Effective health education for adolescents should incorporate a developmentally appropriate, multifaceted approach. Motivational interviewing has been shown to improve adherence to health care advice by using a collaborative approach (Gance-Cleveland, 2007). In this process, the adolescent is encouraged to introspectively explore ambivalence and develop solutions for effecting change. Education alone is not enough to change behavior. Effective programs for adolescents must include opportunities to improve communication skills and enhance their social network to make more positive connections (Tuttle, Campbell-Heider, and David, 2006).

As adolescents progress through adolescence, they are able to assume additional responsibility for their own health, including maintaining health practices, taking prescribed medications, keeping appointments, and performing procedures when necessary. Health care professionals who work with adolescents should consider the adolescent's increasing independence and responsibility while

TABLE 35-1 GROWTH AND DEVELOPMENT DURING ADOLESCENCE

EARLY ADOLESCENCE (11-14 YR)	MIDDLE ADOLESCENCE (15-17 YR)	LATE ADOLESCENCE (18-20 YR)
Growth		
Rapidly accelerating growth Reaches peak velocity Secondary sex characteristics appear	Growth decelerating in girls Stature reaches 95% of adult height Secondary sex characteristics well advanced	Physically mature Structure and reproductive growth almost complete
Cognition		
Explores newfound ability for limited abstract thought Clumsy groping for new values and energies Comparison of "normality" with peers of same sex	Developing capacity for abstract thinking Enjoys intellectual powers, often in idealistic terms Concern with philosophic, political, and social problems	Established abstract thought Can perceive and act on long-range options Able to view problems comprehensively Intellectual and functional identity established
Identity		
Preoccupied with rapid body changes Trying out of various roles Measurement of attractiveness by acceptance or rejection of peers Conformity to group norms	Modifies body image Very self-centered; increased narcissism Tendency toward inner experience and self-discovery Has a rich fantasy life Idealistic Able to perceive future implications of current behavior and decisions; variable application	Body image and gender-role definition nearly secured Mature sexual identity Phase of consolidation of identity Stability of self-esteem Comfortable with physical growth Social roles defined and articulated
Relationships with Parents		
Defining independence-dependence boundaries Strong desire to remain dependent on parents while trying to detach No major conflicts over parental control	Major conflicts over independence and control Low point in parent-child relationship Greatest push for emancipation; disengagement Final and irreversible emotional detachment from parents; mourning	Emotional and physical separation from parents completed Independence from family with less conflict Emancipation nearly secured
Relationships with Peers		
Seeks peer affiliations to counter instability generated by rapid change Upsurge of close, idealized friendships with members of the same sex Struggle for mastery takes place within peer group	Strong need for identity to affirm self-image Behavioral standards set by peer group Acceptance by peers extremely important—fear of rejection Exploration of ability to attract opposite sex	Peer group recedes in importance in favor of individual friendship Testing of romantic relationships against possibility of permanent alliance Relationships characterized by giving and sharing
Sexuality		
Self-exploration and evaluation Limited dating, usually group Limited intimacy	Multiple plural relationships Internal identification of heterosexuality, homosexual, or bisexual attractions Exploration of "self appeal" Feeling of "being in love" Tentative establishment of relationships	Forms stable relationships and attachment to another Growing capacity for mutuality and reciprocity Dating as a romantic pair May publicly identify as gay, lesbian, or bisexual Intimacy involves commitment rather than exploration and romanticism
Psychologic Health		
Wide mood swings Intense daydreaming Anger outwardly expressed with moodiness, temper outbursts, and verbal insults and name-calling	Tendency toward inner experiences; more introspective Tendency to withdraw when upset or feelings are hurt Vacillation of emotions in time and range Feelings of inadequacy common; difficulty in asking for help	More constancy of emotion Anger more apt to be concealed

GUIDELINES

Interviewing Adolescents

- Ensure confidentiality and privacy; interview adolescent without parents present.
- Show concern for adolescent's perspective: "First, I'd like to talk about your main concerns" and "I'd like to know what you think is happening."
- Offer a nonthreatening explanation for the questions you ask: "I'm going to ask a number of questions to help me better understand your health."
- Maintain objectivity; avoid assumptions, judgments, and lectures.
- Ask open-ended questions when possible; move to more directive questions if necessary.
- Begin with less sensitive issues and proceed to more sensitive ones.
- Use language that both the adolescent and you understand. Clarify terms, such as "having sex."
- Restate or summarize: reflect back to adolescents what they have said, along with feelings that may be associated with their descriptions.
- Ask the adolescent if he or she minds if the practitioner shares general (or specific) information gathered in the health examination and interview with the parent. Reiterate that the teen's confidentiality will be maintained if he or she refuses to give permission (unless life-threatening information is shared).

CRITICAL THINKING CASE STUDY

Respecting Privacy

Jamie, a 17-year-old girl, arrives at the adolescent clinic with her mother, Mrs. S, for a routine history and physical examination with the nurse practitioner. As the nurse practitioner walks with Jamie to an examination room, Mrs. S whispers to the nurse practitioner, "I need to speak with you in private." How should the nurse practitioner respond to Mrs. S's request?

1. Evidence—Is there sufficient evidence to formulate a response to Jamie's mother?
2. Assumptions—Describe an underlying assumption about each of the following topics:
   a. The role of the adolescent in health care
   b. The role of the parents in the health of their adolescent
   c. Adolescents and confidentiality
3. What implications for nursing care should be established at this time?
4. Does the evidence objectively support your argument (conclusion)?

maintaining privacy and ensuring confidentiality (see Guidelines box and Critical Thinking Case Study). Parents should also respect their teenager's independence and move toward the role of consultant about health issues while also maintaining some level of parental involvement throughout adolescence.

Several professional organizations have published guidelines aimed at improving and maintaining health care for adolescents and young adults. The American Academy of Pediatrics (AAP), American Academy of Family Physicians, American Medical Association, and U.S. Preventive Services Task Force have similar guidelines for health supervision of adolescents. These guidelines emphasize the need to provide health services to adolescents that meet their physical and emotional needs. They place great import on provision of health care by health care providers who are trained in meeting the adolescents' needs. Bright Futures (Duncan and Pirretti, 2009) emphasizes the following issues be addressed with adolescents at each health visit:

- Physical growth and development (physical and dental health, body image, healthy nutrition, physical activity)
- Social and academic competence (relationships with peers and family, school performance, interpersonal relationships)
- Emotional well-being (mental health, sexuality)
- Risk reduction (tobacco, alcohol, other drugs, pregnancy, STIs)
- Violence and injury prevention

Some practical suggestions for addressing the adolescent's individual health care needs are found in the following mnemonic*:

H—Home environment, belonging, decision making
E—Education/Employment
E—Eating/nutrition
A—Activities, physical activities
D—Drugs (including smoking and alcohol use)
S—Sexuality
S—Suicide/depression
S—Safety

The following discussion of adolescent health will focus on some of the topics from this mnemonic as well as the Bright Futures topics listed above; other adolescent health issues are discussed later in this chapter.

Immunizations

An immunization update is an important part of adolescent preventive care. Obtaining a record of the teenager's prior immunizations is important. The Tdap (tetanus, diphtheria, acellular pertussis) vaccine is recommended for adolescents 11 to 18 years old who have not received a tetanus booster (Td) or Tdap dose and have completed the childhood DTaP/DTP series. When the Tdap is used as a booster dose, it may be administered earlier than the previous 5-year interval to provide adequate pertussis immunity (regardless of interval from the last Td dose) (Centers for Disease Control and Prevention [CDC], 2011). Meningococcal vaccine (MenACWY-D [Menactra] or MenACWY-CRM [Menveo]) should be given to adolescents 11 to 12 years of age with a booster dose before 16 years of age. If not previously vaccinated, they should receive 1 dose between 13 and 18 years of age (CDC, 2013a) (see also Immunizations, Chapter 31).

The quadrivalent human papillomavirus (HPV) vaccine or the bivalent HPV vaccine is recommended for the prevention of cervical precancers and cancers for girls beginning at a minimum age of 9 years. The quadrivalent HPV vaccine is recommended for males ages 9 through 18 years to reduce their likelihood of genital warts (CDC, 2013b). Each one of the HPV vaccines is administered in a three-dose series; it is important to follow the recommended dose intervals for optimal effectiveness.

All adolescents who have not previously received three doses of hepatitis B vaccine should be vaccinated against hepatitis B virus. The hepatitis A vaccine should be given to adolescents who live in areas where vaccination programs target older children or who are at increased risk for infection or for whom immunity against hepatitis A is desired (CDC, 2013b). Annual influenza vaccination with either the live attenuated influenza vaccine or inactivated influenza vaccine is recommended for all children and adolescents. All adolescents should also be assessed for previous history of varicella infection or vaccination. Vaccination with the varicella vaccine is

*From Duncan P, Pirretti AE: Bright futures for the busy clinical practice, American Academy of Pediatrics, *Adolescent Health Update* 22(1):1–10, 2009; Goldenring JM, Rosen DS: Getting into adolescent heads: an essential update, *Contemp Pediatr* 21:64–90, 2004.

recommended for those with no previous history; for those with no previous infection or history, the varicella vaccine may be given in two doses 4 or more weeks apart to adolescents 13 years of age or older (CDC, 2013b). Adolescents should receive a tuberculin skin test if they have been exposed to active tuberculosis (TB), have lived in a homeless shelter, have been incarcerated, have lived in or come from an area with a high prevalence of TB, or currently work in a health care setting.

Nutrition

The rapid and extensive increase in height, weight, muscle mass, and sexual maturity of adolescence is accompanied by increased nutritional requirements. Because nutritional needs are closely related to the increase in body mass, the peak requirements occur in the years of maximum growth, during which the body mass almost doubles. The caloric and protein requirements during this time are higher than at almost any other time of life. As a result of this increased anabolic need, the adolescent is highly sensitive to caloric restrictions.

Current guidelines for caloric intake are provided by a number of sources. The Dietary Reference Intakes (DRIs) provide age-specific guidelines for nutrients (see Chapters 29 and 32). The 2010 Dietary Guidelines for Americans* recommend specific caloric intakes for adolescents based on their levels of activity (sedentary, moderately active, and active) as well as a recommendation to decrease the amount of fat to approximately 25% to 36% of total daily intake. A recent change in guidelines is reflected in the new MyPlate,† which takes the place of MyPyramid as a scheme for eating a balanced diet of the five main food groups—fruits, grains, protein, vegetables, and dairy products. Recent guidelines by the National Heart, Lung, and Blood Institute (NHLBI) include dietary recommendations to reduce the risk for cardiovascular disease. Included in these guidelines for adolescents is a total daily fat intake of 25% to 30% of estimated energy requirements, with emphasis on a reduction of saturated fat and avoidance of *trans* (unsaturated) fat. The guidelines also address the need for an increased intake of dietary fiber (26 grams/day [females 14 to 18 years old] and 38 grams/day [males 14 to 18 years old]), consumption of three meals per day, avoidance of tobacco, and routine screening for **hyperlipidemia** and hypertension in children and adolescents. Estimated energy requirements for adolescents of both sexes are provided based on three levels of activity: sedentary, moderately active, and active (National Heart, Lung, and Blood Institute, 2011). Caloric intake can be tailored to meet adolescents' increased growth needs as well as activity level such as involvement in sports. Additional guidelines recommend the reduction in added sugars; adolescents consume most of their added sugars in sweetened beverages such as soda and energy and sports drinks (Van Horn, Johnson, Flickinger, et al., 2010). Studies have shown that decreasing the daily intake of sugar-sweetened beverages resulted in significant BMI reductions in children and adolescents (Clabaugh and Neuberger, 2011; Levy, Friend, and Wang, 2011).

Adolescents usually have sufficient intake of protein to meet their needs except for those who limit their food intake because of economic problems or in an attempt to lose weight. There is a substantial increase in the need for the minerals *calcium, iron,* and *zinc* during periods of rapid growth: calcium for skeletal growth, iron for expansion of muscle mass and blood volume, and zinc for the generation of both skeletal and bone tissue. The estimated average requirement (EAR) for calcium in adolescents 14 to 18 years of age is 1100 mg (Institute of Medicine, 2010). Girls with heavy or frequent menses may be especially susceptible to iron deficiency resulting from blood loss. Calcium intake from food sources is essential during adolescence to assist in the prevention of osteoporosis. Eventual bone mass is a balance between the amount of bone laid down during adolescence and the amount later lost with aging. Overall, osteoporosis is a result of polygenic and multiple environmental factors such as nutrition, economics, and exercise (Ongphiphadhanakul, 2007). Dietary intervention should promote the regular consumption of breakfast and a balanced intake of a variety of foods.

Eating Habits and Behavior

Eating and attitudes toward food are primarily family centered during early and middle childhood, and food habits are largely related to cultural and individual family preferences and patterns. With adolescence and the move toward independence, family influences on the child diminish. Children's interests, attitudes, and routines are altered as an increasing number of meals are eaten away from home. These changes are largely a result of the high value that teenagers place on peer acceptability and sociability. Their peers easily influence their eating habits.

Pressure for time and commitments to activities adversely affect teenagers' eating habits. Omitting breakfast or eating a breakfast that is nutritionally poor in quality is frequently a problem. Snacks, usually selected on the basis of accessibility rather than nutritional merit, become increasingly a part of the habitual eating pattern during adolescence (Fig. 35-7). Excess intake of calories, sugar, fat, cholesterol, and sodium is common among adolescents and is found in all income and racial or ethnic groups and both sexes. Inadequate intake of certain vitamins (folic acid, vitamin B_6, vitamin A) and minerals (iron, calcium, zinc) is also evident, particularly among

FIG 35-7 Snacking on empty calories is common among adolescents, especially during inactivity. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

*Dietary Guidelines for Americans, Institute of Medicine, www.health.gov/dietaryguidelines.
†MyPlate, www.choosemyplate.gov.

girls and teenagers of low socioeconomic status. In combination with other factors, these dietary patterns could result in increased risk for obesity and chronic diseases such as heart disease, osteoporosis, and some types of cancer later in life. Maximum bone mass is also acquired during adolescence; therefore the calcium deposited during these years determines the risk for osteoporosis. Milk is usually passed over in favor of soft drinks.

Overeating or undereating during adolescence presents special problems. When they experience the normal increase in weight and fat deposition of the growth spurt, teenage girls often resort to dieting. The desire for a slim figure and a fear of becoming "fat" prompt teenage girls to embark on nutritionally inadequate reducing regimens that drain their energy and deprive their growing bodies of essential nutrients. They resort to diets on their own or with peers in an effort to conform. Many adopt current fad diets and are victims of food misinformation. Boys are less inclined to undereat. They are more concerned about gaining size and strength. However, they tend to eat foods high in calories but low in other essential nutrients.

Obesity is increasing among both children and adolescents in the United States. Poor dietary habits and increasingly sedentary lifestyles have caused this obesity epidemic. Currently 16.9% of children ages 2 to 19 years are obese. The vast majority (90%) of obese adolescents remain obese into their 30s: 94% of women overall and 88% of men (Gordon-Larsen, The, and Adair, 2010).

Health problems traditionally thought of as adult comorbidities of obesity, including type 2 diabetes mellitus, obstructive sleep apnea, and nonalcoholic steatohepatitis, are occurring in adolescents. Lifestyle changes necessary for adolescents to lose weight require the involvement of family members who provide support and encourage active participation.

Hypertension and Hyperlipidemia

As adolescents experience sexual maturation, along with increases in height and weight, blood pressure increases from the onset of adolescence and continues to rise until the end of pubertal growth. This trend is especially apparent among males. Approximately 1% of adolescents have sustained **hypertension,** defined as a blood pressure greater than the 95th percentile of standards. The detection of hypertension during adolescence is important because hypertension is one of the major preventable risk factors for adult cardiovascular disease. With increasing levels of obesity, there have been reports of increasing incidence of hypertension among adolescents (Hansen, Gunn, and Kaelber, 2007; LaRosa and Meyers, 2010). Screening for hypertension and associated risk factors should take place annually beginning at age 3 years. Specific guidelines for monitoring and treatment of hypertension in adolescents are found in the 2011 NHLBI summary report (see also Chapter 42).

Along with hypertension, smoking, and obesity, elevated serum cholesterol and triglyceride levels are major risk factors for the development of adult cardiovascular disease.

The NHLBI (2011) recently issued a recommendation for universal lipid (nonfasting or fasting) screening of all children and adolescents between the ages of 9 and 11 years and again between the ages of 17 and 21 years. Low-density lipoprotein (LDL) cholesterol–lowering drug therapy is recommended for children and adolescents 10 years of age and older whose LDL remains elevated after 6 months to 1 year on a restricted fat diet, lifestyle modification (exercise), and weight management (NHLBI, 2011). Additional information and practice guidelines for monitoring cholesterol levels and initiation of cholesterol–lowering medication as well as specific dietary modifications are found in the 2011 NHLBI summary report at www.nhlbi.nih.gov/guidelines/cvd_ped/summary.htm#chap5.

CARE MANAGEMENT

Adolescents should receive at a minimum an annual assessment of weight, height, and BMI for age plotted on a standard growth chart. Healthy dietary habits should be discussed with all adolescents. The frequency of eating at fast-food and other restaurants, consumption of sweetened beverages, and consumption of excessive portion sizes should be identified. In addition to food intake, the nurse should assess the level of physical activity, sedentary behaviors, and sleep patterns. Readiness to change; environmental supports and barriers; and family history of diabetes, heart disease, and early stroke must be considered when planning nutritional education and guidance. Nurses in the school setting can assist in advocating for comprehensive nutritional services for preschool through grade 12 students.

Sleep and Rest

Teenagers vary in their need for sleep and rest. Rapid physical growth, the tendency toward overexertion, and the overall increased activity of this age contribute to fatigue in adolescents. During growth spurts, the need for sleep is increased. Their propensity for staying up late makes it difficult to arise in the morning, and they may sleep late at every opportunity. Adequate sleep and rest at this time are important to a total health regimen.

Exercise and Activity

Although today's youth are less fit than children 20 years ago, adolescents probably spend more time and energy practicing and participating in sports activities than members of any other age-group. Many adolescents participate in sports within school settings (Fig. 35-8). School-based, health-oriented physical education may provide both immediate effects of the activity and sustained effects

FIG 35-8 Adolescents should be encouraged to participate in activities that contribute to lifelong physical fitness. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

through encouragement of lifelong activity patterns. High schools continue to cut physical education classes, with only half of high school students attending physical education classes in 2011. Fewer than half of students (31.5%) attended these classes daily, and the majority of classes included only 20 minutes of exercise (CDC, 2012b). To improve health outcomes, school-age children and adolescents should engage in 60 minutes or more of moderate to vigorous physical activity daily (U.S. Department of Health and Human Services, 2008b).

The practice of sports, games, and even dancing contributes significantly to growth and development, the education process, and better health. These activities provide exercise for growing muscles, interactions with peers, and a socially acceptable means of enjoying stimulation and conflict. In addition, competitive activities help teenagers in the process of self-appraisal and the development of self-respect and concern for others. Because physical fitness appears to be a major influence on one's lifelong health status, children should be encouraged to participate in activities that contribute to lifelong physical fitness. Nurses can encourage participation as a way to promote health and build self-esteem. However, adolescents should not be encouraged to engage in physical activities that are beyond their physical or emotional capacity (see Sports Participation and Injury, Chapter 48).

Dental Health

Dental health should not be neglected during adolescence, although the rate of caries formation is not as great as in childhood. Dental care is an aspect of preventive care that is not received by substantial proportions of children in the United States. It is recommended that an evaluation for caries takes place at a minimum of every year and optimally at 6-month intervals. Pit and fissure sealants are a safe and effective technique for dental caries prevention. Early adolescence is usually when corrective orthodontic appliances are worn, and these are frequently a source of embarrassment and concern to teens. Reassurance regarding the temporary nature of the annoyance and anticipation of an improved appearance help adolescents tolerate the inconvenience. It is also important to reinforce the orthodontist's directions regarding use and care of the appliances and to emphasize careful attention to toothbrushing during this time (see also Chapters 32 and 33). During late adolescence, the third molars (wisdom teeth) should be evaluated to determine appropriate management (American Academy of Pediatric Dentistry, 2012).

Personal Care

Body-conscious teenagers are highly amenable to discussion and counseling about personal care and hygiene. Body changes associated with puberty bring special needs for cleanliness. The hyperactive sebaceous glands and newly functioning apocrine glands make frequent bathing or showering a necessity, and underarm deodorants assume an important place in personal care. Adolescents discover that hair requires more frequent shampooing, and girls often have questions about hair removal, use of cosmetics, and menstrual hygiene. Peer-group discussions center on the advantages of particular products or methods. Adolescents are continually bombarded with messages from the media regarding the best way to enhance their popularity and attractiveness. Nurses are in a position to help them evaluate the relative merits of commercial products.

Vision

Regular vision testing is an important part of health care and supervision during adolescence. During adolescence, visual refractive difficulties reach a peak that is not exceeded until the fifth decade of life. The increased demands of schoolwork make adequate vision essential for academic success. Consequently, teenagers are more likely to be referred for visual evaluation. The need for corrective lenses can create psychologic problems for teenagers if they believe that glasses spoil their appearance or do not fit their body image. Contact lenses may be a preferred solution; a variety of lenses are now available at fairly reasonable prices. For some, the impact of a visual defect, no matter how slight, may be stressful.

Hearing

Considerable concern has focused on current teenage practices that damage hearing. Cochlear damage from relatively continuous exposure to the loud sound levels of rock music has been documented. The popularity of personal music players with lightweight earphones that are inserted into the ear canal is of particular concern to health care professionals. When these units are used for extended periods, permanent hearing loss can occur. Although appeals for more judicious use are not always successful, teenagers should be informed of the risk. (See Chapter 37 for a discussion of noise-related hearing loss.)

Posture

Many adolescents demonstrate altered posture. Rapid skeletal growth is often associated with slower muscular growth, and as a result, some teenagers may appear awkward or slump and fail to stand or sit upright. However, some postural defects of adolescence require early medical intervention. Scoliosis is a defect of the spine that occurs frequently in adolescence and is more common in girls than in boys (see Idiopathic Scoliosis, Chapter 48). The majority of cases are idiopathic, and the defect manifests as a painless curvature of the spine. Fortunately, most of these spinal curvatures will not require treatment. However, because there is no way to predict which curvatures will progress, all curvatures of the spine should be referred for further evaluation.

Body Art

Body art (piercing and tattooing) is an aspect of adolescent identity formation. The skin has become the latest source of parent-adolescent conflict. Adolescents often seek body art as an expression of their personal identity and style. Tattoos may mark significant life events such as new relationships, births, and deaths. Piercing the ear, nose, nipple, eyebrow, labia, navel, penis, or tongue may sometimes create a health problem. It is a nursing responsibility to caution girls and boys against having piercing performed by friends, parents, or themselves. Although in most cases piercings have few, if any, serious side effects, there is always a risk for complications such as infection, cyst or keloid formation, bleeding, dermatitis, or metal allergy. Using the same unsterilized needle to pierce body parts of multiple teenagers presents the same risk for human immunodeficiency virus (HIV), hepatitis C virus, and hepatitis B virus transmission as occurs with other needle-sharing activities. A recent report highlighted the danger of contaminated tattoo ink, which occurred in association with an outbreak of nontuberculous *Mycobacterium chelonae* skin infections (Kennedy, Bedard, Younge, et al., 2012).

A qualified operator using proper sterile technique should perform the procedure. This is especially important if an adolescent has a history of diabetes, allergies, or skin disorders. Adolescents should be informed about the approximate time for healing after body piercing and the care of the pierced area during and after healing. Some body sites need extra precautions. For example,

cartilage (ear, nose) has a poor blood supply and heals slowly and scars easily; nipple piercing puts adolescents at risk for breast abscesses. Finally, migration of the piercing is common with naval and other flat skin surface piercing. Piercing guns should not be used for piercing anything other than the earlobe because guns place the piercing too deeply.

The presence of body art in the form of tattoos and branding is common among adolescents and young adults. Professionals as well as amateur artists administer tattoos. The risk to adolescents receiving tattoos is low. The greatest risk is for the tattoo artist, who comes in contact with the client's blood. Adolescents who are amateur tattoo artists benefit from discussions about Standard Precautions and the hepatitis B vaccination. Many states either have no regulations or do not enforce existing regulations of piercing and tattooing facilities. The local health department is a source of information about local regulatory requirements. The Centers for Disease Control and Prevention (CDC) has an excellent website that outlines safety concerns for persons performing and receiving body art (http://www.cdc.gov/niosh/topics/body_art/).

Tanning

The quest for an attractive appearance leads many teenagers to excessive sunbathing and artificial means for tanning. However, this practice has serious long-term risks, and adolescents should be educated regarding the detrimental effects of sunlight on the skin (see Sunburn, Chapter 47). Long-term effects include premature aging of the skin; increased risk for skin cancer; and, in susceptible individuals, phototoxic reactions.

The increasing popularity of artificial tanning has prompted concern from health care professionals regarding the use of sunlamps and tanning machines. The long-term effects of tanning machines are similar to those of the sun; dermatologists do not recommend tanning by this means. Those who insist on using tanning equipment should be warned that goggles must be worn in tanning booths to prevent serious corneal burning. Education on the use of sunscreens, including hypoallergenic products, with a sun protective factor (SPF) of at least 15 and a nonalcohol base without lanolin, parabens, or fragrance, is important. Broad-spectrum sunscreens that protect against both ultraviolet A and ultraviolet B (UV-A and UV-B) are the most effective. Self-tanning creams safely simulate the appearance of a tan; however, teens using these products should be cautioned that sun protection is still required. Targeting health education messages to adolescents and incorporating educational components relating to sun protection behaviors in school health curricula and in health care visits will increase adolescents' knowledge and awareness.

Stress Reduction

The multiple changes occurring in adolescence can result in great stress (Fig. 35-9 and Box 35-3). Adolescents are faced with pressures from peers that often involve taking serious health risks, including pressures for sexual experimentation; use of drugs, alcohol, and cigarettes; and potentially dangerous physical activities.

Early-maturing girls and late-maturing children are especially sensitive to the stresses of being different from their peers. Many feel intense anxiety over their identity. Both early- and late-maturing children feel out of place among their classmates, but slow-maturing children appear to experience the most pronounced inner turmoil and may be hesitant to voice their concerns. Slow-maturing adolescents need support and reassurance that they are not abnormal and need only be patient until the time comes when they, too, will mature physically.

FIG 35-9 Adolescents use being alone as a method of coping with stress. Health care professionals need to assess whether this indicates clinical depression. (Copyright © 2011 Photos.com, a division of Getty Images. All rights reserved.)

BOX 35-3 AREAS OF STRESS IN ADOLESCENCE

- Body image
- Sexuality conflicts
- Scholastic pressures
- Competitive pressures
- Relationships with parents
- Relationships with siblings
- Relationships with peers
- Dating
- Finances
- Decisions about present and future roles
- Career planning
- Ideologic conflicts

Sexuality Education and Guidance

The average American teenager spends more than 7 hours every day in front of some type of medium. This potentially exposes them to unrealistic sexual messages and images, usually without adult supervision or interaction. Research has demonstrated that adolescents whose parents limit their television viewing are less likely to engage in earlier sex (American Academy of Pediatrics [AAP] Council on Communications and Media, 2010). In addition, social media use is a routine part of contemporary adolescents' daily lives, and there are many positive benefits including enhancing communication, social connection, and computer skills. However, some evidence indicates that there are often online expressions of sexual experimentation, including sending and receiving sexually explicit messages, photographs, or images via cell phones and computers (O'Keeffe and Clarke-Pearson, 2011). All media sources provide adolescents potential exposure to information that may be inaccurate, riddled with cultural and moral judgments, and not very helpful.

The responsibility for providing sexuality education has been assumed by parents; schools; churches; community agencies such as Planned Parenthood Federation of America, Inc.;* and health care professionals, especially nurses. Many adolescents perceive nurses, especially school nurses, as individuals who possess important information and who are willing to discuss sex with them. To be able to discuss the topic adequately, nurses must have not only an understanding of the physiologic aspects of sexuality and a knowledge of cultural and societal values but also an awareness of their own attitudes, feelings, and biases about sexuality.

*434 West 33rd St., New York, NY 10001; 800-230-PLAN (7526); www.plannedparenthood.org.

Comprehensive information about sexuality education is offered by the Sexuality Information and Education Council of the United States (SIECUS)* and the Sex Information and Education Council of Canada.† The SIECUS maintains that every sexuality education program should present the topic from six aspects, including biologic, social, health, personal adjustments and attitudes, interpersonal associations, and the establishment of values.

Whether nurses counsel young people on an individual basis, in mixed groups, or in groups segregated by gender makes little difference. Ideally, boys and girls should be able to discuss sexuality objectively with one another and in groups, but this is not always possible. The differences in the rate of maturation between boys and girls and among different members of the same sex often make it desirable to discuss certain aspects of sexuality in segregated groups for early adolescents. As a rule, the need for separate discussion groups diminishes as young people mature.

Sexuality education should consist of instruction concerning normal body functions and should be presented in a straightforward manner using correct terminology. When discussing sex and sexual activities, nurses should use simple but correct language—not street language, highly scientific terminology, or evasive jargon. After they understand the meaning of biologic terms such as uterus, testicles, and vagina, most teenagers prefer to use them in their discussions.

Many girls arrive at menarche with ambivalent attitudes, myths, and illogical beliefs. Even girls adequately prepared for menstruation do not always understand its relationship to the total process of reproduction. Many are under the incorrect impression that the "safe" time for sexual intercourse is midway between menstrual periods.

Teenagers' curiosity and desire for information extend beyond the need for anatomic and physiologic knowledge. They need to know more than the mechanics of conception, pregnancy, and birth. Adolescents, girls in particular, want answers to questions such as: "What is it like?" "Does it hurt?" "What happens when …?" and "Is it all right if you …?" Boys are often concerned about the fallacy that a relationship exists between penis size and sexual function. They need reassurance that masturbation is a normal and common practice, that some degree of homosexuality in early adolescence is not unusual, and that oral-genital relations can be normal substitutes for intercourse.

Teenagers need to discuss intercourse, alternative methods of sexual satisfaction, and how to resist peer pressure. With the increased incidence of sexually transmitted infections, especially HIV infection, the topic of "safe sex," especially abstinence or the use of condoms, is essential. Role playing can help teenagers learn effective approaches to dealing with difficult situations. Sex and sexuality cannot be taught without discussions of mature decision making, sexual responsibility, and values clarification. Adolescents may receive inaccurate and ambiguous messages regarding sexual behavior; for example, an adolescent may be told that abstinence from vaginal intercourse will prevent transmission of a sexually transmitted infection. Accurate and unbiased information regarding sexual practices should be provided in a setting wherein the adolescent feels comfortable asking questions without being degraded or made to feel uncomfortable for seeking information.

Adolescents need role models and life experiences with delayed gratification. Most important, they need problem-solving experience and decision-making skills so they can anticipate the positive and negative outcomes of their decisions. With this type of assistance, teenagers can become sexually responsible young adults (see also Contraception, Chapter 5).

Safety Promotion and Injury Prevention

Physical injuries are the greatest single cause of death in the adolescent age-group and claim more lives than all other causes combined. The most vulnerable ages are the years 15 to 24 years, when accidental injuries account for a significant percentage of fatalities. Motor-vehicle traffic-related deaths decreased 41% during the years 2000 to 2009 among adolescents ages 15 to 19 years, yet these accidents account for the leading cause of unintentional injury among persons from birth to 19 years of age (CDC, 2012a).

During adolescence, peak physical, sensory, and psychomotor function give teenagers a feeling of strength and confidence that they have never experienced before, and the physiologic changes of puberty give impetus to many basic instinctual forces. One manifestation of this is an increase in energy that simply must be discharged through action, often at the expense of logical thinking and other control mechanisms. Their propensity for risk-taking behavior plus feelings of indestructibility makes adolescents especially prone to injuries. Some of the developmental characteristics of teenagers and injury prevention suggestions are outlined in Box 35-4.

Motor Vehicle–Related Injuries

Adolescents' newly acquired ability to drive and the normal developmental need for independence and freedom make automobiles an attractive part of their lives. Motor vehicle crashes are the single greatest source of unintentional injury and death in young people in the United States. Many factors contribute to the higher rate of crashes among young drivers, including lacking driving experience and maturity, following too closely, driving too fast, having other teen passengers in the car, texting or answering a cell phone while driving, and driving under the influence of alcohol. Young drivers' elevated crash risk is highest between ages 16 and 17 years but persists through age 19 or 20 years. These data lend support to efforts in the United States to delay full licensure beyond age 16 years. There is also evidence that graduated licensing systems that phase in unsupervised driving in higher risk situations such as nighttime driving and having passengers in the car are effective in decreasing the motor vehicle crash risk for adolescents (McCartt, Mayhew, Braitman, et al., 2009).

There has been recent attention on distracted teenage driving and cell phone talking or texting while driving. Studies have shown that drivers using handheld devices are considerably more distracted and spend less time looking at the road or paying attention to driving conditions (Hosking, Young, and Regan, 2009; Owens, McLaughlin, and Sudweeks, 2011). According to the 2011 Youth Risk Behavior Surveillance, 32.8% of adolescents nationwide reportedly texted or e-mailed while driving a car or other vehicle at least 1 day during a 30-day period before the survey (CDC, 2012b).

Nurses should educate teenagers and their parents about the risk of driving while drinking alcohol or of riding in an automobile with a drunk driver. Many families arrange a no-questions-asked ride home to prevent an adolescent from riding with a drunk driver. Families should also require adolescents to log several hours of supervised practice driving before taking the car out alone. Educational efforts should also discuss that the major risk for death in a motor vehicle accident is failure to use a safety restraint.

Other Vehicle Injuries. The increasing use of motorcycles, all-terrain vehicles, jet skis, and snowmobiles has caused an increase in

BOX 35-4 INJURY PREVENTION DURING ADOLESCENCE

Developmental Abilities Related to Risk for Injury

- Need for independence and freedom
- Testing independence
- Age permitted to drive a motor vehicle (varies)
- Inclination for risk-taking behaviors
- Feeling of indestructibility
- Need for discharging energy, often at expense of logical thinking and other control mechanisms
- Strong need for peer approval
- Desire to attempt hazardous feats
- Peak incidence for practice and participation in sports
- Access to more complex tools, objects, and locations
- Can assume responsibility for own actions

Injury Prevention

Pedestrian

- Emphasize and encourage safe pedestrian behavior:
  - At night, walk with a friend.
  - If someone is following you, go to nearest place with people.
  - Do not walk in secluded areas; take well-traveled walkways.

Motor or Nonmotor Vehicles

- Passenger—Promote appropriate behavior while riding in a motor vehicle.
- Driver—Provide competent driver education; encourage judicious use of vehicle; discourage drag racing on regular streets, "playing chicken"; discourage text messaging; maintain vehicle in proper condition (brakes, tires, etc.).
- Teach and promote safety and maintenance of two-wheeled vehicles.
- Encourage wearing of safety apparel such as helmet, long trousers.
- Reinforce the dangers of drugs, including alcohol, when operating a motor vehicle.

Falls

- Teach and encourage general safety measures in all activities.

Drowning

- Teach nonswimmer to swim.
- Teach basic rules of water safety:
  - Judicious selection of place to swim
  - Sufficient water depth for diving
  - Swimming with companion
  - Wear life vest with water sports (e.g., boating, skiing)
  - Avoid swimming, boating, or other water sports after or during alcohol consumption

Burns

- Reinforce proper behavior in areas involving contact with burn hazards (gasoline, electric wires, fires).
- Advise regarding excessive exposure to natural or artificial sunlight (ultraviolet burn).
- Discourage smoking.
- Encourage use of sunscreen.

Poisoning

- Educate in hazards of drug use, including alcohol.

Bodily Damage

- Promote acquisition of proper instruction in sports and use of sports equipment.
- Instruct in safe use of and respect for firearms and other devices with potential danger (e.g., power tools, fireworks).
- Provide and encourage use of protective equipment when using potentially hazardous devices (e.g., motorcycles, power tools) or when engaging in sports activities such as skate boarding.
- Promote access to and/or provision of safe sports and recreational facilities.
- Be alert for signs of depression (potential suicide).
- Instruct regarding proper use of corrective devices (e.g., glasses, contact lenses, hearing aids).
- Encourage and foster judicious application of safety principles and prevention.

injuries among young people who are below the legal age for driving automobiles. Many adolescents ride bicycles without helmets and without lights at night, and the overwhelming majority of deaths from bicycle injuries (primarily head injuries) involve teenagers. In-line skating and skateboarding without protective gear also contribute to a significant number of traumatic brain injuries in U.S. adolescents and young people.

Firearms

Firearms are the major cause of intentional fatal injuries in the United States. Adolescence is the peak age for being either a victim or an offender in an injury involving a firearm. Gun carrying among adolescents is on the rise and is not limited to the stereotypic inner-city youth. Family members and acquaintances are a common source of guns for young people. Gun availability in the home is strongly linked to unintentional death and injury to children (Glatt, 2005). In addition, the presence of a gun in the home increases the risk for adolescent suicide and homicide. All families should be assessed for the presence of a gun in the home and informed of this risk. They must take preventive action to ensure that the guns are never loaded, that guns are locked up in a safe place, and that ammunition is stored and locked up separately in a location accessible only to appropriate adults.

Sports Injuries

Because the degree of physical maturation, size, coordination, and endurance varies greatly among adolescents of the same age, sports competition among young people who differ greatly in strength and agility is unfair and hazardous. Matching candidates for sports should be done relative to physical maturity, height, weight, and physical fitness and skills, particularly in sports involving rigorous body contact. Age is a less important consideration.

Every sport has some potential for injury, whether one participates in serious competition or engages in the activity for pure enjoyment. Overuse injuries are common in adolescents and result in more time missed from the activity than fractures. The increase in strength and vigor in adolescence may tempt adolescents to overextend themselves. Injuries sustained in sports or recreational activities can involve any part of the body and range from relatively minor cuts, bruises, and abrasions to totally incapacitating central nervous system injuries or death. Recently attention has focused on traumatic brain injuries resulting from concussions incurred in contact sports.

CARE MANAGEMENT

Safety promotion and injury prevention is an ongoing part of nursing responsibility throughout the teenage years. Anticipatory

guidance to parents and children regarding the expected problems and hazards related to growth and development does not end as adolescents approach maturity. They need education in basic safety precautions, instruction in skills required in the performance of activities such as sports, instruction in handling motor vehicles, and information about using proper protective equipment and properly maintaining equipment. During adolescence, however, health and safety education and guidance are more effective when the young people are involved directly. Parents and health care professionals can emphasize the importance of safety during performance of activities and the proper conditioning and preparation for sports.

Prevention can occur on a variety of levels. Safety advocacy, public policy changes, and legislation can curtail injuries. Examples of such approaches are laws that mandate wearing seat belts, prohibiting handheld cell phone usage while the car is in motion, using helmets while driving moving vehicles other than automobiles, keeping the legal drinking age at 21 years, and instituting curfews for teen drivers. In addition to improvements in the environment, health education for teenagers and significant adults is essential. Helping adolescents understand their need for engaging in risky behavior, exploring possible negative outcomes, and weighing possible alternatives are critical components of injury prevention.

Anticipatory Guidance—Care of Families

Both adolescents and their parents are often confused and perplexed about the changes and behavior of this stage of development. Parents need support and guidance to help them through this period. They need to understand the changes taking place and to accept the expected behaviors that accompany the process of detachment. Parents may need help to "let go" and to promote the changed relationship from one of dependence to one of mutuality (see Patient Teaching box).

PATIENT TEACHING

Guidance During Adolescence

Encourage Parents to:

- Accept adolescent as a unique individual
- Respect adolescent's ideas, likes and dislikes, and wishes
- Be involved with school functions and attend adolescent's performances, whether it be a sporting event or a school play
- Listen and try to be open to teenager's views, even when they disagree with parental views
- Avoid criticism about no-win topics
- Provide opportunity for choosing options and accept natural consequences of these choices
- Allow young person to learn by doing, even when choices and methods differ from those of adults
- Provide adolescent with clear, reasonable limits
- Clarify house rules and consequences for breaking them
- Let society's rules and consequences teach responsibility outside the home
- Allow increasing independence within limitations of safety and well-being
- Be available but avoid pressing teenager too far
- Respect adolescent's privacy
- Try to share adolescent's feelings of joy or sorrow
- Respond to feelings, as well as words
- Be available to answer questions, give information, and provide companionship
- Try to make communication clear
- Avoid comparisons with siblings
- Assist adolescent in selecting appropriate career goals and preparing for adult role
- Welcome adolescent's friends into the home and treat them with respect
- Provide unconditional love
- Be willing to apologize when mistaken

Be Aware That Adolescents:

- Are subject to turbulent, unpredictable behavior
- Are struggling for independence
- Are trying to establish their own identity separate from parents and family
- Are extremely sensitive to feelings and behavior that affect them
- May receive a different message from what was sent
- Consider friends extremely important
- Have a strong need to belong to a peer group of friends and not necessarily to family (except in certain circumstances)

SPECIAL HEALTH PROBLEMS

DISORDERS OF THE FEMALE REPRODUCTIVE SYSTEM

Disorders related to the female reproductive system such as amenorrhea and dysmenorrhea are discussed in Chapter 4. Sexually transmitted infections are also discussed in Chapter 4.

DISORDERS OF THE MALE REPRODUCTIVE SYSTEM

Many obvious anomalies, such as hypospadias, hydrocele, phimosis, and cryptorchidism, are identified with corrective measures instituted during early childhood. The most frequent problems related to the reproductive organs in later childhood are:

- Infections, such as urethritis (see Urinary Tract Infection, Chapter 44)
- Hematuria
- Penile problems, such as nonretractable foreskin in uncircumcised males, drug-induced priapism, carcinoma, and trauma
- Scrotal conditions, such as varicocele (elongation, dilation, and tortuosity of the veins superior to the testicle)
- Testicular torsion (a condition in which the testicle hangs free from its vascular structures, which can result in partial or complete venous occlusion with rotation)

Tumors of the testes are not common (≈8000 cases per year in the United States [Feldman, Bosl, Sheinfeld, et al., 2008]), but when manifested in adolescence, they are generally malignant and demand immediate evaluation. Testicular cancer is the most common solid tumor in adolescent boys and men 15 to 34 years of age. The usual presenting symptom for testicular cancer is a heavy, hard mass (either smooth or nodular) that is palpated on the testis; approximately 40% of men present with a painful mass. If a firm swelling is noted, the adolescent should be evaluated by ultrasonography and immediately referred for direct biopsy if the mass is found to be solid.

Treatment involves surgical removal of the affected testicle (orchiectomy) and adjacent lymph nodes (if affected) and possibly chemotherapy and radiation following surgery. Fertility may be regained after chemotherapy and surgery; however, sperm banking before the initiation of chemotherapy is recommended. Assisted

CRITICAL THINKING CASE STUDY

Testicular Self-Examination

At a recent faculty meeting, Paul, the pediatric nurse practitioner who runs the school-based health clinic, presented his plan for a class on testicular self-examination (TSE) to be delivered to the sophomore boys. Several teachers questioned the value of providing such a class when there is limited time to deliver content relating to "routine academic subjects." What important issues regarding testicular cancer and TSE should Paul use to justify providing this class to the sophomore boys?

1. Evidence—Is there sufficient evidence to justify teaching sophomore boys about TSE?
2. Assumptions—Describe the underlying assumption about each of the following:
   a. Detection of testicular cancers in adolescence
   b. Usual presenting symptom of testicular cancer
   c. Knowledge of genital anatomy among adolescent boys
   d. Ways to teach adolescent boys about their anatomy
3. What priorities and implications for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

reproduction is also an option, and successful paternity is reported to be between 50% and 85% (Feldman, Bosl, Sheinfeld, et al., 2008). Recurrence of testicular cancer in the contralateral testis may occur; therefore follow up is essential.

CARE MANAGEMENT

Adolescent boys are also self-conscious about their changing bodies and need preparation for a genital examination. The most successful approach is to assume a matter-of-fact attitude toward the examination, explain precisely what will take place, and maintain a continuous commentary about what is being done and the findings at each phase of the examination.

The routine health assessment of every adolescent boy should include teaching about testicular cancer and how to perform a testicular self-examination (TSE) every month. This rare malignancy is curable if detected early. Nurses are in an ideal position to teach TSE in a manner that is respectful of the adolescent boy's anxieties and that promotes early treatment (see Critical Thinking Case Study).

In the TSE, each testicle is examined individually, preferably after a warm bath or shower when scrotal skin is more relaxed, using the thumbs and fingers of both hands and applying a small amount of firm, gentle pressure. The normal testicle is a firm organ with a smooth, egg-shaped contour; the epididymis is palpated as a raised swelling on the superior aspect of the testicle and should not be taken for an abnormality.

Gynecomastia

Male breasts, although not strictly part of the male reproductive system, respond to hormonal changes. Some degree of bilateral or unilateral breast enlargement occurs frequently in boys during puberty. It is estimated that approximately half of adolescent boys have transient gynecomastia, usually lasting less than 1 year, which subsides spontaneously with achievement of male development. A careful assessment of the pubertal stage at the onset of gynecomastia; medication history, including anabolic steroids; and the exclusion of renal, liver, thyroid, and endocrine disorders or dysfunction allow the examiner to reassure the adolescent that the changes are pubertal gynecomastia and that no further assessment is indicated. Gynecomastia may also be drug induced; calcium channel blockers, cancer chemotherapeutic agents, histamine$_2$-receptor blockers, and oral ketoconazoles have all been shown to cause the condition.

If the condition persists or is extensive enough to cause embarrassment or excessive stress in the young boy, plastic surgery may be indicated for cosmetic and psychologic considerations. Administration of testosterone has no effect on breast development or regression and may aggravate the condition.

CARE MANAGEMENT

Treatment of gynecomastia usually consists of assurance to the adolescent and his parents that this is a benign and temporary situation. A physical examination with palpation is necessary to differentiate gynecomastia from increased adiposity caused by being overweight. Adolescents who are distressed about physical integrity and masculinity may benefit from the knowledge that this condition occurs in more than 50% of all adolescent boys.

NUTRITIONAL AND EATING DISORDERS

Obesity

Few problems in childhood and adolescence are so obvious to others, are so difficult to treat, and have such long-term effects on health as obesity. Several different definitions have been proposed for obesity and overweight. Obesity has been defined as an increase in body weight resulting from an excessive accumulation of body fat relative to lean body mass. Overweight refers to the state of weighing more than average for height and body build. Currently, the body mass index (BMI) measurement is recommended as the most accurate method for screening children and adolescents for obesity. The BMI measurement is strongly associated with subcutaneous and total body fat and with skinfold thickness measurements. It is also highly specific for children with the greatest amount of body fat. Pediatric growth charts that include BMI for age and sex are available from the CDC.* Children with a BMI between the 85th and 95th percentiles are considered overweight, and obesity is defined by a BMI greater than or equal to the 95th percentile (Gahagan, 2011).

Regardless of the definition used, the number of overweight children in the United States is increasing and has reportedly reached epidemic status (Spruijt-Metz, 2011). Approximately 12.5 million children are overweight or obese (Ogden, Carroll, and Flegal, 2008). Numerous studies dating back to the early 1960s have documented childhood overweight through comprehensive evaluations of dietary intake, physical activity, and anthropometric measures (CDC using the various National Health and Nutrition Examination Surveys [NHANES], I, II, III, and IV) (Ogden, Carroll, and Flegal, 2008; Ogden, Kuczmarski, Flegal, et al., 2002; Ogden, Troiano, Briefel, et al., 1997). In children ages 6 to 11 years, the prevalence of childhood overweight remained fairly constant in between 1963 and 1974 at approximately 4% and 5.5%, respectively. However, more recent NHANES surveys have seen these numbers steadily climb to reach 17% in 2- to 19-year-old children. Between 1999/2000 and 2009/2010, a significant increase in obesity was observed in males 2 to 19 years of age but not in females of the same age (Ogden, Carroll, Kit, et al., 2012). African-American and Hispanic children are disproportionately represented by a higher

*www.cdc.gov/growthcharts.

prevalence of overweight and obesity (23.1% and 21.0%, respectively) compared with non-Hispanic white children (15.9%) (Ogden, Carroll, and Flegal, 2008). A study of 9464 Native-American schoolchildren ages 5 to 18 years found that 39% were overweight, and a further review of tribes across the United States found that 30% to 46% of Native Americans were at risk for overweight (Hardy, Harrell, and Bell, 2004).

Because adult obesity is associated with increased mortality and morbidity from a variety of complications, both physical and psychologic, adolescent obesity is a serious condition. Research indicates that overweight children and adolescents are at risk for continuing to be obese as adults, thereby experiencing the health and social consequences of obesity much earlier than children and adolescents of normal weight. Parental obesity increases the risk for overweight by twofold to threefold (Baker, Barlow, Cochran, et al., 2005). The probability that overweight school-age children will become obese adults is estimated at 50%, and the likelihood that overweight adolescents will become obese adults is estimated at 70% to 80% (National Institute for Health Care Management Foundation, 2003).

Obesity in childhood and adolescence has been related to elevated blood cholesterol, high blood pressure, respiratory disorders, orthopedic conditions, cholelithiasis, some types of adult-onset cancer, nonalcoholic fatty liver disease (NAFLD), and type 2 diabetes mellitus. The incidence of metabolic syndrome was 50% in a study group of overweight and obese adolescents (Weiss, Dziura, Burgert, et al., 2004). Common emotional consequences of obesity include poor body image, low self-esteem, social isolation, and feelings of depression and rejection (Sjöberg, Nilsson, and Leppert, 2005).

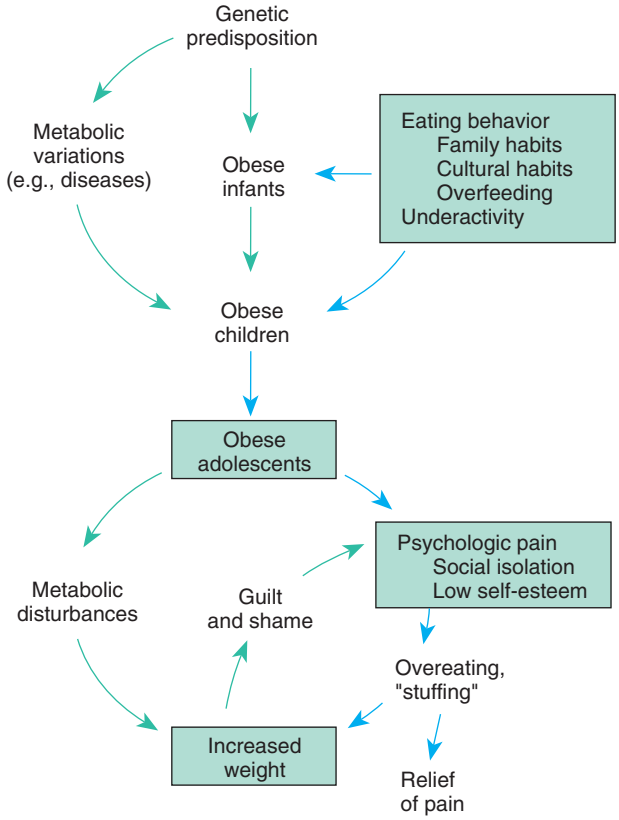

FIG 35-10 Complex relationships in obesity.

Etiology and Pathophysiology

Obesity results from a caloric intake that consistently exceeds caloric requirements and expenditure and may involve a variety of interrelated influences, including metabolic, hypothalamic, hereditary, social, cultural, and psychologic factors (Fig. 35-10). Because the etiology of obesity is multifactorial, the treatment requires multilevel interventions.

A balance between energy intake and energy expenditure is a critical factor in regulating body weight. Factors that raise energy intake or decrease energy expenditure by even small amounts can have a long-term impact on the development of overweight and obesity. For example, a positive balance of one serving of a sweetened juice or soft drink (≈120 kcal) per day would produce a 50-kg (110-pound) increase in body mass over a 10-year period (Hill, Wyatt, Reed, et al., 2003).

Familial influence is an epidemiologic consideration in regard to children's weight. Twin studies suggest that approximately 35% to 50% of the tendency toward obesity is inherited (Beaty, 2007). Twin studies have also suggested that this tendency is a combination of genetic and environmental factors. Mothers seem to play a greater role in the gestational weight of their children (Jaquet, Swaminathan, Alexander, et al., 2005). When both parents are obese, there is a 60% to 80% increase in the likelihood of the child becoming obese (Koeppen-Schomerus, Wardle, and Plomin, 2001; Wardle, Carnell, Haworth, et al., 2008). The specific influences of genes and environment within developing children are not well defined. The increasing rates of obesity within genetically stable populations suggest that environmental and some perinatal factors (e.g., bottle feeding) are contributors to the current increases in childhood obesity (National Institute for Health Care Management Foundation, 2003).

Birth weight does not seem to be a long-term contributing factor in detection and prediction of childhood obesity (Kain, Corvalán, Lera, et al., 2009; McCarthy, Hughes, Tilling, et al., 2007); obese children do not have higher birth weights than nonobese children. There is, however, a high correlation between childhood adiposity and parental adiposity (Boney, Verma, Tucker, et al., 2005; Bouchard, 2009; Li, Kaur, Choi, et al., 2005). One study found that the best determinant of adult obesity was the child's weight at 5 years of age or an increased weight gain from 1 to 5 years of age (McCarthy, Hughes, Tilling, et al., 2007).

Fewer than 5% of the cases of childhood obesity can be attributed to an underlying disease. Such diseases include hypothyroidism; adrenal hypercorticoidism; hyperinsulinism; and dysfunction or damage to the central nervous system (CNS) as a result of tumor, injury, infection, or vascular accident. Obesity is a frequent complication of muscular dystrophy, paraplegia, Down syndrome, spina bifida, and other chronic illnesses that limit mobility.

A major focus of obesity research has been on appetite regulation. The expression of appetite is chemically coded in the hypothalamus by distinctive circuitry. Orexigenic substances produce signals that promote eating behaviors, and anorexigenic substances promote the cessation of eating behaviors. Feedback loops between signals have been identified where one signal peptide is able to alter the secretion of another signal peptide. No one signal has been identified as the gatekeeper of appetite. It is apparent that an entire network of signals, including their frequency and amplitude, is responsible for triggering eating behaviors.

There is little evidence to support a relationship between obesity and "low metabolism." Small differences may exist in regulation of dietary intake or metabolic rate between obese and nonobese children that could lead to an energy imbalance and inappropriate weight gain, but these small differences are difficult to accurately quantify. No differences in basal metabolic rate, sleeping metabolic

rate, respiratory quotient, heart rate, or total energy expenditure have been found in normal weight children with or without a familial predisposition to overweight (Baker, Barlow, Cochran, et al., 2005). Whereas in childhood, overeating is the dominant feature in obesity, in adult life, reduced physical activity with normal intake is more likely.

The tendency toward obesity is manifested whenever environmental conditions are favorable to excessive caloric intake, such as an abundance of food, limited access to low-fat foods, reduced or minimal physical activity, and snacking combined with excessive television viewing. Family and cultural eating patterns, as well as psychologic factors, play important roles; many families and cultures consider fat to be an indication of good health. It is common for obese children to have families that emphasize large meals or admonish children for leaving food on their plates. Parents may have an exaggerated concept of the amount of food children require and expect them to eat more than they need. The prevalence of obesity shows a marked difference between children in upper-socioeconomic groups and lower-socioeconomic groups, with the differences often becoming apparent before 6 years of age. Lower socioeconomic groups have a greater prevalence of obesity, especially in girls. Physical activity may also be influenced by sociocultural factors.

Some community factors that influence activity patterns include unsafe neighborhoods that keep children from playing outside. Many communities lack affordable and accessible areas for low-income youth to be active, thus limiting opportunities for young people to participate in physical activities. Social policies also contribute to obesity. The increased availability of high-fat foods, pricing strategies that promote unhealthy food choices, and overzealous food advertising that targets children and adolescents with high-fat and high-sugar foods are some examples.

Institutional factors also influence patterns of obesity and decreased physical activity. Many school policies allow students to leave school for lunch. Vending machines in school often are filled with high-fat and high-calorie foods and soft drinks. Although well-balanced, nutritious school lunches may be available to students, they often opt for less nutritious choices such as high-fat snacks.

Physical inactivity has also been identified as an important contributing factor in the development and maintenance of childhood overweight. There is little doubt that physical activity has decreased in elementary and secondary schools in the United States in past years. Although there have been positive attempts to incorporate more physical activity into schools within the past several years, most of children's physical activity must occur within the family or outside of school. Decreased physical activity within the family is a powerful influence on children because children imitate their parents and other adults. Parental obesity and low levels of physical activity are correlated with decreased physical activity in children.

The growing attraction and availability of many sedentary activities, including television, handheld video games, computers, and the Internet, have also greatly influenced the amount of time that children spend participating in sedentary behaviors. When combining television viewing with video games, it is estimated that children may spend as much as 6 hours per day on various media, which takes time away from meaningful activities such as exercise and reading (Roberts and Foehr, 2008). The AAP (2011) recently issued a policy statement encouraging parents to limit media viewing in children to 2 hours or less per day. The AAP asserts that media time, especially advertisements of food products, has a direct correlation with the increased incidence of childhood obesity in the United States.

Psychologic factors also affect eating patterns. In infancy, children experience relief from discomfort through feeding and learn to associate eating with a sense of well-being, security, and the comforting presence of a nurturing person. Eating is soon associated with the feeling of being loved. In addition, the pleasurable oral sensation of sucking provides a connection between emotions and early eating behavior. Many parents use food as a positive reward for desired behaviors. This practice may become a habit, and the child may continue to use food as a reward, a comfort, and a means of dealing with depression or hostility. Many individuals eat when they are not hungry or in response to boredom, loneliness, sadness, depression, or tiredness. Difficulty in determining feelings of satiety can lead to weight problems and may compound the factor of eating in response to emotional rather than physical hunger cues.

Eating behaviors are closely related to memory. Memory and appetite are chemically encoded, with each individual having his or her own circuitry relating to eating behaviors. Similar to memory, the circuitry can be modified over time (Feldman, Friedman, and Sleisenger, 2002).

Diagnostic Evaluation

A careful history is obtained regarding the development of obesity, and a physical examination is performed to differentiate simple obesity from increased fat that results from organic causes. A family history of obesity, diabetes, coronary heart disease, and dyslipidemia should be obtained for all children who are overweight or at risk for overweight. Specific information from the patient and family about the effects of obesity on daily functioning—for example, problems with nighttime breathing and sleep, daytime sleepiness, joint pain, inability to keep up with family activities and peers at school—is helpful. The physical examination should focus on identifying comorbid conditions and identifiable causes of obesity. For some, psychologic assessment by interviews and standardized personality tests may provide insight into the personality and emotional problems that contribute to obesity and that might interfere with therapy.

It is useful to estimate the degree of obesity to determine the component of body weight that can be modified. All of the following methods have been used to assess obesity: BMI, body weight, weight-height ratios, weight-age ratios, hydrostatic (underwater) weight, skinfold measurements, bioelectrical analysis, computed tomography, magnetic resonance imaging, and neutron activation. Each of these methods has advantages and disadvantages. Hydrostatic, or underwater, weighing provides the most accurate measurement of lean body weight.

Body mass index is currently considered the best method to assess weight in children and adolescents. The calculation is based on the individual's height and weight. In adults, BMI definitions are fixed measures without regard for sex and age. The BMI in children and adolescents varies to accommodate age- and sex-specific changes in growth. The formula for BMI calculation is:

$$\text{Weight in pounds} \div (\text{Height in inches})^2 \times 703$$

OR

$$\text{Weight in kilograms} \div (\text{Height in meters})^2$$

BMI measures in children and adolescents are plotted on growth charts that enable heath care professionals to determine BMI for age for the patient (see Appendix A).

The initial assessment of obese children and adolescents should include screening to evaluate for comorbidities. The history is an important guide to determine the workup. A complete physical examination is important. Some areas to focus on include (1) skin

for stretch markings and discolorations (e.g., acanthosis nigricans), (2) joints for swelling and evidence of pain, and (3) airway for evidence of obstruction and enlarged tonsils. Basic laboratory studies include a fasting lipid panel; fasting insulin level; fasting glucose hepatic enzymes, including γ-glutamyltransferase (GGT); and in some institutions, hemoglobin $A1_c$. Other studies, such as a sleep study, metabolic studies, and radiographic evaluations, may be added based on the history and physical examination. These assessments may determine whether the patient needs a referral to specialty services for more focused evaluation and treatment, such as endocrinology (insulin resistance, diabetes), hepatology (elevated liver enzymes, NAFLD), orthopedics (Blount disease), or pulmonary medicine (sleep-disordered breathing, noninvasive continuous positive airway pressure).

Therapeutic Management

The best approach to the management of obesity is a preventive one. Early recognition and control measures are essential before the child or adolescent reaches an obese state. Health care providers must educate families about the medical complications of obesity, and families are encouraged to be involved in the treatment plan.

The treatment of obesity is difficult. Many approaches do not achieve long-term success. The average individual loses only about 5% to 10% of his or her weight with available therapies. Losing weight can have a significant positive effect on many comorbidities, but unfortunately, the lost weight is frequently regained in a year or two.

Diet modification is an essential part of weight-reduction programs. Dietary counseling is directed toward improving the nutritional quality of the diet rather than toward dietary restriction. Children and adolescents should avoid fad diets. Most dietitians and nutrition experts recommend a diet with no *trans* fats, low-saturated fat, moderate total fat (≤30%) and a half plate of fruits and vegetables daily, consistent with the MyPlate* food guide for children. Also, promoting high-fiber foods and avoiding highly refined starches and sugars decrease caloric intake. The Dietary Guidelines for Americans† may be used as a guide for caloric intake for adolescents concerned about weight control; these guidelines also emphasize daily exercise in weight management for children and adolescents. Many programs recommend using a food diary as a helpful tool to increase awareness of food choices and eating behaviors. The goal is to encourage the individual to make healthy choices in food selection and discourage eating food by habit or to appease boredom. Box 35-5 contains helpful suggestions.

In patients with severe obesity, strict diets have been used, such as the protein-sparing modified fast—a hypocaloric, ketogenic diet that is designed to provide enough protein to minimize loss of lean body mass during weight loss. Such diets need to be closely monitored and should be used only with multidisciplinary teams that include a physician, nutritionist, and behavioral therapist. Generally, the diet consists of 1.5 to 2.5 g of protein per kilogram. The intake of carbohydrates is low enough to induce ketosis. The benefits of the diet are relatively rapid weight loss and anorexia induced by ketosis. Potential complications include protein losses, hypokalemia, hypoglycemia, inadequate calcium intake, and orthostatic hypotension. Potassium and calcium supplements and adequate calorie-free beverages can minimize these complications (Baker, Barlow, Cochran, et al., 2005). It is difficult to sustain such diets over the long term, and the long-term outcomes of using these diets have not been established.

BOX 35-5 RECOMMENDED BEHAVIORS FOR PREVENTING OBESITY

In counseling adolescents whose body mass index is between the 5th and 84th percentiles, physicians and health care providers should recommend the following steps to prevent obesity:

- Limit or avoid consumption of sugar-sweetened beverages.
- Consume recommended quantities of fiber, fruits, and vegetables.
- Limit television and other screen time to no more than 2 hours per day.
- Remove television and computer screens from primary sleeping areas.
- Eat breakfast daily.
- Limit eating at fast food restaurants.
- Have frequent family meals in which parents and youth eat together.
- Limit portion sizes.

Adapted from Davis DM, Gance-Cleveland B, Hassink S, et al: Recommendations for prevention of childhood obesity, *Pediatrics* 120(Suppl):S229–S253, 2007.

Researchers continue searching for medications that will successfully treat obesity. The Food and Drug Administration (FDA) has approved sibutramine, an appetite suppressant, for use in adolescents 16 years old and older for the treatment of obesity (U.S. Preventive Services Task Force, 2010). Orlistat, a lipase inhibitor, has been approved for adolescents 12 to 18 years of age who have BMIs more than 2 units above the 95th percentile for age and sex; however, side effects of the drug include fatty or oily stools and possible malabsorption of fat-soluble vitamins (Kanekar and Sharma, 2010). There are currently no drugs approved for use in overweight or obese children younger than the age of 12 years. Other drugs have been used to promote weight loss in children with certain conditions, such as metformin in obese adolescents with insulin resistance and hyperinsulinism, octreotide for hypothalamic obesity caused by intracranial tumors, growth hormone in children with Prader-Willi syndrome, and leptin for congenital leptin deficiency.

Combining behavioral modifications with pharmacologic therapy in children 12 years and older have produced mixed results referent to total weight loss maintained over a significant period of time (U.S. Preventive Services Task Force, 2010). Reports suggest modest benefits with moderate to high behavioral interventions (measured in number of contact hours) in decreasing mean BMI of children and adolescents involved in such programs over a period of 6 to 12 months (Whitlock, O'Connor, Williams, et al., 2010). Programs including family-based behavioral modification, dietary modification, and exercise have been shown to be successful in reducing obesity in some children (AAP, 2006).

Bariatric surgery may be the only practical alternative for increasing numbers of severely overweight adolescents who have failed organized attempts to lose or maintain weight loss through conventional nonoperative approaches and who have serious life-threatening conditions. Until recently, there were few studies in adolescents that suggested surgical weight loss improved the early mortality of patients with severe obesity. In recent years, there has been an increase in bariatric surgery among teens, especially involving the laparoscopic adjustable gastric band procedure (although the FDA has not approved its use in adolescents). The laparoscopic Roux-en-Y gastric bypass is commonly performed for weight loss in adolescents. Data suggest that bariatric surgery in adolescents

*www.choosemyplate.gov/index.html.
†www.health.gov/dietaryguidelines.

results in sustained weight loss, a decrease in BMI, and a decrease in the incidence of comorbidities such as type II diabetes (Barnett, 2011). Best practice recommendations for childhood and adolescent weight loss surgery are published elsewhere (Pratt, Lenders, Dionne, et al., 2009). Physicians must define clear, realistic, and restrictive guidelines to apply with younger patients when surgery is considered. Candidates for surgery should be referred to centers that offer a multidisciplinary team experienced in the management of childhood and adolescent obesity. The surgery should be performed by surgeons who have participated in subspecialty training in bariatric medical and surgical care as detailed by the American College of Surgeons and the American Society for Metabolic and Bariatric Surgery.

CARE MANAGEMENT

Nurses play a key role in the adherence and maintenance phases of many weight-reduction programs. Nurses assess, manage, and evaluate the progress of many overweight adolescents. They also play an important role in recognizing potential weight problems and assisting parents and adolescents in preventing obesity.

The presence of obesity may not be obvious from appearance alone. Regular assessment of height and weight and computation of the BMI facilitate early recognition. Published guidelines are available for childhood obesity prevention and treatment (Barlow and Expert Committee, 2007). Children with BMIs greater than or equal to the 95th percentile for age and sex should receive in-depth medical assessment. Children with BMIs in the 85th to 95th percentile range should be evaluated for secondary complications (e.g., diabetes, hypertension, and hyperlipidemia) and family history. Evaluation includes a height and weight history of the adolescent and family members, eating habits, appetite and hunger patterns, and physical activities. A psychosocial history is also helpful in understanding the impact of obesity on the child's life.

Before initiating a treatment plan, it is important to be certain that the family is ready for change. Lack of readiness may result in failure, frustration, and reluctance to address the problem in the future. The nurse should explore with adolescents the reasons behind the desire to lose weight because motivation to lose weight is the key to success. Adolescents need to take a personal responsibility for their dietary habits and physical activity. Young persons who are forced by their parents to seek help are seldom motivated, become rebellious, and are unwilling to control their dietary intake.

Nutritional Counseling. Preventing an increase in body fat during growth is a realistic approach. This is often accomplished by adjusting four aspects of eating: (1) reducing the quantity eaten by purchasing, preparing, and serving smaller portions; (2) altering the quality consumed by substituting low-calorie, low-fat foods for high-calorie foods (especially for snacks); (3) eating regular meals and snacks, particularly breakfast; and (4) altering situations by severing associations between eating and other stimuli, such as eating while watching television.

The most successful diets are those that use ordinary foods in controlled portions rather than diets that require the avoidance of specific foods.

Teach adolescents and parents how to incorporate favorite foods into their diet and to select satisfying substitutes. Dieting teens should eat what the rest of the family eats but less of it. When parents buy and prepare smaller amounts, they eliminate tempting second helpings and leftovers. To maintain a healthy diet, it is necessary to encourage the consumption of high-nutrient foods such as fruits, vegetables, whole grains, and low-fat dairy protein products. Keep calories and fat to a healthy level without being significantly restricted. To be successful, a dietary program should be nutritionally sound with sufficient satiety value, produce the desired weight loss, and be accompanied by nutrition education and continued support. Children and adolescents should not initiate a reduction diet without health assessment and counseling. Davis, Gance-Cleveland, Hassink, et al. (2007) describe steps to approaching behavior change with youth (Box 35-6).

Behavioral Therapy. Altering eating behavior and eliminating inappropriate eating habits are essential to weight reduction, especially in maintaining long-term weight control. Most behavioral modification programs include the following concepts:

- A description of the behavior to be controlled, such as eating habits
- Attempts to modify and control the stimuli that govern eating
- Development of eating techniques designed to control speed of eating
- Positive reinforcement for these modifications through a suitable reward system that does not include food

Box 35-5 includes specific strategies to modify eating habits.

Group Involvement. Commercial groups (e.g., Weight Watchers) and diet workshops composed primarily of adults may be helpful to some teenagers; however, a peer group is often more effective. Teenage groups include summer camps designed for obese young people and conducted by health care professionals, school groups organized and led by a school nurse, and groups associated with special clinics.

These groups are concerned not only with weight loss but also with the development of a positive self-image and the encouragement of physical activity. Nutrition education, diet planning, and the improvement of social skills are essential components of these groups. Improvement is determined by positive changes in all aspects of behavior.

Family Involvement. There is a definite connection among family environment, interaction, and obesity. The nurse needs to educate parents in the purposes of the therapeutic measures and their role in management. The family needs nutrition education and counseling regarding the reinforcement plan, alterations in the food environment, and ways to maintain proper attitudes. They can support their child in efforts to change eating behaviors, food intake, and physical activity.

Research indicates that family meals may also play a role in decreasing obesity and high risk behaviors among adolescents by promoting healthy eating habits; however, more quality research is needed to clarify the protective role of such interactions in regard to adolescent obesity (Fulkerson, Neumark-Sztainer, Hannan, et al., 2008; Fulkerson, Story, Mellin, et al., 2006; Larson, Neumark-Sztainer, Hannan, et al., 2007).

Parents can also affect the child's eating habits by decreasing media time viewed by the entire family and by discussing food advertisements that promote unhealthy food and eating habits.

Physical Activity. The current recommendation for physical activity for children and adolescents is to participate in a combined total of 60 minutes of physical activity daily; this can be moderate to vigorous intensive exercise or activity (U.S. Department of Health and Human Services, 2008b). Regular physical activity is incorporated into all weight-reduction programs. Any form of increased physical activity is beneficial, provided that the activities are age-appropriate and enjoyable. Recommendations for physical activity

BOX 35-6 PEDIATRIC OBESITY PREVENTION PROTOCOL FOR PRIMARY CARE

Step 1: Assess
- Explain and conduct assessments of:
  - Weight, height, and body mass index percentile
  - Dietary intake (fruit, vegetables, sweetened beverages, and fast food)
  - Activity (screen time, moderate to vigorous activity)
  - Eating behaviors (breakfast, portion sizes, family meals)
- Provide and elicit feedback on body mass index and behaviors found to be inside and outside the optimal range.

Step 2: Set Agenda
- Explore interest in changing behaviors not in the optimal range.
- Agree on target behaviors with the patient and caregiver.

Step 3: Assess Motivation and Confidence
- With regard to interest in changing weight status or behaviors, assess:
  - Willingness
  - Perceived importance
  - Confidence in having success
- Probe the patient regarding ratings of willingness, perceived importance, and confidence to explore the advantages and disadvantages of changing.

Step 4: Summarize and Probe Possible Changes
- Summarize the advantages and disadvantages of change.
- Query possible next steps.
- Offer ideas for getting started in making a change as needed.
- Summarize the change plan.
- Provide positive feedback.

Step 5: Schedule Follow-Up Visit
- If a change plan is made, agree on a follow-up appointment within a specified number of weeks or months.
- If no change plan is made, agree to revisit the topic within a specific number of weeks or months.

Adapted from Davis DM, Gance-Cleveland B, Hassink S, et al: Recommendations for prevention of childhood obesity, *Pediatrics* 120(Suppl):S229–S253, 2007.

need to consider the current health status and developmental level of the child or adolescent. The best choice for exercise is any form that is enjoyable and likely to be sustainable. Aerobic and endurance exercises help oxidize body fats. Light exercises such as walking may provide an opportunity for the family to increase time together and increase caloric expenditure. Walking for 30 minutes each day and decreasing caloric intake by 500 calories per day may significantly reduce the risk for chronic disease. Weight training can increase the basal metabolic rate and replace fat mass with muscle mass. However, weight training is not generally recommended for prepubertal children until they have reached physical and skeletal maturity. In prepubertal children, increasing outdoor playtime is likely to be beneficial. Many children find exercise videos and treadmills boring and may not continue these activities. There are a great variety of physical activities to choose from that are likely to appeal to different people. Team sports and individual sports such as dance, bike riding, swimming, and karate are some examples. Limiting sedentary activities such as television viewing (while eating snacks!) is the most effective way to encourage physical activity.

Prevention. Weight loss programs do not enjoy the success of therapeutic interventions for other disorders. Gradual accumulation of adipose tissue during childhood establishes a pattern of eating that is difficult to reverse in adolescence. Prevention of obesity should begin in early childhood with the development of healthy eating habits, regular exercise patterns, and a positive relationship between parents and children. Prevention of adolescent obesity is best accomplished by early identification of obesity in the preschool, school-age, and preadolescent periods. Health care professionals should encourage frequent health care visits for children who are overweight or obese and incorporate a dietary history and counseling into each well-infant, well-child, and well-adolescent visit.

Anorexia Nervosa and Bulimia Nervosa

Anorexia nervosa (AN) is an eating disorder characterized by a refusal to maintain a minimally normal body weight and by severe weight loss in the absence of obvious physical causes. Approximately 5% of adolescent girls in the United States have AN, and 5% to 10% of all cases occur in boys and men (AAP Committee on Adolescence, 2010). The average age of onset is 13 years, but the disorder can occur as early as 10 years of age and as late as 25 years of age. Individuals with AN are described as perfectionists, academically high achievers, conforming, and conscientious. Typically, they have high energy levels even with marked emaciation. Patients with AN may eventually develop bulimia.

Bulimia (from the Greek meaning "ox hunger") refers to an eating disorder similar to AN. Bulimia nervosa (BN) is observed more commonly in older adolescent girls and young women; boys and men with bulimia are less common. BN patients may be of average or slightly above average weight. BN is characterized by repeated episodes of binge eating followed by inappropriate compensatory behaviors, such as self-induced vomiting; misuse of laxatives, diuretics, or other medications; fasting; or excessive exercise (AAP Committee on Adolescence, 2010). The binge behavior consists of secretive, frenzied consumption of large amounts of high-calorie (or "forbidden") foods during a brief time (usually <2 hours). The binge is counteracted by a variety of weight control methods (purging). These binge-purge cycles are followed by self-deprecating thoughts, a depressed mood, and an awareness that the eating pattern is abnormal. Nonpurging bulimic individuals may use other inappropriate compensatory behaviors such as fasting or excessive exercising but do not regularly engage in self-induced vomiting or the abuse of laxatives, enemas, or diuretics (American Psychiatric Association [APA], 2000).

Although persons with BN have many issues in common with those who have other eating disorders, impulse control and satiety regulation are important problems in BN. Many individuals with BN begin with only occasional binges and purges "just for fun," enjoying the control over their weight while eating amounts of food that would normally produce obesity. As the condition progresses, the frequency of binges increases, the amount of food consumed increases, and they gradually lose control over the binge-purge cycle. The frequency of binging can be anywhere from once per week to 7 or 8 times per day. Because persons with BN usually binge on high-calorie foods, especially sweets, ice cream, and pastries, insulin production is stimulated to cope with the added carbohydrates. When the food is vomited, the unused insulin stimulates hunger and the desire to eat.

A third eating disorder, identified as eating disorder not otherwise specified (EDNOS), has components of both AN and BN with

varying degrees of symptomatology that are not always characteristic of the established diagnostic criteria for AN and BN (American Dietetic Association, 2006). Binge eating disorder (BED) is a type of EDNOS. Persons with BED may diet in an attempt to control their weight but without the extreme weight control compensatory practices of vomiting, laxative use, diuretics, and excessive exercise (American Dietetic Association, 2006; Forman, 2011).

A fourth type of eating disorder, avoidant/restrictive food intake disorder (ARFID), has been proposed and is scheduled to appear in the American Psychiatric Association's (APA's) *DSM-V* classification of eating disorders of children. In this disorder, there is an apparent lack of interest in eating or food with significant weight loss, nutritional deficiency, and dependence on enteral feeding; there is also significant psychosocial functioning with this disorder, and it is not associated with AN or BN (APA, 2010).

BOX 35-7 CLINICAL MANIFESTATIONS OF ANOREXIA NERVOSA

- Severe and profound weight loss
- Secondary amenorrhea (if menarche attained)
- Primary amenorrhea (if menarche not attained)
- Sinus bradycardia
- Lowered body temperature
- Hypotension
- Intolerance to cold
- Dry skin and brittle nails
- Appearance of lanugo hair
- Thinning hair
- Abdominal pain
- Bloating
- Constipation
- Fatigue
- Lightheadedness
- Evidence of muscle wasting (cachectic appearance)
- Bone pain with exercise

Etiology and Pathophysiology

The etiology of these disorders remains unclear. There is a distinct psychologic component, and the diagnosis is based primarily on psychologic and behavioral criteria. Dieting appears to be common to the initiation of both AN and BN. The disorders appear to be caused by a combination of genetic, neurochemical, psychodevelopmental, and sociocultural factors. The dominant aspects of AN are a relentless pursuit of thinness and a fear of fatness, usually preceded by a period of mood disturbances and behavior changes.

Weight loss may be triggered by a typical adolescent crisis such as the onset of menstruation or a traumatic interpersonal incident that precipitates serious, out-of-control dieting. Situations of severe family stress (e.g., parental separation or divorce) or circumstances in which the adolescent perceives a lack of personal control (e.g., teasing at school, changing schools, or going to college) may precipitate a desire for control and the decision not to eat. Frequently, there is an exaggerated misinterpretation of the normal fat deposition characteristic of early adolescence or anxiety because of comments that the adolescent is putting on weight.

Many experts have associated the development of an eating disorder with family characteristics such as an adolescent perception of high parental expectations for achievement and appearance, difficulty managing conflict and poor communication styles, enmeshment and occasionally estrangement among family members, devaluation of the mother or the maternal role, and marital tension. Families struggling with an eating disorder have been characterized as often having difficulties responding positively to the changing physical and emotional needs of the adolescent. Family stress of any kind may become a significant factor in the development of an eating disorder (Forman, 2011).

Society's emphasis and the media's focus on tall, thin individuals may also play a role. Studies evaluating the possible association of eating disorders and sexual abuse have been conflicting. Childhood sexual abuse may be a factor in some cases of AN.

Patients with eating disorders commonly have psychiatric problems, including affective disorder, anxiety disorder, obsessive-compulsive disorder (OCD), and personality disorder. Adult women with eating disorders were found to have higher rates of obsessive-compulsive behavior traits in their childhoods. Patients with eating disorders have also been found to have higher reported rates of substance abuse, with alcohol problems being more common in those with BN than AN (Forman, 2011). It is important to note that many of the clinical findings are directly related to the state of starvation and improve with weight gain.

Many sports and artistic endeavors that emphasize leanness (e.g., ballet and running) and sports in which the scoring is partly subjective (e.g., gymnastics) have been associated with a higher incidence of eating disorders such as AN. The term **female athlete triad,** characterized by disordered eating behavior, amenorrhea, and osteoporosis, has been applied to young women with restrictive eating disorders and amenorrhea (Landry, 2011).

A genetic role has been postulated for eating disorders; a significant number of young women with a first-degree relative having an eating disorder were at a significantly higher rate of having an eating disorder (Forman, 2011). However, some consider these eating disorders to not be a direct result of family inheritance but, rather, a secondary effect of the manifestations of conditions such as anxiety, depression, and OCD " that may be modulated through the internal milieu of puberty" (Landry, 2011).

Diagnostic Evaluation

Diagnosis of AN is made on the basis of clinical manifestations (Box 35-7) and conformity to the criteria established by the APA (2000). Diagnosis of BN is confirmed, according to the APA's *DSM* (2000), by at least two binge eating episodes per week for the preceding 3 months. Characteristics of BN and AN are listed in Table 35-2.

A complete history and physical examination are important to rule out other causes of weight loss. The medical assessment of an eating disorder focuses on the complications of altered nutritional status and purging. A careful history assesses weight changes, dietary patterns, and the frequency and severity of purging and excessive exercise. The patient's weight and height should be measured and evaluated for appropriateness according to standard weight for height, age, and sex determined according to the percentile of his or her expected body weight or BMI.

The diagnosis of eating disorder (ED) is made clinically, but additional laboratory diagnostic tests may be obtained to identify malnutrition or other associated complications. Additional diagnostic measures may include a complete blood count to evaluate for anemia and other hematologic abnormalities; erythrocyte sedimentation rate or C-reactive protein to detect evidence of inflammation; electrolytes as well as calcium, magnesium, phosphorus, blood urea nitrogen, and creatinine; urinalysis, including specific gravity; and bone density studies for osteopenia, which is commonly observed in patients with AN. In patients with prolonged amenorrhea, human chorionic gonadotropin is assessed to determine the presence of pregnancy. Other tests for patients with amenorrhea include thyroid function tests and measurement of serum prolactin and follicle-stimulating hormone to help rule out prolactinoma (hormone-secreting pituitary tumor), hyperthyroidism, hypothyroidism, or ovarian failure. In addition, a comprehensive cardiac evaluation is often recommended in those with AN. Further

TABLE 35-2 CHARACTERISTICS OF INDIVIDUALS WITH EATING DISORDERS

FACTORS	ANOREXIA NERVOSA	BULIMIA
Food	Turns away from food to cope	Turns to food to cope
Personality	Introverted Avoids intimacy Negates feminine role	Extroverted Seeks intimacy Aspires to feminine role
Behavior	"Model" child Obsessive-compulsive	Often acts out Impulsive
School	High achiever	Variable school performance
Control	Maintains rigid control	Loses control
Body image	Body image distortion	Less frequent body image distortion
Health	Denies illness	Recognizes illness Health fluctuates
Weight	Body weight <85% of expected norm	Within 2.3-7 kg (5-15 lb) of normal body weight or may be overweight
Sexuality	Usually not sexually active	Often sexually active

diagnostic tests may be required based on the history and findings from these diagnostic tests.

Screening Tools. All patients in high risk categories for eating disorders should be screened during routine office visits. The medical history is most important for diagnosing eating disorders because the physical examination findings may be normal, especially early in the illness. A number of screening questionnaires are available to assist with the interview. For example, with the SCOFF questionnaire, 1 point is scored for every "yes." A score of 2 or more indicates a likely case of AN or BN. The questions related to the mnemonic SCOFF are (1) Do you make yourself *sick* because you feel uncomfortably full? (2) Do you worry that you have lost *control* over how much you eat? (3) Have you recently lost more than 6.4 kg (14 pounds or *one* stone) in a 3-month period? (4) Do you believe yourself to be *fat* when others say that you are too thin? and (5) Would you say that *food* dominates your life? (Morgan, Reid, and Lacey, 1999).

Therapeutic Management

The treatment and management of AN involve three major goals: (1) reinstitution of normal nutrition or reversal of the severe state of malnutrition, (2) resolution of disturbed patterns of family interaction, and (3) individual psychotherapy to correct deficits and distortions in psychologic functioning. The treatment of eating disorders requires the cooperative efforts of an interdisciplinary team composed of a primary care practitioner, nurse, dietitian, and mental health care provider with pediatric and adolescent health care experience. Because of the psychogenic nature of the disorder, the treatment may be long. Recent studies suggest that family-based therapy is more effective than individual cognitive behavioral therapy in reducing the maladaptive eating behaviors in adolescents with AN (Lock, 2010).

Most adolescents are treated on an outpatient basis, but those with problems requiring immediate medical attention, such as severe malnutrition or electrolyte or psychiatric disturbances (severe depression or suicidal ideation), require hospitalization. Persons with BN may benefit from cognitive behavioral therapy, other psychotherapy, antidepressant medications, or a combination of antidepressant medication and psychotherapy (Kreipe, 2011).

Nutrition Therapy. The most important goal is to treat any life-threatening malnutrition and to restore dietary stability and weight gain. This may require the administration of tube feedings or intravenous fluids if the malnutrition is severe. In most cases, it is best to reintroduce food and snacks slowly in a stepwise manner. A reasonable goal is to reach an eventual intake of 2000 to 3000 kcal per day and a weight gain of 0.22 to 0.45 kg (0.5-1 pound) per week (American Dietetic Association, 2006). When restoring nutrition, health care professionals must avoid the **refeeding syndrome,** which consists of cardiovascular, neurologic, and hematologic complications that occur when nutritional replacement is given too rapidly. This syndrome can be avoided with slow refeeding and the addition of phosphorus when total body phosphorus is depleted. Treatment goal weights are individualized and based on age, height, stage of puberty, premorbid weight, and previous growth charts. In young women who have reached menarche, resumption of menses is an objective measure of return to biologic health.

Dietary interventions are combined with behavioral therapy to improve the underlying psychologic misconceptions about weight loss. Another aspect of treatment is to relieve the anxiety related to eating and the depression that accompanies the disorder. The administration of antianxiety or antidepressant medications is beneficial. However, when these drugs are used, patients should be carefully monitored for cardiovascular side effects.

Cognitive Behavioral Therapy. Behavioral interventions are often necessary to encourage patients to accomplish the desired caloric intake and weight gain. Weight restoration as an outpatient is accomplished with behavioral contracts negotiated between the therapists and patient. The goal is to increase the patient's feelings of control and responsibility toward achieving recovery. The contract can stipulate at what weight tube feedings will be implemented. Individual psychotherapy is aimed at helping the young person resolve the adolescent identity crisis, particularly as it relates to a distorted body image. If the disorder is related to a dysfunctional family situation, therapy is most successful when it is started soon after the onset of illness and directed toward disengagement and redirection of malfunctioning processes in the family.

Pharmacotherapy. Pharmacotherapy in the treatment of AN has been disappointing so far. None of the randomized controlled trials (RCTs) have shown improvement in weight gain in adults treated with pharmacotherapy, and no studies have been conducted in children and adolescents (Golden and Attia, 2011). The few studies that have been done have primarily evaluated medications' efficacy in the treatment of comorbid disorders such as OCD and depression. Anxiolytic medications may be helpful before meals to relieve some patients' anxiety.

Tricyclic antidepressants (TCAs) and fluoxetine belong to a group of medications known as *selective serotonin reuptake inhibitors (SSRIs),* which have been more successful when used with BN. There is also some evidence that TCAs such as desipramine, imipramine, and amitriptyline; monoamine oxidase inhibitors; and buspirone

CRITICAL THINKING CASE STUDY

Anorexia Nervosa

Jane is a 13-year-old girl whose grades have been excellent and whom the teachers describe as a "model student." Recently, Jane's teacher told the nurse practitioner that Jane's parents were in the middle of a "messy divorce." In addition, several of Jane's friends told the nurse practitioner that they are concerned about Jane because she runs every day at lunchtime and seldom eats lunch with them. Jane told her friends that she gained weight over the winter months and that she is running because she wants to qualify for the track team this spring. At the time of her routine health interview and sports physical examination, the nurse practitioner notes that Jane's oral temperature is 36° C (96.8° F) and that she weighs 34 kg (75 pounds). Jane has lost 9 kg (20 pounds) since her last sports physical. Jane tells the nurse practitioner that she has not had her menstrual period for 3 months.

1. Evidence—Is there sufficient evidence to draw any conclusions about Jane's behavior?
2. Assumptions—Describe some underlying assumptions about the following:
   a. Personality characteristics of individuals with anorexia nervosa (AN)
   b. Factors influencing the development of AN
   c. Clinical manifestations of AN
   d. Treatment of AN
3. What priorities for nursing care should be established for Jane at this time?
4. Does the evidence objectively support your argument (conclusion)?

are more effective compared with a placebo in decreasing binging and vomiting in patients with BN. Some of the latter medications, however, may have side effects that may preclude their utility in such patients (Golden and Attia, 2011). Topiramate, an antiepileptic agent, and the selective serotonin antagonist *ondansetron* have demonstrated some benefit in treating patients with BN. As with AN, pharmacotherapy should be an adjunct to behavioral therapy.

CARE MANAGEMENT

Nurses need to adopt and maintain a kind and supportive yet firm manner in managing the care of the adolescent with eating disorders without creating a passive-dependent attitude. The individual requires sustained support and reassurance to cope with ambivalent feelings related to body concept and the desire to be seen as cooperative, reliable, and worthy of receiving kindness. Encouraging the adolescent with education and activities that strengthen self-esteem facilitates the resocialization process and promotes social acceptance among peers. The nursing process in the care of adolescents with an eating disorder such as overweight or obesity is outlined in the Nursing Care Plan.

It is important for nurses to be aware of the physical side effects of AN. Patients frequently limit their fluid intake. Urinary tract problems are common, and ketones and protein may be detected in the urine as a result of breakdown of fat and protein. Vital sign instability can be severe and can include orthostatic hypotension; the pulse becomes irregular, and the rate decreases markedly. Electrolyte imbalances can be life threatening, and bradycardia and hypothermia can result in cardiac arrest (see Critical Thinking Case Study).

The team responsible for the management of young people with AN arranges a carefully structured environment. First, there must be consistency. The team decides on an approach and adheres to it. The plan is structured with reality testing regarding caloric intake and body image perception as an essential component. The team members provide a unified front to avoid any possibility of manipulation or inconsistency. Second, all team members are involved; responsibility for the program cannot be left to one person. The role and boundaries of each member are clearly spelled out. Third, continuity of team members is important; it is helpful to have the same team members all the time.

Fourth, communication among team members is essential. Communication with the patient regarding what is expected is also important. Sometimes the limit setting may seem unreasonable; if the adolescent does not understand the rationale for the limits, he or she may sabotage the entire program. It is also important to communicate with the family. Fifth, the plan must provide for support of the adolescent, the family, and team members. The adolescent's efforts should be supported, and positive feedback should be provided for accomplishments made in normalizing eating habits. Meetings are held to discuss the feelings and concerns of the patient, immediate caregivers, and team members.

A behavioral contract, an agreement that the adolescent makes with others to change a maladaptive behavior, has proved to be effective in some cases. The written contract is constructed by the therapeutic team and approved and signed by the adolescent. Unless the adolescent agrees to its terms, the contract can become the source of a power struggle. However, it can be an effective tool that places the responsibility for weight gain or other behavioral change on the adolescent.

Family-based therapy is often used in the treatment of adolescent eating disorders, specifically in the treatment of AN. In particular, the Maudsley approach aims to help parents rediscover their own resources and take an active role in their children's recovery. Encourage families to explore how it has become problematic to follow the normal developmental course of their family life cycle by looking at how the eating disorder and the interactional patterns in the family have become entangled.

Nursing care of the adolescent with BN is similar to care of the patient with AN. Acute care involves careful monitoring of fluid and electrolyte alterations and observation for signs of cardiac complications. Nutritional consultation and follow-up care are essential. The nurse should encourage the adolescent and family members to structure the environment to reduce the binging behavior. Getting rid of binge foods; restricting eating to one room of the house; not engaging in other activities while eating; and substituting exercise, crafts, visualization, and relaxation techniques for binging are helpful interventions.

Nurses, patients, and families can find assistance and information from several organizations. The National Association of Anorexia Nervosa and Associated Eating Disorders* provides counseling, referral, and self-help programs for young people with AN. The National Eating Disorders Association† provides information and support services for both patients and families.

HEALTH PROBLEMS WITH A BEHAVIORAL COMPONENT

Substance Abuse

Although experimentation with drugs during childhood and adolescence is widespread, most children and teens do not become high

NURSING CARE PLAN

The Adolescent with an Eating Disorder

NURSING DIAGNOSIS	EXPECTED OUTCOME	INTERVENTIONS	RATIONALES
Imbalanced Nutrition: Less Than Body Requirements related to altered self-image, inadequate nutrient intake, and chronic vomiting	Nutrient intake is sufficient to maintain optimal cellular and metabolic function.	If adolescent's life is in immediate danger as result of malnutrition, implement plan for restoring physiologic homeostasis: electrolyte and fluid replacement, enteral feedings as required, monitoring of vital signs, and restoration of fluid and electrolyte balance	To prevent death or multiorgan failure To restore fluid balance and prevent life-threatening electrolyte imbalance
Child's/Family's Defining Characteristics *(Subjective and Objective Data)* Body weight 20% or more under ideal		Develop mutually agreeable targeted daily caloric intake goal (specify goal)	To give adolescent sense of control over nutrient intake and establish realistic plan for weight gain
		Observe eating behaviors	To detect detrimental habits such as purging or binging after meals
		Monitor nutritional intake and behavior thereafter for 1 hour	To detect physiologic changes that may be life threatening
		Monitor vital signs as warranted by patient status; obtain baseline vitals on admission	To detect life-threatening conditions such as dehydration or hyponatremia
		Monitor fluid and electrolyte status	To detect early warning signs of dehydration or fluid and electrolyte imbalance
		Set mutually agreeable target intake of fluids per day	To prevent further weight loss
		Establish mutually agreeable targeted goal for daily exercise that is congruent with nutrient intake and weight gain	To prevent self-harm
		Monitor activities for detrimental behaviors such as administering enemas, purging, binging (bulimic), and excessive exercise	To clarify expectations and provide limits for control of behaviors that are not acceptable
		Set limits and clearly define expectations in relation to therapeutic plan to increase nutrient intake	To establish mutually agreed-on plan for nutrient intake and weight gain
		Develop behavioral contract for nutrient intake and cessation of behaviors related to eating that are detrimental	To promote verbalization of concerns and fears
Disturbed Body Image related to altered self-perception	Adolescent displays evidence of developing and maintaining positive self-image.	Encourage adolescent to verbalize feelings and concerns regarding view of self in relation to peers and family members	To enhance self-esteem and alter misconception of self in relation to others
Child's/Family's Defining Characteristics *(Subjective and Objective Data)* Negative feelings about body		Provide opportunity for adolescent to engage in activities that have potential to build self-esteem	To promote self-esteem
		Encourage self-care in relation to dietary management and weight control	To set limits for behavior
		Encourage discussion of maladaptive behaviors surrounding food and fluid intake: binging, purging, laxative use, excess exercise	To provide consistency in therapy and allow mutual discussion
		Provide therapeutic discussion (over time) of personal attributes perceived as positive	To enhance reality-based self-perception
		Involve adolescent in activities designed to promote positive image of self-worth and accomplishment	To promote sense of accomplishment and enhance self-image
		Involve family members and adolescent in group family counseling to discuss expectations and members' roles within family	To promote expression of perceptions about self within family and identify any distorted patterns of interaction that require clarification or modification

risk users. *Monitoring the Future* has been providing long-term research about the rates of substance use among adolescents, young adults, and adults since 1975. The 2010 survey found that marijuana use and acceptance of marijuana use have been on the rise since 2007. Alcohol use has been on the decline since the early 1980s and reached historically low levels in 2010. Cigarette use was on a steady decline since the mid-1990s but showed some increase in 2010, which followed a leveling off of the perceived risk of cigarette use. The use of illicit drugs other than marijuana has shown minimal change. However, 15% of 12th graders in 2010 reported the use of prescription drugs without medical supervision (Johnston, O'Malley, Bachman, et al., 2011).

Drug abuse, misuse, and addiction are culturally defined and are voluntary behaviors. Drug tolerance and physical dependence are involuntary physiologic responses to the pharmacologic characteristics of drugs, such as opioids and alcohol. Consequently, an individual can be addicted to a narcotic with or without being physically dependent. A person can also be physically dependent on a narcotic without being addicted (e.g., patients who use opioids to control pain).

The CRAFFT questionnaire is a brief screening tool which can be used in the primary care setting to identify adolescent substance abuse; the mnemonic stands for C-car; R-relax; A-alone; F-forget; F-friends; T-trouble. The six questions relate to the use of drugs in the settings described by the mnemonic. Two or more positive answers to the items in the tool indicate the need for further referral for possible substance abuse (Knight, Sherritt, Shrier, et al., 2002).

Motivation

Most drug use begins with experimentation. The drug may be used only once, may be used occasionally, or may become part of a drug-centered lifestyle. Children and adolescents initiate drug use out of curiosity. Adolescents who use drugs may fall into one of two broad categories—experimenters and compulsive users—or they may fall into a third category somewhere on the continuum between these extremes, referred to as *recreational users,* principally of drugs such as marijuana, cocaine, alcohol, and prescription drugs. For many, the goal is peer acceptance; these users fit more closely with the experimenting, intermittent users. For others, the goal is intoxication or the sustained intense effects from using a particular drug; these users resemble the compulsive users. These users may engage in periodic heavy use, or binges. The groups of greatest concern to health care workers are those whose patterns of use involve high doses or mixed drugs with the danger of overdose and compulsive users with the threat of dependence, withdrawal syndromes, and altered lifestyle.

Types of Drugs Abused

Any drug can be abused, and most are potentially harmful to adolescents still going through formative life experiences. Although rarely considered drugs by society, the chemically active substances frequently abused are the xanthines and theobromines contained in chocolate, tea, coffee, and colas. Ethyl alcohol and nicotine are other drugs that are legal and socially sanctioned. Any of these substances can produce mild to moderate euphoric or stimulant effects and can lead to physical and psychologic dependence.

Drugs with mind-altering abilities that are available on the "street" and are of medical and legal concern are the hallucinogenic, narcotic, hypnotic, and stimulant drugs. In addition, health care professionals are concerned about the use of alcohol and volatile substances that are inhaled to achieve altered sensation (e.g., gasoline, antifreeze, plastic model airplane cement, typewriter correction fluid, organic solvents). The abuse of prescription and synthetic drugs such as oxycodone, alprazolam (Xanax), dextromethorphan, and amphetamine-dextroamphetamine (Adderall) has been reported to have reached epidemic proportions among adolescents and young people (Bryner, Wang, Hui, et al., 2006; Maxwell, 2011). Studies show that adolescents prefer pain relievers to stimulants, sedatives, or tranquilizers; females tend to prefer pain relievers to stimulants, and abuse of these substances was also strongly correlated with other illicit substances (Young, Glover, and Havens, 2012). Others report that adolescents believe that prescription medications, although not taken under practitioner orders, are safer than illicit substances. Cough and cold preparations such as NyQuil, Coricidin, and Robitussin were reported in 2006 to be favorite substances abused to get high among persons ages 12 to 25 years (U.S. Department of Health and Human Services, 2008a). Many of the prescription drugs are available at a decreased cost compared with the more exotic drugs of abuse and are often found in the medicine or kitchen cabinet at home. Websites also promote the "safe use" of some psychoactive drugs and supply information on new "designer" drugs that are not detectable on a standard urine drug screening test.

Tobacco. Cigarette smoking has been on a slow decline since the peak in 1999 despite multiple efforts, including increased costs, changes in community attitudes about smoking among adults, media campaigns with counter-advertising, and tobacco-free environments (CDC, 2010a). Use of all tobacco products among youth did not change between 2006 and 2009 (CDC, 2010b).

Although the number of adult and adolescent smokers has declined in recent years, cigarette smoking is still considered the chief avoidable cause of death. The hazards of smoking at any age are undisputed; however, a preventive approach to teenage smoking is especially important. Because of its addictive nature, smoking begun in childhood and adolescence can result in a lifetime habit, with increased morbidity and early mortality.

The effects of secondhand smoke exposure are also well known and include increased incidence of low birth weight and subsequent illness, increased incidence of sudden infant death syndrome (maternal smoking during and after pregnancy), increased incidence of acute lower respiratory tract infections, and exacerbation of asthma symptoms (wheezing, cough, phlegm, breathlessness) in children with asthma (U.S. Department of Health and Human Services, 2006).

Etiology. Teenagers begin smoking for a variety of reasons, including imitation of adult behavior; peer pressure; a desire to imitate behaviors and lifestyles portrayed in movies and advertisements; and a desire to control weight, especially among young women. Teenagers who do not smoke usually have family members and friends who do not smoke or who oppose smoking. Most teens who refrain from smoking have a desire to succeed in academics or athletics (particularly high-performance sports, such as basketball, swimming, and track) and plans to go to college (see Community Focus box). Although smoking among college students has increased in recent years, rates of smoking are highest among adolescents who do not complete high school.

Smokeless Tobacco. The term *smokeless tobacco* refers to tobacco products that are placed in the mouth but not ignited (e.g., snuff and chewing tobacco). This substitute for cigarettes continues to pose a hazard to adolescents, although use had steadily declined by about 50% since the peak prevalence in 1995; the 2010 data showed a slight increase. Children and adolescents continue to recognize the risk of smokeless tobacco and have expressed high rates of disapproval (Johnston, O'Malley, Bachman, et al., 2011). These

COMMUNITY FOCUS

Early Sexual Maturation, Alcohol, and Cigarettes

Smoking cigarettes and drinking alcohol among adolescents are complex behaviors that are not explained by any one factor. Some theorists and investigators believe there is a relationship between biologic maturation and risk-taking behaviors. For example, young girls who are sexually mature at an earlier age than their peers are often attracted to older girls and boys who may engage in risk-taking behaviors. If older teens smoke, drink, and drive while under the influence of alcohol with no adverse consequences (e.g., no motor vehicle accidents), young girls may believe that they, too, will be safe while smoking, drinking, or riding in an automobile with friends who are drinking.

Although parents and nurses cannot influence the time of biologic maturation, they can identify young girls who are at risk for the initiation of risk-taking behaviors because of early puberty. Parents need to understand that an early-maturing daughter might be uncomfortable with her body, and they should take advantage of opportunities to build her self-esteem. Parental sensitivity to the importance of peer-group acceptance and parental support of a teenage daughter who feels left out or different are crucial. School nurses can provide anticipatory guidance to these girls and help them role-play coping strategies for situations that involve offers to smoke and drink. In addition, school nurses can provide information about physical development during puberty and emphasize that not all teenagers mature at the same time or rate.

Teachers, coaches, and community and church leaders can provide opportunities for these girls to "fit in" with their same-age peers through activities that stress mutual goals. For example, an early-maturing girl is typically taller than her age-mates and can be an asset in sports such as basketball and track-and-field events.

products have also been proved to be carcinogenic, and regular use can cause dental problems, foul-smelling breath, and tooth erosion or loss.

CARE MANAGEMENT

Prevention of regular smoking in teenagers is the most effective way to reduce the overall incidence of smoking. A variety of methods have been used. Posters, charts, displays, statistics, and the use of examples of actual damaged lungs to communicate the hazards of smoking all have their supporters and doubters. Some schools also use films and demonstrations in science classes.

For the most part, smoking prevention programs that focus on the negative, long-term effects of smoking on health have been ineffective. Youth-to-youth programs and those emphasizing the immediate effects are more effective but primarily in improving teenagers' attitudes toward not smoking. Because smoking and smoking-related behaviors are social symbols, antismoking campaigns must address the norms of potential smokers. Anything that ridicules or threatens the social norms of the peer group can be unproductive or counterproductive. Investigators have found that teaching resistance to peer pressure to smoke is effective in early adolescence. Although the effects of these programs may decrease with time, the effects can be enhanced in older adolescents by presenting information in class instead of simply handing out written material to the students.

Two areas of focus for antismoking programs are peer-led programs and use of media in smoking prevention (e.g., CDs, videotapes, and films). Peer-led programs emphasizing the social consequences of smoking have proved most successful. If a significant number of influential peers can "sell" their classmates on the idea that the habit is not popular, the followers will imitate their behavior. Such programs emphasize short-term rather than long-term consequences (e.g., the effects of smoking on personal appearance, such as unattractive stains on teeth and hands and unpleasant odor of breath and clothing).

The use of pharmacologic agents for smoking cessation include nicotine replacement therapy, bupropion, and varenicline. Varenicline taken orally for 12 weeks was shown to be safe and effective in assisting persons who wish to stop smoking (Cahill, Stead, and Lancaster, 2011), but side effects such as nausea and abdominal distention may make the drug less palatable for some. None of these three drugs has been specifically approved for use in children and adolescents for smoking cessation.

The impact of school-based antismoking programs can be strengthened by expanding these programs to include parents, mass media, youth groups, and community organizations. For example, mass media efforts that involve antismoking radio campaigns have been identified as the most cost-effective mass media intervention.

Smoking bans in schools also accomplish several goals: (1) they discourage students from starting to smoke; (2) they reinforce knowledge of the health hazards of cigarette smoking and exposure to environmental tobacco smoke; and (3) they promote a smoke-free environment as the norm (see Community Focus box).

Alcohol. Acute or chronic abuse of alcohol (ethanol) is responsible for many acts of violence, suicide, accidental injury, and death. Alcohol drinking is likely to begin in the middle-school years and increases with age. By 18 years of age, 80% to 90% of adolescents have tried alcohol. Ethanol is a depressant that reduces inhibitions against aggressive and sexual acting out. Severe physical and psychologic symptoms accompany abrupt withdrawal, and long-term use leads to slow tissue destruction, especially of the brain and liver cells. The most noticeable effects of alcohol occur within the CNS and include changes in cognitive and autonomic functions such as judgment, memory, learning ability, and other intellectual capacities. Young people with alcoholism often drink alone and cannot control their use of alcohol. They often rely on the substance as a defense against depression, anxiety, fear, or anger. Not all of these characteristics are observed in adolescents who are abusing alcohol, but if several signs are evident, the child or adolescent should be considered at risk. Referral to a health care professional and detoxification therapy may be necessary. Information about alcohol and answers to questions are available through the Alcohol Hotline.* Other groups that provide support and counseling for families are Al-Anon, Ala-Teen, Ala-Tot, and Alcoholics Anonymous (an organization that has listings in all local directories).

Cocaine. Although cocaine is not pharmacologically considered a narcotic, it is legally categorized as such. Cocaine is available in two forms: water-soluble cocaine hydrochloride, which is administered by "snorting" or intravenous injection; and nonsoluble alkaloid (freebase) cocaine, which is used primarily for smoking. Crack, or "rock," is a purer, more menacing form of the drug. It can be produced cheaply and smoked in either water pipes or mentholated cigarettes.

Cocaine creates a sense of euphoria, or an indefinable high. Withdrawal does not produce the dramatic symptoms observed in

COMMUNITY FOCUS

Nonsmoking Strategies

Nurses who work in schools, hospitals, and community agencies can take advantage of all opportunities to provide education about the dangers of smoking, to discourage smoking initiation by children and adolescents, to encourage smoking cessation, and to promote smoke-free environments. In particular, school nurses must be alert to the vulnerability of young preteens when they enter junior high or middle school. These nurses are in an ideal position to assess stress, personal conflict, weight concerns, peer pressures, and other factors that place preteens at risk for smoking initiation. Nurses should serve as counselors to student, teacher, and parent groups and as advocates for antismoking legislative efforts. The following additional strategies are recommended:*

- Provide only brief information about long-term health consequences (e.g., cardiovascular and cancer risks).
- Discuss immediate physiologic consequences (e.g., changes in heart rate, blood pressure, respiratory symptoms, and blood carbon monoxide concentrations).
- Mention alternatives to smoking that also establish a self-image that appears independent, mature, or sophisticated (e.g., weight lifting; jogging; dancing; joining a boys' or girls' club; engaging in volunteer work for a hospital, political, religious, or community group).
- Mention the negative effects in detail (e.g., earlier wrinkling of skin; yellow stains on teeth and fingers; tobacco odor on breath, hair, and clothing).
- Mention the increasing ostracism of smokers by nonsmokers, both legal and informal, in the workplace and in public places.
- Mention the increasing evidence that secondhand smoke is injurious to the health of nonsmokers who are regularly exposed, especially small children.
- Acknowledge that many adults, who were enticed to start smoking as teenagers because of its social benefits, now wish they could stop smoking.
- Give cooperative adolescents effective arguments to deal with peer pressure (e.g., by not smoking, a teenager demonstrates independence and nonconformity, traits normally prized by youth).
- Request posters or pamphlets from local agencies (e.g., American Cancer Society, American Heart Association, and American Lung Association) to display in prominent places at school.

*The Centers for Disease Control and Prevention has information on the effects of tobacco, smoking cessation, and tobacco control programs; 1600 Clifton Road, Atlanta, GA 30333; 800-232-4636; e-mail: tobaccoinfo@cdc.gov; www.cdc.gov/tobacco.

withdrawal from other substances. The effects are those commonly seen in depression, including lack of energy and motivation, irritability, appetite changes, psychomotor delay, and irregular sleep patterns. More serious symptoms include cardiovascular manifestations and seizures. Physical withdrawal should not be confused with the so-called *crash* after a cocaine high, which consists of a long period of sleep. Answers to questions about the risks of using cocaine are available at the National Cocaine Hotline,* which also provides referrals to support groups and treatment centers.

*800-COCAINE (800-262-2463).

Narcotics. Narcotic drugs include opiates, such as heroin and morphine, and opioids (opiate-like drugs), such as hydromorphone (Dilaudid), hydrocodone, fentanyl, meperidine (Demerol), and codeine. These drugs produce a state of euphoria by removing painful feelings and creating a pleasurable experience and a sense of success accompanied by clouding of the consciousness and a dream-like state. Physical signs of narcotic abuse include constricted pupils; respiratory depression; and, often, cyanosis. Needle marks may be visible on the arms or legs in chronic users. Physical withdrawal from opiates is extremely unpleasant unless controlled with supervised tapering doses of the opioid or substitution of methadone.

As important as the physical effects are the indirect consequences related to the illegal status of narcotic use and the problems associated with securing the drug (e.g., the time-consuming searches to obtain the drug and the often illegal methods used to meet the high cost of purchasing it). Health problems also result from self-neglect of physical needs (nutrition, cleanliness, dental care); overdose; contamination; and infection, including HIV and hepatitis B and hepatitis C infection.

Central Nervous System Depressants. Central nervous system depressants include a variety of hypnotic drugs that produce physical dependence and withdrawal symptoms on abrupt discontinuation. They create a feeling of relaxation and sleepiness but impair general functioning. Drugs in this category include barbiturates, nonbarbiturates, and alcohol. Barbiturates combined with alcohol produce a profound depressant effect. Flunitrazepam (Rohypnol), known as the "date rape drug," is a hypnotic drug abused by adolescents. Many women and men report being raped after unknowingly being given Rohypnol in a drink. Rohypnol is 10 times more powerful than diazepam (Valium). It produces prolonged sedation, a feeling of well-being, and short-term memory loss.

Central Nervous System Stimulants. Amphetamines and cocaine do not produce strong physical dependence and can be withdrawn without much danger. However, psychologic dependence is strong, and acute intoxication can lead to violent aggressive behavior or psychotic episodes characterized by paranoia, uncontrollable agitation, and restlessness. When combined with barbiturates, the euphoric effects are particularly addictive.

Methamphetamine can be snorted, injected, swallowed, or smoked and produces a burst of energy in its users, along with intense, alternating attacks of boldness and paranoia. It provokes excitement far more intense than that caused by cocaine. The drug, with the street names *crank, meth,* and *crystal,* is inexpensive and has a longer period of action than cocaine. Instead of a short (few minutes) high, as achieved with cocaine, a user can remain "up" for hours on a similar dose of crank.

Health care professionals are concerned about the use of various volatile substances, or inhalants such as gasoline, model airplane cement, and organic solvents; these substances are inhaled by the user to achieve an altered sensation, and the most recent surveillance has indicated a modest increase in use after nearly a decade of decline. Adolescents breathe or place these substances into paper or plastic bags or soda cans from which they rebreathe the fumes to produce a feeling of euphoria and altered consciousness. These substances contain chemical solvents and are extremely hazardous. Dusters contain Freon, a substance that can cause fatal cardiac dysrhythmias. Inhalants are the only substance that has a higher incidence of use among young adolescents. This is probably related to the fact that the products are readily available and may be the only substances available for young teens. Many young children are

unaware of the dangers of "sniffing" or "huffing." In addition to rapid loss of consciousness and respiratory arrest, these substances may cause visual scanning problems, language deficiencies, motor instability, memory deficits, and attention and concentration problems.

Mind-Altering Drugs. Hallucinogens (psychedelics, psychotomimetics, psychotropics, or illusionogenics) are drugs that produce vivid hallucinations and euphoria. These drugs do not produce physical dependence, and they can be abruptly withdrawn without ill effect. However, the acute and long-term effects are variable, and in some individuals, the dissociative behavior may be prolonged. Cannabis (marijuana, hashish) and lysergic acid diethylamide (LSD) are also included in this category of drugs.

CARE MANAGEMENT

Nurses who have contact with children and adolescents are in an excellent position to provide information about substance abuse and to serve as patient advocates. Nurses most often encounter young substance abusers when they are (1) experiencing overdose or withdrawal symptoms, (2) manifesting bizarre behavior or confusion secondary to drug ingestion, (3) worried that they are or will become addicted, or (4) worried about a friend or family member who is addicted.

In particular, nurses who care for hospitalized adolescents need to know if these youths use drugs compulsively. Drug withdrawal can seriously complicate other illnesses. Nurses should be alert for any physical or behavioral clues that indicate the onset of withdrawal or the effects of drugs. School nurses and nurses who work in the community play an essential role in identifying children, adolescents, and families with substance abuse problems. The school nurse may be the first to identify a child or adolescent who has ingested a particular drug by the child's erratic behavior in class or on the school grounds (see Critical Thinking Case Study). Early identification of those at risk for substance abuse problems is an essential aspect of prevention. Pediatric health care professionals also prevent substance abuse by creating trusting relationships so that children and adolescents feel comfortable asking questions about drugs, and health care professionals can alert them to websites and other aspects of society that encourage experimentation with drugs.

Acute Care. Adolescents experiencing toxic drug effects or withdrawal symptoms are usually seen initially in the emergency department. Experienced emergency department personnel are familiar with the management of acute drug toxicity and the signs, symptoms, and behavioral characteristics associated with a variety of substances. When the drug is questionable or unknown, knowledge of these factors facilitates management and treatment. Often, observation or description of the child's or adolescent's behavior is more valuable than reports by patients or their friends.

The treatment for drug toxicity or withdrawal varies according to the drug and the method used. Every effort is made to determine the type, time of ingestion, amount of drug taken, mode of administration, and factors related to the onset of presenting symptoms. It is helpful to know the individual's pattern of use. For example, if two types of drugs are involved, they may require different treatments. Historically, gastric lavage has been used when the drug has been ingested recently and the cough reflex is intact, but it is of little value when the drug has been administered by the intravenous ("mainlined") or intranasal ("sniffed") route.

CRITICAL THINKING CASE STUDY

Prescription Medication Abuse in Adolescence

An eighth grade teacher calls the school nurse, Sally, to her classroom and reports that a girl is behaving "strangely"; the girl slept most of the period before lunch and has not participated in class discussions. Sally, RN, takes the girl to her office and performs an initial assessment. Upon assessment, the girl demonstrates short-term memory lapse and has slightly slurred speech and her pupillary reaction to light is delayed; her blood pressure is 112/68 mm Hg, respirations are 14 breaths/min and regular, and heart rate is 102 beats/min. She denies taking any pills or liquid initially but then states she had a migraine on arrival to school and a friend gave her two blue pills to help with the headache. She refuses to say who gave her the pills and does not know what they were but thought they were Tylenol. She states that she does not know where her mother or father are but thinks they are at work.

1. Evidence—Is there sufficient evidence for Sally to implement a plan of care for this adolescent?
2. What should Sally's next course of action involve? What is her professional responsibility in this case?
3. Assumptions—Describe the underlying assumptions about the following:
   a. The school nurse's physical assessment findings
   b. The misuse of prescription medications by adolescents
4. What nursing priorities and implications for care can be made at this time? What type of care should this eighth grader receive?

Single-dose activated charcoal has been used for acute poisoning, but there is considerable controversy regarding the benefits and effects over time (Chyka, Seger, Krenzelok, et al., 2005; Elder, 2010; Isbister and Kumar, 2011). Some experts recommend supportive care as the mainstay of overdose treatment in pediatrics (Hanhan, 2008). The administration of a drug antidote such as naloxone and the early (within 1-2 hours of ingestion) administration of activated charcoal may be used for opioid overdose. Because the actual content of most street drugs is highly questionable, other pharmaceutic agents are administered with caution except perhaps the narcotic antagonists in cases of suspected opiate overdoses. It is also necessary to assess for possible trauma sustained while the patient was under the influence of the drug.

Long-Term Management. A major factor in the treatment and rehabilitation of young drug users is careful assessment in the nonacute stage to determine the function that the drug plays in the adolescent's life. The motivation phase is directed toward exploring the factors that influence drug use. It also involves establishing a feeling of self-worth and a commitment to self-help in the teen.

Rehabilitation begins when adolescents decide that they can and are willing to change. Rehabilitation involves fostering healthy interdependent relationships with caring and supportive adults and exploring alternate mechanisms for problem solving while simultaneously reducing or eliminating drug use. Persons working with troubled youth must be prepared for recidivism, or the tendency to relapse, and maintain a plan for reentry into the treatment process.

Family Support. Most treatment programs for substance abusers are based on adult 12-step models such as Alcoholics Anonymous. Research is needed to determine whether these adult

models are effective for adolescents. Tough Love* is one program that is based on the conviction that parents have the right and responsibility to be the policymakers in the family, to set limits on the behavior of their children, and to take control of the household from out-of-control adolescents. The premise is that allowing teenagers to experience the negative consequences of their behavior will bring them closer to accepting help or changing their behavior. Another group that provides support and counseling for families experiencing substance abuse and seeking strategies to cope with their children is Parents Anonymous.† Another source of information is the Substance Abuse and Mental Health Services Administration's National Clearinghouse for Alcohol and Drug Information.‡ The National Institute on Drug Abuse (NIDA) also contains an abundance of information for adolescents on the effects of abused substances, prevention, and treatment (www.drugabuse.gov/students-young-adults).

Prevention. Nurses play an important role in education efforts, as well as in individual observation, assessment, and therapy related to substance abuse. In recent years, a variety of educational programs have been applied with promising results. The most effective prevention strategies are those that are part of a broader, more general effort to promote overall health and success. Health-compromising behaviors are often interconnected and have common antecedents. Prevention efforts that focus on changing only one behavior (e.g., alcohol, other drug use) are less likely to be successful. Successful programs are those that have promoted parenting skills, social skills among distractible children, academic achievement, and skills to resist peer pressure.

Peer pressure is a powerful tool and can be used effectively in substance abuse prevention. A group that has had some success in reducing injury from drunk driving is Students Against Destructive Decisions (SADD).§ Techniques used by this group include peer counseling, parental guidelines for teenage parties, and community awareness. Nurses should encourage the formation of SADD chapters in the high schools in their communities.

Suicide

Suicide is defined as the deliberate act of self-injury with the intent that the injury results in death. Most experts distinguish among suicidal ideation, suicide attempt (or parasuicide), and suicide.

Suicidal ideation involves a preoccupation with thoughts about committing suicide and may be a precursor to suicide. Although it is common for adolescents to experience occasional suicidal thoughts, expressions of preoccupation with suicide should be taken seriously and an assessment should be conducted for appropriate referral. A suicide attempt is intended to cause injury or death. The term parasuicide is used to refer to behaviors ranging from gestures to serious attempts to kill oneself. *Parasuicide* is a preferred term because it makes no reference to intent and because a person's motive may be too difficult or complex to determine. However, all parasuicidal activity should be taken seriously.

! NURSING ALERT

A history of a previous suicide attempt is a serious indicator for possible suicide completion in the future. Studies of adolescent suicides have found that as many as half of the adolescents had made previous attempts.

Results from the 2011 Youth Risk Behavior Surveillance indicated that 7.8% of students nationwide had attempted suicide at least once during the 12 months preceding the survey; the range of suicide attempts by adolescents across the states varied from 3.6% to 11.3% (CDC, 2012b). The overall incidence of youth suicide has decreased since 1992, yet the CDC and other experts note that the incidence is still too high. Approximately 12.8% of the students in this survey reported that they had made a specific plan to attempt suicide in the 12 months preceding the survey. Suicide is currently the third leading cause of death during the teenage years, surpassed only by death from motor vehicle crashes and homicides (see Chapter 27).

Etiology

Individual, family, and social or environmental factors have all been implicated in suicide. The single most important individual factor is the presence of an active psychiatric disorder (depression, bipolar disorder, psychosis, substance abuse, or conduct disorder). Alcohol use in particular has been associated with more than 50% of suicides (Shain and AAP Committee on Adolescence, 2007). For some teens, suicide becomes the final pathway for release from their psychiatric and social problems. Child and adolescent suicide victims are reported to have higher rates not only of depression but also of conduct disorders; bipolar disorders; substance abuse; interpersonal problems with parents; and a family history of depression, substance abuse, and suicidal behavior.

Gay, lesbian, and bisexual adolescents are at particularly high risk for suicide attempts, especially if raised in an environment where they are denied support systems (Saewyc, Skay, Hynds, et al., 2007) (see Community Focus box). Family factors influencing suicide include parental loss; family disruption; a family history of suicide, depression, substance abuse, or emotional disturbance; child abuse or neglect; unavailable parents; poor communication and isolation within the family; family conflict; and unrealistically high parental expectations or parental indifference with low expectations. Families who respect individuality, are cohesive and caring, balance discipline with a supportive and understanding relationship, have good systems of communication, and have at least one attentive and caring parent available to the child protect adolescents from suicidal outcomes. Social or environmental factors include incarceration, isolation, acute loss of a boyfriend or girlfriend, lack of future options, and availability of firearms in the home.

Methods

Firearms are by far the most commonly used instruments in completed suicides among males and females (Shain and AAP Committee on Adolescence, 2007). For adolescent males, the second and third most common means of suicide are hanging and overdose, respectively; for females, the second and third most common means are overdose and strangulation, respectively.

The most common method of suicide *attempt* is overdose or ingestion of a potentially toxic substance, such as drugs. The second most common method of suicide attempt is self-inflicted laceration.

COMMUNITY FOCUS

Suicide, Sexual Identity, and Sexual Orientation

A significant number of teenage suicides occur among homosexual youths. Gay or lesbian adolescents who live in families or communities that do not accept homosexuality are likely to suffer low self-esteem, self-loathing, depression, and hopelessness as a result. Such internalization, without treatment and support, can lead to substance abuse and, eventually, suicide. Youths most at risk are those who struggle with gender identity issues such as gay identity formation at a young age, intrapersonal conflict regarding sexuality, and nondisclosure of orientation to others.

Supportive parents, friends, or relationships serve as protective factors against suicide. However, many gay, lesbian, and bisexual adolescents do not feel supported, understood, or accepted by their friends, parents, and families. Nurses who interact with adolescents must be aware of the association between suicide and adolescent homosexuality and gender nonconformity. School nurses may be the first individuals to discuss issues of sexual identity and orientation with adolescents or their families. In their professional capacity, nurses can serve as support persons for these adolescents. Nurses can also provide guidance and resources to families so that they understand how best to nurture and support their child.

Nurses must also capitalize on opportunities or experiences that promote the healthy development of self-esteem in youths who choose nontraditional or alternative sexual orientation. Educational programs to raise the level of consciousness about the risk factors for and warning signs of suicide are one example. Another possibility could be programs conducted in or outside of school that are designed to foster peer relationships and competency in social skills among high risk adolescents and young adults, such as support groups and social organizations for these young people.

! NURSING ALERT

Given what is known about youth suicide, nurses should ask parents, especially those with at-risk teenagers, if firearms are available in the house and, if so, recommend their removal. Parents must ensure that their children—especially those who are depressed, have poor problem-solving skills, or use drugs or alcohol—do not have access to firearms. Parents must also be educated on the warning signs of suicide (Box 35-8).

Motivation

Suicidal ideation is common in adolescents. It represents numerous fantasies, such as relief from suffering, a means of gaining comfort and sympathy, or a means of revenge against those who have hurt them. Adolescents have the erroneous perception that the act of suicide will evoke remorse and pity and that they will be able to return and witness the grief. Angry children or adolescents who are unable to directly punish those who have injured or insulted them may take revenge on those who love them through self-destruction ("They'll be sorry when they find me dead"; "They'll be sorry they were mean to me").

For adolescents who are severely depressed, suicide seems to be the only release from their despair. These adolescents rarely provide evidence of their intent and frequently conceal their suicidal thoughts. Many adolescents, however, tell their peers of their suicidal thoughts or plans but avoid telling adults. Social isolation is a significant factor in distinguishing adolescents who will kill themselves from those who will not. It is also more characteristic of those who complete suicide than of those who make attempts or threats.

BOX 35-8 WARNING SIGNS OF SUICIDE

- Preoccupation with themes of death—focuses on morbid thoughts
- Wants to give away cherished possessions
- Talks of own death, desire to die
- Loss of energy, loss of interest, listlessness
- Exhaustion without obvious cause
- Changes in sleep patterns—too much or too little
- Increased irritability, argumentativeness, or stubbornness
- Physical complaints—recurrent stomachaches, headaches
- Repeated visits to physician, nurse practitioner, or emergency department for treatment of injuries
- Reckless behavior
- Antisocial behavior—engages in drinking, uses drugs, fights, commits acts of vandalism, runs away from home, becomes sexually promiscuous
- Sudden change in school performance—lowered grades, cutting classes, dropping out of activities
- Resists or refuses to go to school
- Remains distant, sad, remote—flat affect, frozen facial expression
- Describes self as worthless
- Sudden cheerfulness after deep depression
- Social withdrawal from friends, activities, interests that were previously enjoyed
- Impaired concentration
- Dramatic change in appetite

The frequency of contagion or copycat suicides (i.e., an increase in youth suicide that occurs after the suicide of one teenager is publicized) is disturbing and may indicate that teenagers perceive suicide as glamorous. In addition, young people may not realize the finality of suicide because they have become desensitized from constantly viewing violence and death on television.

Diagnostic Evaluation

Depression is common among adolescents who attempt suicide. Depression is characterized by both subjective symptoms and objective signs that reflect the adolescent's sadness and despair. Adolescents describe feelings of sadness, despair, helplessness, hopelessness, boredom, loss of interest, and isolation. They may also feel self-reproach, self-deprecation, and guilt. Subjective symptoms of depression or specific changes in behavior place an adolescent at risk for suicide (Box 35-9).

Therapeutic Management

Threats of suicide should always be taken seriously. There has been a tendency to dismiss suicide attempts as impulsive acts resulting from temporary crises or depression. If a suicide attempt fails to draw attention to their problems or makes them worse, the child or adolescent may conclude that suicide is the only answer. Children and adolescents need to know that someone cares and must be provided with swift and efficient crisis intervention. Although ordinary practitioners can manage an acute depressive reaction without difficulty, the adolescent who has made a serious attempt or has a specific plan for suicide should receive immediate attention and competent psychiatric care.

Youths who are actively suicidal need inpatient care, monitoring, and treatment. Medications for depression and bipolar disorder often take several weeks to reach therapeutic levels. The time until

BOX 35-9 CHARACTERISTICS OF CHILDREN OR ADOLESCENTS WITH DEPRESSION

Behavior

- Predominantly sad facial expression with absence or diminished range of affective response (most of the day)
- Solitary play or work; tendency to be alone; lack of interest in play with friends
- Withdrawal from previously enjoyed activities and relationships
- Lowered grades in school; lack of interest in doing homework or achieving in school; refuses to wake up for school
- Diminished motor activity; tiredness
- Tearfulness or crying
- Inability to concentrate
- Dependent and clinging or aggressive and disruptive
- Recurrent suicidal thoughts or talk

Internal States

- Utterance of statements reflecting lowered self-esteem, sense of hopelessness, or guilt
- Suicidal ideations

Physiology

- Constipation
- Loss of energy; fatigue
- Nonspecific complaints of not feeling well
- Change in appetite resulting in weight loss or gain
- Alterations in sleeping pattern, sleeplessness, or hypersomnia

medications and therapy begin to take effect can be trying for the adolescent and the family. It is important to encourage families to support their teen in adherence to the regimen prescribed. The SSRIs are often prescribed for depression, but teens who are taking such medications need careful, frequent monitoring.

! NURSING ALERT

Adolescents who express suicidal feelings and have a specific plan should be monitored at all times. They should not have access to firearms, prescription or over-the-counter drugs, belts, scarves, shoestrings, sharp objects, matches, or lighters. If they are intoxicated, they must be restrained or placed in a protective environment until a psychiatrist or psychologist can assess them.

CARE MANAGEMENT

Nurses play a pivotal role in reducing adolescent suicide. Nurses have the opportunity to provide anticipatory guidance to parents and adolescents. They can teach parents to be supportive and to develop positive communication patterns that help teens feel connected with and loved by their families. To foster healthy development, parents can be encouraged to provide teens with creative outlets and to assist young people in accepting strong emotions—pain, anger, and frustration—as a normal part of the human experience.

Care of suicidal adolescents includes early recognition, management, and prevention. The most important aspect of management is the recognition of warning signs that indicate that an adolescent is troubled and might attempt suicide. The nurse must take any suicidal remarks seriously and not leave the young person alone until the degree of suicidality is assessed. A mnemonic for the assessment process is *SLAP:* specificity, lethality, accessibility, and proximity. The first step (specificity) is to ask adolescents whether they feel suicidal or as though they would like to take their own lives. If so, have they chosen a means of suicide and do they have a specific plan? The second stage of assessment (lethality) involves determining the lethality of the methods available to them. Do they plan to use a gun or knife? Have they chosen highly lethal medications, hanging, or carbon monoxide poisoning? The third stage (accessibility) involves determining the availability of the means of suicide, and the fourth stage (proximity) involves assessing whether they have determined a time to commit suicide and when.

Health care professionals must be alert to the signs of depression, and anyone who exhibits such behavior should be referred for thorough psychologic assessment. Depression is manifested differently in children and adolescents than in adults. In teens, it may be masked by impulsive aggressive behaviors. Defiance, disobedience, behavior problems, and psychosomatic disturbances can indicate underlying depression, suicidal ideation, and impending suicide attempts.

! NURSING ALERT

No threat of suicide should be ignored or challenged. Threats are a symptom that must be taken seriously. Too often, suicidal threats or minor attempts are confused with bids for attention. It is also a mistake to be lulled into a false sense of security when an adolescent's depression is apparently relieved. The improvement in attitude may mean that the adolescent has made the decision and found the means to carry out the threat.

Peers and other confidants are valuable observers and excellent sources of information about potential suicide attempts. They may not be able to diagnose depression, but they are able to sense when a friend has undergone a marked personality change. It is important to emphasize that the peer who detects any changes in a friend is a potential rescuer and should not remain silent about the observations. Friendship does not imply collusion. A peer who believes that a friend may be suicidal should alert someone who can help (e.g., a parent, teacher, guidance counselor, school nurse).

Routine health assessments of adolescents should include questions that assess the presence of suicidal ideation or intent. The following questions can be asked (Greydanus and Pratt, 1995):

1. Do you consider yourself more a happy person, an unhappy person, or somewhere in the middle?
2. Have you ever been so unhappy or upset that you felt like being dead?
3. Have you ever thought about hurting yourself?
4. Have you ever developed a plan to hurt yourself or kill yourself?
5. Have you ever attempted to kill yourself?

If adolescents answer "yes" to questions 2, 3, or 4, they should be asked if they feel that way now to assess for current suicidality. If teens say they have attempted suicide in the past, assess the number of times and ask them to describe what they were feeling, which method they used, what happened, if they would make a similar attempt, and how they would handle their despair now. Any previous suicide attempt indicates an increased risk for a future attempt. The risk for a suicide attempt in the near future increases as the frequency of suicidal ideation increases.

! NURSING ALERT

The National Suicide Prevention Lifeline (800-273-TALK [8255]; in Spanish, 888-628-9454) offers someone to talk to 24/7.

If children or adolescents express suicidal intent, nurses make a contract, asking them to sign an agreement that they will not attempt suicide during an agreed-on period and that they will call the 24-hour crisis line immediately if they feel that they cannot keep to their contract. The amount of time an adolescent feels comfortable contracting is usually an indication of his or her risk and stability.

Because a suicide attempt is frequently an outgrowth of family distress, it is essential to intervene with the family. It is important to assess family interactions and to recognize disturbed relationships. The most effective approach is recognition of susceptible adolescents during the early stages of family distress so that family counseling can be started. Prevention must be directed toward improving childrearing practices through support and education of parents and changing societal conditions that generate defeat, despair, and maladaptive behavior.

Although confidentiality is an essential part of adolescent counseling, in the case of self-destructive behaviors, confidentiality cannot be honored. Suicidal behavior is reported to the family and other professionals, and adolescents are informed that this will be done. Such action conveys an important message to the youth: that the professionals understand and care.

Many schools have instituted suicide prevention programs. These programs include services such as drop-in counseling and a peer counseling telephone line. Information can also be obtained from the American Association of Suicidology.*

KEY POINTS

- The pubescent growth spurt that begins around age 10 years in girls and age 12 years in boys signals the beginning of adolescence.
- Biologic development during puberty is characterized by increased activity of the pituitary gland, which results in sexual maturity and the appearance of secondary sex characteristics.
- According to Erikson, the major developmental crisis of adolescence is establishing a sense of identity.
- Spiritual development is characterized by the questioning of family values and ideals, a move to more philosophic thinking, and emphasis on personal religion.
- Adolescent relationships with parents may be strained; the influence of the peer group increases, and intimate relationships assume importance.
- Teenagers demonstrate a wide variety of interests, and their increased physical and cognitive skills allow them to engage in increasingly difficult and complex activities.
- Adolescents' emotions fluctuate.
- Nutritional needs may not be met by teenagers' eating habits, such as snacking and irregular mealtimes.
- Motor vehicle injuries are the primary cause of death from injury in the adolescent years.
- The rapid changes, growth, and stress accompanying the transition to adulthood may predispose adolescents to faulty problem solving.
- Cognitive development in adolescence includes abstract thought, thinking beyond the present, logical reasoning, and a sense of idealism.
- Development of body image is closely tied to body changes and social interactions.
- According to Kohlberg's theory of moral development, adolescents begin to question existing moral values and learn to make choices.
- Eating disorders observed in middle and late childhood are obesity, AN, BN, and EDNOS.
- Tobacco smoking is a widespread problem among teenagers. Reasons for smoking include social pressure, mass media influence, and a need to develop a self-concept.
- The substances abused by children and adolescents are alcohol, marijuana, narcotics, central nervous system depressants, central nervous system stimulants, hydrocarbons and fluorocarbons, and mind-altering drugs.
- Suicide, the deliberate act of self-injury with the intent to kill, may occur because of difficulties coping with stress, disturbed family environment, substance abuse or dependency, or mental health disorder.
- No threat of suicide by an adolescent should be ignored.
- Signs of depression in children and adolescents are often subtle and require astute observation by parents and health care professionals.

CHAPTER

36

Chronic Illness, Disability, and End-of-Life Care

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify the scope of and changing trends in care of children with special needs.
- Identify the major reactions of and effects on the family of a child with a special need.
- Define the stages of adjustment to the diagnosis of a chronic condition.
- Recognize the impact of the illness or condition on the developmental stages of childhood.
- Outline nursing interventions that promote the family's optimal adjustment to the child's chronic disorder.
- Outline nursing interventions that support the family at the time of death.
- Define the usual symptoms of normal grief.

PERSPECTIVES ON THE CARE OF CHILDREN AND FAMILIES LIVING WITH OR DYING FROM CHRONIC OR COMPLEX DISEASES

Scope of the Problem

Advances in medical and nursing care such as the increasing viability of extremely preterm infants, the portability of life-sustaining technology (e.g., total parental nutrition, ventilatory support), and life-extending treatments for children with conditions that previously would have led to an early death (e.g., malignancies, genetic conditions) (Burke and Alverson, 2010) have led to an exponential rise in the prevalence of children with complex and chronic diseases. These children have complex conditions involving several organ systems and require multiple specialists, technologic supports, and community services to help them function to their healthiest potential. The complexity, high level of skill required to meet their daily health care needs, and continuous nature and potential volatility of the condition sets this group apart from the broader population of children with special health care needs (Harrigan, Ratliffe, Patrinos, et al., 2002; Rehm and Bradley, 2005). A range of terms such as *medically complex*, *technology dependent*, and *multiply handicapped* have been used to describe this vulnerable population of children (Carnevale, Rehm, Kirk, et al., 2008; Cohen, Friedman, Nicholas, et al., 2008; Harrigan, Ratliffe, Patrinos, et al., 2002; Miles, Holditch-Davis, Burchinal, et al., 1999; O'Brien and Wegner, 2002; Watson, Townsley, and Abbott, 2002). Frequent and prolonged hospitalizations; complex and multisystem health and developmental needs; and reliance on technology and care that cross hospital, clinic, and home settings are the key characteristics that all of these terms seek to signify about the children they are used to represent (Harrigan, Ratliffe, Patrinos, et al., 2002).

The nature and severity of childhood chronic and complex conditions is widely heterogeneous. However, it is the health and developmental consequences of these diagnoses such as ongoing functional impairment; neurodevelopmental disability; dependence on medical technology; and the need for ongoing skilled, supportive care from health care providers and family members that render these children and families particularly vulnerable. The impact of chronic and complex illness in children is wide ranging. Although many authors have described the rise in prevalence that has come about because of advances in medical care (Cohen, Friedman, Nicholas, et al., 2008; Council on Children with Disabilities, 2005; Haffner and Schurman, 2001; Mentro, 2003), accurate estimates of the numbers of affected families are not known (Carnevale, Rehm, Kirk, et al., 2008). These conditions present most families with additional tasks, responsibilities, and concerns (Ray, 2002). A child's activity level and developmental opportunities can be affected. Days can be lost from school. Children with complex chronic conditions may be at increased risk for behavior or emotional problems. Parents may lose days from work, experience financial strain, and be challenged both emotionally and physically as they cope with care of the child.

Siblings are also affected by having a "different" brother or sister and may simultaneously feel guilt and anger or jealousy toward their ill sibling. Clinicians need to know that siblings of children with chronic illnesses are at risk for negative psychologic effects (Sharpe and Rossiter, 2002). Parents need encouragement and assistance in understanding the reactions of siblings to having a chronically ill family member (e.g., behavioral regression, anxiety, withdrawal, apathy). In addition, secondary losses such as the ability to participate in extracurricular activities or social events occur because of routines imposed by the affected child's chronic condition.

Trends in Care

Developmental Focus

Focusing on the child's developmental level rather than chronologic age or diagnosis emphasizes the child's abilities and strengths rather than disabilities. Attention is directed to normalizing experiences, adapting the environment, and promoting coping skills. Nurses often are in vital positions to redirect attention from the pathologic model with its focus on weaknesses and problems to the developmental model to meet the unique needs of the child and family.

A developmental focus also considers family development. The life cycle of the family unit reflects both the changing ages and needs of family members and changing external demands. A family member's serious illness can cause significant stress or crisis at any stage of the family life cycle. Just as with individual development, family development may be interrupted or even regress to an earlier level of functioning. Nurses can use the concept of family development to plan meaningful interventions and evaluate care.

Family-Centered Care

Children's physical and emotional health and their cognitive and social functioning are strongly influenced by how well their families function (Schor, 2003). The importance of family-centered care—a philosophy that considers the family as the constant in the child's life—is especially evident in the care of children with special needs (see also Family-Centered Care, Chapter 26). As parents learn about the child's health care needs, they often become experts in delivering care. Health care providers, including nurses, are adjuncts to the child's care and need to form partnerships with parents. Effective communication and negotiation between parents and nurses are essential to forming trusting and effective partnerships and finding the best ways to meet the needs of the child and family (Corlett and Twycross, 2006). Collaborative relationships are characterized by communication, dialog, active listening, awareness, and acceptance of others' differences (Schor, 2003).

Family–Health Care Provider Communication. The disclosure of a serious chronic or complex condition in a child is one of the most stressful aspects of communication between families and health care professionals. Often parents have suspected for some time that something is wrong with their child and believe that their concerns were minimized or ignored by health care professionals (Smaldone and Ritholz, 2011; Thomlinson, 2002; Whitehead and Gosling, 2003). After a diagnosis is made, numerous studies have shown that parents are not always satisfied with the way in which information is given. Factors that influence parent dissatisfaction with communication include disrespectful attitudes, breaking bad news in an insensitive manner, withholding information, and changing a treatment course without preparing the child and family (Hsiao, Evan, and Zeltzer, 2007). Conversely parents report satisfaction when they perceive health care providers to be available, demonstrate competence, and engage the child and parent in care decision making (Hsiao, Evan, and Zeltzer, 2007). Similar factors are important in communication of changes in the child's condition throughout the course of the illness.

Providing information to families with a chronically ill child should be a process of repeated discussions to allow the family to process the information and their reactions to that information and to ask for clarification and further information. Nurses play an important role in ensuring that families' needs are met during discussions related to the child's diagnosis, condition, and treatment. This requires assessing the amount of information with which the family is comfortable, how much they understand of the information already given to them, and how they are coping with the information both cognitively and emotionally. Nurses should ensure that the appropriate health care professionals address any concerns or further questions that families may have.

Establishing Therapeutic Relationships. Another important aspect of family-centered care of children with chronic and complex conditions is establishing a therapeutic relationship with the child and family, which has been shown to predict improved health-related outcomes (Denboba, McPherson, Kenney, et al., 2006). Families, most often the mother, take on enormous responsibility in providing technical care and symptom management of their child's condition outside the health care institution (O'Brien and Wegner, 2002; Raina, O'Donnell, Rosenbaum, et al., 2005; Swallow and Jacoby, 2001). To build successful therapeutic relationships with families, it is necessary for nurses to recognize parents' expertise with regard to their child's condition and needs. Care conferences, especially multidisciplinary meetings that include the family and key health professionals, provide an opportunity for sharing ideas and expressing feelings or concerns. Health care environments for children with serious illnesses are fraught with obstacles that serve as barriers to successful therapeutic relationships with families. For example, the complex, multidisciplinary care required is often characterized by fragmented, noncohesive approaches to care. Continuity of care can be a challenge in acute care hospitals today, and this makes it difficult to establish relationships and understand communication styles.

Individual discussions, especially with the case manager, primary nurse, clinical nurse specialist, or nurse practitioner, help establish a consistent and flexible care plan that can prevent conflicts or deal with these conflicts before they disrupt care. In family-centered care the goal is to maintain the integrity of the leadership role and support the family during times of crisis or stress.

The Role of Culture in Family-Centered Care. Issues of culture, ethnicity, and race affect access to services, use, and follow-through with referrals and recommendations (Coker, Rodriguez, and Flores, 2010; van Dyck, Kogan, McPherson, et al., 2004; Wise, Wampler, Chavkin, et al., 2002; Wood, Smith, Romero, et al., 2002; Zuvekas and Taliaferro, 2003). For some ethnic and minority populations, cultural understandings of illness, the structure of family life, social roles for individuals with disabilities, and other factors related to the perception of children may differ from those of mainstream American culture. These factors may affect family needs and choices regarding the care of their child with special needs.

Although culture cannot completely explain how an individual will think and act, understanding cultural perspectives can help the nurse anticipate and understand why families may make certain decisions. Cultural attributes such as values and beliefs regarding illness or chronic condition and its causation, social roles for people

who are ill or disabled, family structure, the role of children, childrearing practices, self-versus-group orientation, spirituality, and time orientation also affect a family's response to illness or chronic condition in a child (Carnevale, Alexander, Davis, et al., 2006; Carter, 2002; Marshall, Olsen, Mandleco, et al., 2003; Rehm, 1999; Sterling and Peterson, 2003).

When parents are informed of their child's chronic illness, interpreters familiar with both culture and language should be used. Children, family members, and friends of the family should not be used as translators because their presence may prevent parents from openly discussing the issues. When working with people of cultural backgrounds different from their own, nurses must listen carefully with an initial goal of understanding and articulating the family's perspective. The ability to interpret the mainstream medical culture to the family is also important. Furthermore, every effort is made to incorporate traditional cultural beliefs of a family into treatment plans. It is important to keep in mind that "cultural norms" may not always apply to every family from a shared background. Nurses who assess the unique needs of each family, listen, and keep themselves open to novel ways of meeting the individual needs of the child and family will likely be successful in establishing a therapeutic relationship. Developing a care plan in conjunction with the family, considering their preferences and priorities, is an important first step in formulating a plan that best meets the family's needs, no matter what their cultural background (Ahmann, 1994; Coker, Rodriguez, and Flores, 2010; Ochieng, 2003).

Shared Decision Making

Shared decision making among the child, family, and health care team can result from open, honest, culturally sensitive communication and the establishment of a therapeutic relationship among the family and health care providers. In a shared decision-making model, the health care professionals provide honest, clear information regarding diagnosis, prognosis, treatment options, and risk-benefit assessment. The patient and family then share information with the health care team regarding important family values, acceptable levels of discomfort or inconvenience, and the ability to comply with treatments being recommended (Charles, Gafni, and Whelan, 1997; Kon, 2010). This process allows them to discuss all options in terms of the risks and benefits to the child and family, the prognosis or expected course of the illness, and the impact on the family's resources (Box 36-1). Together the parents and health care team can make decisions that are best for the family and child at the time the decision is made (Kon, 2010).

BOX 36-1 FACILITATING SHARED DECISION MAKING

- Continually assess the impact of the child's illness and treatment on the family.
- Provide honest, accurate information regarding the trajectory of the disease, anticipated complications, and prognostic information.
- Discuss what the family desires for the child's quality of life.
- Avoid personal opinion or judgment of the family's questions and decisions.
- Be aware of nurses' personal and cultural assumptions and the ways these assumptions impact communication, decision making, and judgment.

Normalization

Normalization refers to the efforts that family members make to create a normal family life, their perceptions of the consequences of these efforts, and the meanings they attribute to their management efforts (Knafl, Darney, Gallo, et al., 2010). For chronically ill children such efforts may include attending school, pursuing hobbies and recreational interests, and achieving employment and a level of independence. For their families it may entail adapting the family routine to accommodate the ill or disabled child's health and physical needs (McDougal, 2002).

Children with chronic and complex conditions and their families face numerous challenges in achieving normalization. Families move between the "normal" of living with the experience of chronic childhood illness and the "normal" of the healthy outside world; they often redefine "normal" based on their particular experiences, needs, and circumstances (Deatrick, Knafl, Murphy-Moore, 1999; Gantt, 2002; Nelson, 2002). Normalization may be an important mediator of illness-related stressors (e.g., treatment demands, uncertainty) on family outcomes.

Nurses can help families normalize their lives by assessing their everyday life, social support systems, coping strategies, family cohesiveness, and family and community resources. Interventions could include encouraging families to reduce stress through delegation of care and family tasks, identifying ways to incorporate care into current routines, structuring the home environment to encourage the child's engagement in age-appropriate activities, and ensuring that families have access to appropriate community support services (Jokinen, 2004; Shepard and Mahon, 2000). Being supportive of the child's illness and treatment and actively including the family in all aspects of care improves their self-esteem and promotes further development (Shepard and Mahon, 2000).

Home care represents the return to a system and set of priorities in which family values are as important in the care of a child with a chronic health problem as they are in the care of other children. Home care seeks to achieve goals that are consistent with the developmental model (Stein, 1985):

- Normalize the life of the child, including those with technologically complex care, in a family and community context and setting.
- Minimize the disruptive impact of the child's condition on the family.
- Foster the child's maximum growth and development.

With appropriate training and support, families provide complex procedures and treatments in the home. Parents are challenged to retain a homelike setting among monitors, ventilators, and other sophisticated equipment. Throughout this text home care is discussed as appropriate for specific conditions. The process of transition from hospital to home is elaborated on in Chapters 20 and 21.

Paralleling normalization and home care is the process of mainstreaming, or integrating children with disabilities into regular classrooms. Just as the home is the natural environment for children, so school must also be included as an essential component of children's overall physical, intellectual, and social development. Children who attend school have the advantages of learning and socializing with a wide group of peers. There is an increased focus on individualization as plans are made to meet the academic needs of these children along with those of the rest of the students.

A variety of supplemental programs have been designed in the school system to accommodate special needs, both at school age and younger, through early intervention, which consists of any sustained and systematic effort to assist children from birth to age 3 years who have disabilities and are developmentally vulnerable. This change

and increasing opportunities for normalization for children with disabilities in large part have resulted from the passage of (1) the Education for All Handicapped Children Act of 1975 (Public Law 94-142) and its 1990 amendments (Public Law 101-476), which changed the name of the act to the Individuals with Disabilities Education Act (IDEA); (2) the Education of the Handicapped Act Amendments of 1986 (Public Law 99-457), which directs states to develop and implement statewide comprehensive, coordinated, multidisciplinary interagency programs of early intervention services for infants and toddlers with disabilities and support services for their families; and (3) the Americans with Disabilities Act of 1990. Nurses can provide parents with information about these laws and in some cases may participate in the development of individualized educational programs (IEPs) or individualized family service plans (IFSPs) for children with disabilities.

Managed Care

Managed care programs have become the major form of health care provision in the United States (Jackson, 2000). This model of care has brought both opportunities and challenges with respect to the care of children with chronic and complex conditions. Although managed care may promote continuity and coordination of care for children and families with private insurance, it has had an unfavorable impact on relatively resource-limited families caring for children with complex chronic illnesses (Huffman, Brat, Chamberlain, et al., 2010). Children rely on adults for access to health care and follow-up with treatment regimens, making it necessary to manage the child's care in the context of the family (McPherson, Weissman, Strickland, et al., 2004; van Dyck, Kogan, McPherson, et al., 2004).

THE FAMILY OF THE CHILD WITH A CHRONIC OR COMPLEX CONDITION

A major goal in working with the family of a child with chronic or complex illness is to support the family's coping and promote their optimal functioning throughout the child's life. Long-term, comprehensive, family-centered approaches extend beyond supporting the child and family during the critical periods of diagnosis and hospitalization. Rather, comprehensive care involves forming parent-professional partnerships that can support a family's adaptation across the trajectory of the illness to the many changes that may be necessary in day-to-day life, determining expectations of and for the child, and providing a long-term perspective (Box 36-2).

BOX 36-2 ADAPTIVE TASKS OF PARENTS HAVING CHILDREN WITH CHRONIC CONDITIONS

1. Accept child's condition.
2. Manage child's condition on a day-to-day basis.
3. Meet child's normal developmental needs.
4. Meet developmental needs of other family members.
5. Cope with ongoing stress and periodic crises.
6. Help family members manage their feelings.
7. Educate others about child's condition.
8. Establish support system.

From Canam C: Common adaptive tasks facing parents of children with chronic conditions, *J Adv Nurs* 18:46–53, 1993.

The impact of a child's medical or developmental condition is often experienced over time, initially as a crisis at the time of diagnosis, which may occur at birth, after a long period of diagnostic testing, or immediately after a tragic injury. The impact may also be felt before the diagnosis is made, when parents are aware that something is wrong with their child but before medical confirmation (Thomlinson, 2002; Whitehead and Gosling, 2003).

The diagnosis and initial discharge home are critical times for parents (Coffey, 2006). Several factors can make it particularly difficult, including a long duration of uncertainty in the diagnostic process, negative perceptions of chronic illness, insufficient information, and lack of mutual trust between parents and their child's health care team (Garwick, Patterson, Bennett, et al., 1995; Monterosso, Kristjanson, Aoun, et al., 2007; Nuutila and Salanterä, 2006). Parental feelings of shock, helplessness, isolation, fear, and depression are common (Coffey, 2006; Nuutila and Salanterä, 2006). Throughout the first year parents struggle to accept the child's diagnosis, care, and uncertainty of the future (Coffey, 2006). Providing explicit and uncomplicated information to parents in an empathic way (Nuutila and Salanterä, 2006); assessing the family's daily routine, living conditions, background knowledge, skills and abilities, and coping behaviors; and evaluating the family's understanding of the information can encourage optimal support at the time of diagnosis and initial discharge home. It is also necessary to reassess parents' needs for information and support on a routine basis (Nuutila and Salanterä, 2006).

Other critical times include the exacerbation of the child's physical symptoms, which increases parental care. These crises often involve medical intervention and rehospitalization. Frequently the child does not return to his or her precrisis level of functioning, and parents and family must adapt to new care needs and schedules. Instability may also follow transition points on the **illness trajectory.** For example, changes in caregivers and significant chronologic age milestones can increase parental stress, and advocating for the child during these times is essential. Supporting parents, respecting their stress and emotions, and acknowledging their role as team members in the care of their child are important aspects of nursing care (Coffey, 2006; Nuutila and Salanterä, 2006).

Impact of the Child's Chronic Illness

Each member of a family who has a child with a chronic or complex illness is affected by the experience (Sullivan-Bolyai, Sadler, Knafl, et al., 2003). The effects on the parents and their responses may be so intense that they directly influence the other members' reactions and the child's own coping.

Parents

In addition to the stress of grieving for the loss of a perfect child, parents are affected by whether or not they receive positive feedback from interactions with their child. Many parents feel satisfaction and fulfillment from the parenting role. For others parenting may be a series of unrewarding experiences that contribute to feelings of inadequacy and failure (Box 36-3). These responses may be most evident in parents who are responsible for the child's care. For example, parents may become preoccupied with their ability to carry out certain procedures, overlooking the child's personal comfort and satisfaction or failing to offer praise for anything less than perfect cooperation or performance. They may pursue a frustrating activity until they achieve "success"—long after the child has become irritable and uncooperative. As a result parents can become caught in a pattern of interaction that is mutually unrewarding and minimally productive. This situation may become exacerbated by

disagreements or lack of support from other family members and judgment from caregivers and others in the community. For these parents several strategies may be helpful, including education regarding what can reasonably be expected of their child, assistance in identifying the child's strengths, praise for a parental job well done, and respite care so parents can renew their energies.

Parental Roles. Parenting a child with a complex chronic condition requires much more than raising a typical child. In addition to attending to the routine aspects of parenting, parents of chronically ill children take on the added responsibility of performing complex technical care and symptom management, advocating for their child, and seeking and coordinating health and social services for their ill or disabled child (Kirk, Glendinning, and Callery, 2005). These added responsibilities must then be balanced with the needs of other family members, extended family and friends, and personal health and obligations to minimize consequences to the overall functioning of the family (Coffey, 2006; Ray, 2002). Enormous demands may be placed on parental time, energy, and financial resources.

Often one parent or partner remains at home to manage existing family responsibilities while the other remains with the ill child. The partner who is not included in the caregiving activities may feel neglected because all of the attention is directed toward the child and resentful that he or she is not sufficiently informed to be competent in the care. Without active participation in the child's care, the parent has little appreciation of the time and energy involved in performing these activities. When this partner does attempt to participate, the other parent may criticize the less skillful efforts. As a result, communication and support for one another may be adversely affected.

The nurse can help parents avoid role conflicts by providing anticipatory guidance early in the process. Teaching should address stressors often identified as having an impact on the marriage, including (1) the burden of care at home assumed by primarily one parent, (2) the financial burden, (3) the fear of the child dying, (4) pressure from relatives, (5) the hereditary nature of the disease (if applicable), and (6) fear of pregnancy. Other causes of tension may center on the inconveniences associated with care such as long waits for an appointment, lack of parking near care facilities, or lack of overnight accommodations. Certainly these last stressors are within health professionals' domain to minimize, if not eliminate.

BOX 36-3 ANTICIPATED PARENTAL STRESS POINTS

Diagnosis of the condition—Parents require considerable education while dealing with an emotional response.
Developmental milestones—Times that children normally achieve walking, talking, and self-care are delayed or impossible for the child.
Start of schooling—Particularly stressful are situations in which appropriate schooling will not be in a regular class placement.
Reaching the ultimate attainment—Parents must handle situations such as realizing that ambulation will be impossible or that the child will not learn to read.
Adolescence—Issues such as sexuality and independence become prominent.
Future placement—Decisions about placement must be made when the child becomes an adult or when the parents can no longer care for the child.
Death of the child

Mother-Father Differences. Mothers and fathers in the same family often adjust and cope differently as parents of a child with a complex condition. Some mothers experience a peaks-and-valleys periodic crisis pattern, whereas most fathers tend to experience a steady, gradual recovery. Some research suggests that mothers of children with certain conditions may be more susceptible to psychologic distress and fatigue than fathers (Tong, Kandala, Haig, et al., 2002). Mothers are most often the primary caregiver and are more likely than fathers to give up their jobs to care for their children, often resulting in social isolation (Coffey, 2006). Mothers often have greater needs for social support and positive appraisal of the situation, whereas fathers are more likely to use self-controlling behaviors to cope (Goldbeck, 2001; Mastroyannopoulou, Stallard, Lewis, et al., 1997).

Fathers of children with disabilities struggle with issues that may be distinct from those of the mothers (Swallow, Macfadyen, Santacroce, et al., 2012). Fathers may think that their role of protector is challenged because they do not know how to help and cannot protect their family from the seemingly overwhelming recurring problems. With today's increased emphasis on fathers' involvement in the lives of their children, this loss is felt more profoundly than in the past. The extensive stresses in the family can leave fathers feeling depressed, weak, guilty, powerless, isolated, embarrassed, and angry. However, fearful that they will lose control or be viewed as weak or ineffectual, they often hide their feelings and display an outward confidence that may lead others to believe that everything is fine. They worry about what the future holds for their children, their ability to manage the increasing financial burden, and the daily disruptions of the entire family (Davies, Gudmundsdottir, Worden, et al., 2004; Swallow, Macfadyen, Santacroce, et al., 2012). Some fathers use work as an escape to dull the pain. In addition to withdrawal, common coping strategies are problem oriented and include praying, getting information, looking at options, and weighing choices (Mastroyannopoulou, Stallard, Lewis, et al., 1997).

Single-Parent Families. Single-parent families are of special concern. The absence of a parent may result from divorce or death, or the parents may never have married. As the only parent of a child who may require extensive, sophisticated, and lifelong care, the single parent may feel an enormous burden. Available financial and emotional resources may already be stretched to the limit. A special effort should be made to help the single parent find financial and support services that can ease the burden of care. Nurses can also help the single parent identify helping roles that may be acceptable to relatives and friends.

Siblings

Results of studies on how siblings are affected by having a brother or sister with a complex condition are unclear (Anderson and Davis, 2011; Barlow and Ellard, 2006). Generally evidence shows a negative effect on siblings of children with chronic illnesses compared with siblings of healthy children (Gold, Treadwell, Weissman, et al., 2011). Siblings of children with chronic illnesses report psychosocial problems more often than their peers (Gold, Treadwell, Weissman, et al., 2011; Rossiter and Sharpe, 2001). A number of factors increase the risk of negative effects for siblings of ill children. Responsibility for caregiving, differential treatment by parents, and limitations in family resources and recreational time are often the experiences of siblings of ill or disabled children (Lobato and Kao, 2002) (Box 36-4).

An important factor in sibling adjustment and coping is information and knowledge regarding their brother's or sister's illness or complex condition. What siblings piece together or overhear is often

BOX 36-4 SUPPORTING SIBLINGS OF CHILDREN WITH SPECIAL NEEDS

Promote Healthy Sibling Relationships

- Value each child individually and avoid comparisons. Remind each child of his or her positive qualities and contribution to other family members.
- Help siblings see the differences and similarities between themselves and the child with special needs. Create a climate in which children can achieve successes without feeling guilty.
- Teach siblings ways to interact with the child.
- Seek to be fair in terms of discipline, attention, and resources; require the affected child to do as much for himself or herself as possible.
- Let siblings settle their own differences; intervene only to prevent siblings from hurting one another.
- Legitimize reasonable anger. Even children with special needs behave badly sometimes.
- Respect a sibling's reluctance to be with or to include the child with special needs in activities.

Help Siblings Cope

- Listen to siblings to let them know that their thoughts and suggestions are valued.
- Praise siblings when they have been patient, have sacrificed, or have been particularly helpful. Do not expect them to always act in this manner.
- Acknowledge the personal strengths that siblings have and their ability to cope with stress successfully.
- Provide age-appropriate information about the child's condition and update it when appropriate.
- Let teachers know what is happening so they can be understanding and helpful.
- Recognize special stress times for siblings and plan to minimize negative effects.
- Schedule special time with siblings; have a friend or family member substitute when parent is unavailable.
- Encourage siblings to join or help establish a sibling support group.
- Use the services of professionals when needed. If parent thinks that such a service is necessary, it should be provided in as vigorous a manner as a service for the child with special needs.

Involve Siblings

- Seek out ways to realistically include siblings in the care and treatment of the child with special needs.
- Limit caregiving responsibilities and give recognition when siblings perform them.
- Develop a library of children's books on special needs.
- Invite siblings to attend meetings to develop plans for the child with special needs (e.g., individualized educational program, individualized family service plan).
- Discuss future plans with them.
- Solicit their ideas on treatment and service needs.
- Have them visit professionals who work with the child.
- Help them develop competencies to teach the child new skills.
- Provide opportunities for siblings to advocate for the child.
- Allow siblings to set their own pace for learning and involvement.

Data from Powell T, Ogle P: *Brothers and sisters—a special part of exceptional families,* Baltimore, 1985, Paul H Brooks; Spokane Washington Deaconess Medical Center, Pediatric Oncology Unit: Tips for dealing with siblings, *Candlelighters Childhood Cancer Found Q Newslett* 11(3,4):7, 1987; and Carlson J, Leviton A, Mueller M: Services to siblings: an important component of family-centered practice, *ACCH Advocate* 1(1):53–56, 1993.

much worse than the truth. Often they imagine gruesome things regarding the experiences related to the illness, treatment, and hospitalization (Shepard and Mahon, 2000). Latino siblings have reported less accurate information about their siblings' condition than non-Latino siblings (Lobato, Kao, and Plante, 2005). Parents are usually in the best position to impart information, although they are often overwhelmed with the medical crisis at hand (Fleitas, 2000). Nurses can encourage parents to talk with the siblings about how they perceive their sick brother or sister and to be accepting of the siblings' feelings. Nurses can be ideal educators and counselors of siblings during the course of their brother's or sister's illness (Shepard and Mahon, 2000).

Coping with Ongoing Stress and Periodic Crises

Professionals can help families cope with stress by providing anticipatory guidance, providing emotional support, helping the family assess and identify specific stressors, helping them develop coping mechanisms and problem-solving strategies, and working collaboratively with parents so they become empowered in the process (Anderson and Davis, 2011).

Concurrent Stresses Within the Family

The ability to deal with the overwhelming stress of a chronic illness is challenged further when additional stresses are present. Stressors may be situational or developmental. They may be related to marital difficulties, sibling needs, homelessness, or social isolation. Some families may simultaneously be struggling with a family member's alcohol or other drug problem. Even relatively minor stressors such as arranging care for siblings, managing the home, and traveling to distant treatment centers can challenge a family's ability to cope successfully.

Most families, regardless of their income or insurance coverage, have financial concerns. The costs of caring for a child with a complex illness can be overwhelming. Nurses and social workers can help a family review various options for financial assistance, including insurance, managed care, or health maintenance organization policies; Medicaid; Supplemental Security Income; Women, Infants, and Children (WIC) program; the state Program for Children with Special Health Needs; disease-related associations; and local philanthropic organizations.

Coping Mechanisms

Coping mechanisms are behaviors aimed at reducing the tension caused by a crisis. Approach behaviors are coping mechanisms that result in movement toward adjustment and resolution of the crisis. Avoidance behaviors result in movement away from adjustment and represent maladaptation to the crisis. Several approach and avoidance behaviors used in coping with a chronic illness are listed in the Guidelines box on p. 1057. None of the indexes can be used singly to assess the possible success or failure in resolving the crisis. Each behavior must be viewed in the context of all of the variables affecting the family. For example, observing several avoidance behaviors in an emotionally healthy family may denote significantly less risk to the successful resolution of the crisis than an equal number of avoidance behaviors in an individual who has few available supports.

Parental Empowerment

Empowerment can be seen as a process of recognizing, promoting, and enhancing competence. For parents of children with chronic conditions, empowerment may occur gradually as strength and capabilities are drawn on to master the child's care, manage family life, and plan for the future. Advocating for the child and developing parent-professional partnerships are part of taking charge (Ray, 2002).

Helping Family Members Manage Their Feelings

Although some previous research has postulated stages of adaptation to a chronic illness, there is a great deal of individual variation in responses to the diagnosis, adjustments made, and time frames for coming to terms with a diagnosis. It is important that professionals recognize and respect a wide range of reactions and coping mechanisms. In fact, members of the family of a child with a complex chronic condition may experience a number of difficult emotions, including fear, guilt, anger, resentment, and anxiety. Learning to manage these emotions promotes adaptive coping (see Guidelines box). Support from professionals, other family members, and friends can help family members manage their feelings. The following discussion examines some common phases of adjustment and emotional reactions.

Shock and Denial

The initial diagnosis of a chronic illness or complex condition is often met with intense emotion and is characterized by shock, disbelief, and sometimes denial, especially if the disorder is not obvious, as in chronic illness. Denial as a defense mechanism is a necessary cushion to prevent disintegration and is a normal response to grieving for any type of loss. Probably all family members experience various degrees of adaptive denial as they learn of the impact that the diagnosis has on their lives.

Shock and denial can last from days to months, sometimes even longer. Examples of denial that may be exhibited at the time of diagnosis include the following:

- Health care provider shopping
- Attributing the symptoms of the actual illness to a minor condition
- Refusing to believe the diagnostic tests
- Delaying consent for treatment
- Acting happy and optimistic despite the revealed diagnosis
- Refusing to tell or talk to anyone about the condition
- Insisting that no one is telling the truth regardless of others' attempts to do so
- Denying the reason for admission
- Asking no questions about the diagnosis, treatment, or prognosis.

Generally these mechanisms should be respected as short-term responses that allow individuals to distance themselves from the tremendous emotional impact and to collect and mobilize their energies toward goal-directed, problem-solving behaviors.

In children the importance of denial has repeatedly been demonstrated as a factor in their positive coping with the diagnosis. Denial allows the child to maintain hope in the face of overwhelming odds and function adaptively and productively. Similar to hope, denial may be an adaptive mechanism for dealing with loss that persists until a family or patient is ready or needs other responses.

Denial is probably the least understood and most poorly handled reaction. Health professionals typically label denial as maladaptive and act inappropriately by attempting to strip it away by repeated and sometimes blunt explanations of the prognosis. However, denial becomes maladaptive only when it prevents recognition of treatment or rehabilitative goals necessary for the child's optimal survival or development.

GUIDELINES

Assessing Coping Behaviors

Approach Behaviors

- Asks for information regarding diagnosis and child's present condition
- Seeks help and support from others
- Anticipates future problems; actively seeks guidance and answers
- Endows the chronic illness or complex condition with meaning
- Shares burden of disorder with others
- Plans realistically for the future
- Acknowledges and accepts child's awareness of diagnosis and prognosis
- Expresses feelings such as sorrow, depression, and anger and realizes reason for the emotional reaction
- Realistically perceives child's condition; adjusts to changes
- Recognizes own growth through passage of time such as earlier denial and nonacceptance of diagnosis
- Verbalizes possible loss of child

Avoidance Behaviors

- Fails to recognize seriousness of child's condition despite physical evidence
- Refuses to agree to treatment
- Intellectualizes about the illness but in areas unrelated to child's condition
- Is angry and hostile to members of the staff regardless of their attitude or behavior
- Avoids staff, family members, or child
- Entertains unrealistic future plans for child with little emphasis on the present
- Is unable to adjust to or accept a change in progression of disease
- Continually looks for new cures with no perspective toward possible benefit
- Refuses to acknowledge child's understanding of disease and prognosis
- Uses magical thinking and fantasy; may seek "occult" help
- Places complete faith in religion to point of relinquishing own responsibility
- Withdraws from outside world; refuses help
- Punishes self because of guilt and blame
- Makes no change in lifestyle to meet needs of other family members
- Resorts to excessive use of alcohol or drugs to avoid problems
- Verbalizes suicidal intents
- Is unable to discuss possible loss of child or previous experiences with death

Adjustment

For most families adjustment gradually follows shock and is usually characterized by an open admission that the condition exists. This stage may be accompanied by several responses, which are normal parts of the adaptation process. Probably the most universal of these feelings are guilt and self-accusation. Guilt is often greatest when the cause of the disorder is directly traceable to the parent, as in genetic diseases or accidental injury. However, it can occur even without any scientific or realistic basis for parental responsibility. Frequently the guilt stems from a false assumption that the child's condition is a

result of personal failure or wrongdoing such as not doing something correctly during pregnancy or the birth. Guilt may also be associated with cultural or religious beliefs. Some parents are convinced that they are being punished for some previous misdeed. Others may see the illness as a trial sent by God to test their religious strength and faith. With correct information, support, and time, most parents master guilt and self-accusation. The ability to master resentful and self-accusatory feelings of having "caused" the child's disorder is a crucial factor in determining the parents' acceptance of their child.

Children, too, may interpret their serious illness as retribution for past misbehavior. The nurse should be particularly sensitive to the child who passively accepts all painful procedures. This child may believe that such acts are inflicted as deserved punishment. It is vital that parents and health care professionals reassure children that their illnesses are not their fault.

Other common and normal reactions to a diagnosis are bitterness and anger. Anger directed inward may be evident as self-reproaching or punitive behavior such as neglecting one's health and verbally degrading oneself. Anger directed outward may be manifested in either open arguments or withdrawal from communication and may be evident in the person's relationship with any number of individuals (e.g., the spouse, the child, and siblings). Passive anger toward the ill child may be evident in decreased visiting, refusal to believe how sick the child is, or an inability to provide comfort. Among the most common targets for parental anger are members of the staff. Parents may complain about the nursing care, the insufficient time health care providers spend with them, or the lack of skill of those who draw blood or start intravenous infusions.

Children are apt to respond with anger as well, and this includes the affected child and the well siblings. Children are aware of the loss engendered by their illness or complex condition and may react angrily to the restrictions imposed or the feelings of being different. Siblings may also feel anger and resentment toward the ill child and parents for the loss of routine and parental attention. It is difficult for older children and almost impossible for younger children to comprehend the plight of the affected child. Their perception is of a brother or sister who has the undivided attention of their parents, is showered with cards and gifts, and is the focus of everyone's concern.

During the period of adjustment four types of parental reactions to the child influence the child's eventual response to the disorder:

1. *Overprotection,* in which the parents fear letting the child achieve any new skill, avoid all discipline, and cater to every desire to prevent frustration
2. *Rejection,* in which the parents detach themselves emotionally from the child but usually provide adequate physical care or constantly nag and scold the child
3. *Denial,* in which the parents act as if the disorder does not exist or attempt to have the child overcompensate for it
4. *Gradual acceptance,* in which the parents place necessary and realistic restrictions on the child, encourage self-care activities, and promote reasonable physical and social abilities

Reintegration and Acknowledgment

For many families the adjustment process culminates in the development of realistic expectations for the child and reintegration of family life with the illness or complex condition in a manageable perspective. Because a large portion of this phase is one of grief for a loss, total resolution is not possible until the child dies or leaves home as an independent adult. Therefore one can regard adjustment as "increased comfort" with everyday living rather than a complete resolution.

This adjustment phase also involves social reintegration in which the family broadens its activities to include relationships outside of the home with the child as an acceptable and participating member of the group. This last criterion often differentiates the reaction of gradual acceptance during the adjustment period from total acceptance or perhaps is more descriptive of the acknowledgment process.

Many parents of children with chronic illnesses experience **chronic sorrow** (i.e., feelings of sorrow and loss that recur in waves over time). As the child's condition progresses, they experience repeated losses that represent further declines and new caregiving demands. Consequently families must be assessed on an ongoing basis and offered appropriate support and resources as their needs change over time (Bettle and Latimer, 2009; Gordon, 2009). This represents a critical period of time as the approach and support provided by the nursing and medical team during this period of time can directly impact the experience of complicated grief after the death of the child. Complicated grief (Meert, Shear, Newth, 2011), characterized as persistent distress and chronic stress response, may last 6 months or longer after the death of a child and has a significant impact on quality of life of the family left behind. It has been proposed as a new diagnostic entity to be included in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (Meert, Shear, Newth, 2011).

Establishing a Support System

The diagnosis of a child with a complex chronic condition is a major situational crisis that affects the entire family system. However, families can experience positive outcomes as they successfully deal with the many challenges that accompany a child with chronic illness (Hungerbuehler, Vollrath, and Landolt, 2011).

One nursing goal is to assess which families are at greater or lesser risk for succumbing to the effects of the crisis. Several variables (i.e., available support system, perception of the event, coping mechanisms, reactions to the child, available resources, and concurrent stresses within the family) influence the resolution of a crisis. Although most families cope well, the needs of families at risk are great. If they receive emotional support and guidance early, there is an increased likelihood that they will also cope successfully.

Although it is easy to assume that families of children with the most severe illnesses or disabilities would have the poorest adjustment, the severity of the condition reflects only one part of the overall picture. The level of adjustment is significantly influenced by the functional burden on the individual family (Stein, 1985). This concept considers the issues related to caring for and living with the child in relation to the family's resources and ability to cope (Box 36-5). If a family of a child with a high level of technology dependence who demands complex care has many resources and coping skills, they may adjust more successfully to the child's situation than the family of a child with a less serious condition and few resources to counterbalance.

Intrafamilial resources, social support from friends and relatives, parent-to-parent support, parent-professional partnerships, and community resources interweave to provide a flexible web of support for families of children with chronic conditions.

THE CHILD WITH A CHRONIC OR COMPLEX CONDITION

The child's reaction to chronic illness depends to a great extent on his or her developmental level, temperament, and available coping

BOX 36-5 CONCEPT OF FUNCTIONAL BURDEN

Impact of the Child with Special Needs

- Child's need for medical and nursing care
- Child's fixed deficits
- Child's age-appropriate dependency in activities of daily living
- Disruptions in family routine caused by the care
- Psychologic burden of prognosis on family

Family Resources and Ability to Cope

- Family's physical resources
- Family's emotional resources
- Family's educational resources
- Family's social supports and available help
- Competing demands for family members' time and energy

Data from Stein REK: Home care: a challenging opportunity, *Child Health Care* 14(2):90–95, 1985.

FIG 36-1 Children with any type of impairment should have the opportunity to develop their skills. (Courtesy Poyo/Hinton Photography.)

mechanisms; on the reactions of family members or significant others; and to a lesser extent on the condition itself. A child's conceptual understanding of his or her own illness is based not only on age and developmental level but also on the duration and type of experience accumulated with the disease. Knowledge of these variables is essential in providing the kind of information and support needed by these children to cope with an often overwhelming situation.

Developmental Aspects

The impact of a complex chronic illness is influenced by the age at onset. Chronic illness affects children of all ages, but the developmental aspects of each age-group dictate particular stresses and risks for the child. The nurse must also recognize that children need to redefine their condition and its implications as they develop and grow. For example, appearance, skills, and abilities are highly valued by peers (Fig. 36-1); a teenager who is limited in any of these qualities is subject to rejection. This is especially marked when an illness interferes with sexual attractiveness.

Children's developmental concepts of illness are discussed in Chapter 38. An understanding of these developmental factors facilitates planning care to support the child and minimize the risks. Developmental aspects of chronic illness on children are described in Table 36-1.

Coping Mechanisms

Children with chronic conditions tend to use five distinct patterns of coping (Box 36-6). Children with more positive and accepting attitudes about their chronic illness use a more adaptive coping style characterized by optimism, competence, and compliance. They show fewer behavior problems at home and school. The two maladaptive coping patterns—"Feels different and withdraws" and "Is irritable, is moody, and acts out"—are associated with poorer adaptation; children using these strategies have poorer self-concepts, more negative attitudes about their conditions, and more behavior problems at home and school.

Well-adapted children gradually learn to accept their physical limitations and find achievement in a variety of compensatory motor and intellectual pursuits. They function well at home, at school, and with peers. They have an understanding of their disorder that allows them to accept their limitations, assume responsibility for their care, and assist in treatment and rehabilitation regimens. They express appropriate emotions such as sadness, anxiety, and anger at times of exacerbations but confidence and guarded optimism during periods of clinical stability (Fig. 36-2). They are able to identify with other similarly affected individuals, promoting positive self-images and displaying pride and self-confidence in their ability to master a productive, successful life despite their illnesses.

Hopefulness

Children, particularly adolescents, are sensitive to the presence or absence of hope. Hopefulness is an internal quality that mobilizes humans into goal-directed action that may be satisfying and life sustaining. A sense of hopefulness can produce increased participation in health-seeking behaviors and an improved sense of well-being (Ritchie, 2001).

Health Education and Self-Care

Health education is an intervention that promotes coping. Children need information about their condition, the therapeutic plan, and how the disease or therapy might affect their particular situation. Children nearing puberty also need to understand the maturation process and how their chronic illness may alter this event. For example, a youngster with Crohn's disease should understand that this disorder is associated with growth failure and delayed puberty; a child with diabetes needs to know that hormonal changes and increased growth needs alter food and insulin requirements at this time; and a sexually active girl with sickle cell anemia or systemic lupus erythematosus needs to be aware of the risks of pregnancy. The information should not be given all at once but timed appropriately to meet the changing needs of the youngsters, and it should be described and repeated as often as the situation demands.

NURSING CARE OF THE FAMILY AND CHILD WITH A CHRONIC OR COMPLEX CONDITION

Perform an Assessment

Because the nurse may meet a family during any phase of the adjustment process, several assessment areas are important. The family's ability to cope with previous stresses influences the current situation, and answers to questions about their usual coping skills are

TABLE 36-1 DEVELOPMENTAL EFFECTS OF CHRONIC ILLNESS OR DISABILITY ON CHILDREN

DEVELOPMENTAL TASKS	POTENTIAL EFFECTS OF CHRONIC ILLNESS OR DISABILITY	SUPPORTIVE INTERVENTIONS
Infancy		
Develop sense of trust	Multiple caregivers and frequent separations, especially if hospitalized Deprived of consistent nurturing	Encourage consistent caregivers in hospital or other care settings. Encourage parental presence, "rooming in" during hospitalization, and participation in care.
Bond, or attach, to parent	Delayed because of separation; parental grief for loss of "dream" child; parental inability to accept condition, especially visible defect	Emphasize healthy, perfect qualities of infant. Help parents learn special care needs of infant for them to feel competent.
Learn through sensorimotor experiences	More exposure to painful experiences than pleasurable ones Limited contact with environment from restricted movement or confinement	Expose infant to pleasurable experiences through all senses (touch, hearing, sight, taste, movement). Encourage age-appropriate developmental skills (e.g., holding bottle, finger feeding, crawling).
Begin to develop sense of separateness from parent	Increased dependency on parent for care Overinvolvement of parent in care	Encourage all family members to participate in care to prevent overinvolvement of one member. Encourage periodic respite from demands of care responsibilities.
Toddlerhood		
Develop autonomy	Increased dependency on parent	Encourage independence in as many areas as possible (e.g., toileting, dressing, feeding).
Master locomotor and language skills	Limited opportunity to test own abilities and limits	Provide gross motor skill activity and modification of toys or equipment such as modified swing or rocking horse.
Learn through sensorimotor experience; beginning preoperational thought	Increased exposure to painful experiences	Give choices to allow simple feeling of control (e.g., choice of which book to look at, which kind of sandwich to eat). Institute age-appropriate discipline and limit setting. Recognize that negative and ritualistic behaviors are normal. Provide sensory experiences (e.g., water play, sandbox play, finger painting).
Preschool Age		
Develop initiative and purpose Master self-care skills	Limited opportunities for success in accomplishing simple tasks or mastering self-care skills	Encourage mastery of self-help skills. Provide devices that make tasks easier (e.g., self-dressing).
Begin to develop peer relationships	Limited opportunities for socialization with peers; may appear "like a baby" to age mates Protection within tolerant and secure family, causing child to fear criticism and withdraw	Encourage socialization (e.g., inviting friends to play, day care experience, trips to park). Provide age-appropriate play, especially associative play opportunities. Emphasize child's abilities; dress appropriately to enhance desirable appearance.
Develop sense of body image and sexual identification	Awareness of body centering on pain, anxiety, and failure Sex-role identification focused primarily on mothering skills	Encourage relationships with same-sex and opposite-sex peers and adults.
Learn through preoperational thought (magical thinking)	Guilt (thinking he or she caused the illness or disability or is being punished for wrongdoing)	Help child deal with criticisms; realize that too much protection prevents him or her from realities of world. Clarify that cause of child's illness or disability is not his or her fault or a punishment.

TABLE 36-1 DEVELOPMENTAL EFFECTS OF CHRONIC ILLNESS OR DISABILITY ON CHILDREN—cont'd

DEVELOPMENTAL TASKS	POTENTIAL EFFECTS OF CHRONIC ILLNESS OR DISABILITY	SUPPORTIVE INTERVENTIONS
School Age		
Develop sense of accomplishment	Limited opportunities to achieve and compete (e.g., many school absences, inability to join regular athletic activities)	Encourage school attendance; schedule medical visits at times other than school; encourage child to make up missed work.
Form peer relationships	Limited opportunities for socialization	Educate teachers and classmates about child's condition, abilities, and special needs. Encourage sports activities (e.g., Special Olympics). Encourage socialization (e.g., Girl Scouts, Campfire, Boy Scouts, 4-H Club; having a best friend or club membership).
Learn through concrete operations	Incomplete comprehension of imposed physical limitations or treatment of disorder	Provide child with information about his or her condition. Encourage creative activities (e.g., VSA arts).
Adolescence		
Develop personal and sexual identity	Increased sense of feeling different from peers and reduced ability to compete with peers in appearance, abilities, special skills	Help child realize that many difficulties that teenager is experiencing are part of normal adolescence (rebelliousness, risk taking, lack of cooperation, hostility toward authority).
Achieve independence from family	Increased dependency on family; limited job or career opportunities	Provide instruction on interpersonal and coping skills. Encourage increased responsibility for care and management of disease or condition (e.g., assuming responsibility for making and keeping appointment [ideally alone], sharing assessment and planning stages of health care delivery, contacting resources). Discuss planning for future and how condition can affect choices.
Form heterosexual relationships	Limited opportunities for heterosexual friendships; less opportunity to discuss sexual concerns with peers Increased concern with issues such as why did he or she got the disorder and whether he or she can marry and have a family	Encourage socialization with peers, including peers with and without special needs. Encourage activities appropriate for age (e.g., attending mixed-sex parties, sports activities, driving a car). Be alert to cues that signal readiness for information regarding implications of condition on sexuality and reproduction. Emphasize good appearance and wearing stylish clothes, use of makeup. Understand that adolescent has same sexual needs and concerns as any other teenager.
Learn through abstract thinking	Decreased opportunity for earlier stages of cognition impeding achievement of level of abstract thinking	Provide instruction on decision making, assertiveness, and other skills necessary to manage personal plans.

enlightening. Knowledge of concurrent stresses such as financial, marital or nonmarital, and career or unemployment helps identify families who may have fewer resources to cope with the child's needs.

Finally awareness of the family members' reactions to the child and the illness or condition is important. Sample questions that the nurse and family can use to evaluate the support system, perception of the illness, coping mechanisms, resources, and concurrent stresses are listed in Table 36-2. Because factors affecting the family's response may change at any point during the illness, assessment must be a continuous process.

Special challenges exist in assessing the child's feelings about having a chronic condition. Chapter 29 presents several approaches to encourage children to discuss their feelings about their conditions. The nurse should use a variety of communication techniques such as drawing and play as assessment tools rather than relying solely on parental reports. Often children are neglected partners in their care, and their unique needs are not identified (Dixon-Woods, Young, and Henry, 1999; Young, Dixon-Woods, Windridge, et al., 2003).

The needs of working parents and siblings also should be assessed, a goal that requires flexibility in scheduling appointments to include these important family members. When working parents know that their input is valuable, they often change their work schedule to meet with a health professional. Because siblings can be

BOX 36-6 COPING PATTERNS USED BY CHILDREN WITH SPECIAL NEEDS

Develops competence and optimism—Accentuates the positive aspects of the situation and concentrates more on what he or she has or can do than on what is missing or on what he or she cannot do; is as independent as possible

Feels different and withdraws—Sees self as being different from other children because of the chronic health condition; views being different as negative; sees self as less worthy than others; focuses on things that he or she cannot do and sometimes overrestricts activities needlessly

Is irritable, is moody, and acts out—Uses proactive and self-initiated coping behaviors, although usually counterproductive in that the behaviors are not ego enhancing or socially responsible and do not result in desired outcomes; acts out irritability, which may or may not be associated with symptoms of condition

Complies with treatment—Takes necessary medications, treatments; adheres to activity restrictions; also uses behaviors that indicate developing independence (e.g., assumes responsibility for taking medication)

Seeks support—Talks with adults, children, health care providers, and nurses; develops plans to handle problems as they occur; uses downward comparison (i.e., realizes that others have it worse)

Modified from Austin J, Patterson J, Huberty T: Development of the Coping Health Inventory for children, *J Pediatr Nurs* 6(3):166–174, 1991.

FIG 36-2 Periods of sadness and anger are appropriate in the child's adjustment to a chronic illness or disability, especially during exacerbations of the disorder.

of any age, the use of appropriate communication strategies for assessment must be considered. Nonverbal techniques such as those discussed in Chapter 29 should be considered for these children.

Provide Support at the Time of Diagnosis

The diagnosis is a critical time for parents and can influence how they perceive their health care providers throughout care. Although they may not hear or remember all that is said to them, they frequently sense a certain attitude of acceptance, rejection, hope, or despair that may influence their ability to absorb the shock and begin adapting to the family's altered future.

Parents may be encouraged to be together when they are informed of their child's condition, thus avoiding the problem of one parent having to interpret complex findings and deal with the

TABLE 36-2 ASSESSMENT OF FACTORS AFFECTING FAMILY ADJUSTMENT

FACTORS AFFECTING ADJUSTMENT	ASSESSMENT QUESTIONS
Available Support System	
Status of marital relationship	To whom do you talk when you have something on your mind? (If answer is not the spouse, ask for the reason.)
Alternate support systems	When something is worrying you, what do you do? What helps you most when you are upset?
Ability to communicate	Does talking seem to help when you feel upset?
Perception of the Illness or Disability	
Previous knowledge of disorder	Have you ever heard the word (name of diagnosis) before? Tell me about it (if answer is yes).
Imagined cause of disorder	What are your thoughts about the causes of the disorder?
Effects of illness or disability on family	How has your child's illness or disability affected you and your family? How has your lifestyle changed?
Coping Mechanisms	
Reactions to previous crises	Tell me one time you've had another crisis (problem, bad time) in your family. How did you solve that problem?
Reactions to child	Do you find yourself being a little more cautious with this child than with your other children?
Childrearing practices	Do you feel as comfortable disciplining this child as your other children?
Influence of religion	Has your religion or faith been of help to you? Tell me how (if answer is yes).
Attitudes	How is this child different from the siblings or other children of similar age? Describe your child's personality. Is it easy, difficult, or in between? When you think of your child's future, what thoughts come to mind?
Available Resources	
	Which parts of your child's care are causing the most difficulty for you or your family? Which services are available to help? Which services do you need that currently are not available?
Concurrent Stresses	
	What other problems are you facing now? (Be specific; ask about financial, marital, sibling, and extended family or friends concerns.)

FIG 36-3 Information sessions should take place in a private, comfortable setting free of distractions and interruptions.

initial emotional reaction of the other. The informing session should take place in a private, comfortable setting free of distractions and interruptions in an atmosphere in which the parents feel free to express their emotions (Fig. 36-3). Their emotional needs are acknowledged by showing acceptance of such expressions as crying, sadness, anger, and disappointment. Emotional support is offered by having tissues available if a family member cries and demonstrating through facial and body language that indeed this is a difficult and painful period. Although touching is a powerful expression of empathy, it must be used wisely. For example, it can prematurely terminate free expression of feelings, especially when combined with statements such as, "Everything will be all right." Nurses should also be aware of cultural issues regarding touching (see Chapter 27).

Parents should receive the kind of information they desire. This can be assessed by asking questions such as, "Do you prefer to hear detailed information?" Parents or other family members may have different preferences regarding the amount of information they wish to hear. Most parents want a clear, simple explanation of the diagnosis; a prediction of possible future for the child; advice on what to do next; an opportunity to ask questions; a warm, sympathetic listener; and, most important, time. Understanding of explanations is elicited with such questions as: "Do you see what I mean?" or "Is this clear to you?" Technical terms are used with simple definitions. If the parents are unaware of the term, they are given written literature or at least a written summary of the diagnosis.

Finally the informing conference does not end with the presentation of devastating news. Instead the child's strengths, appealing behaviors, and potential for development are stressed, as are available rehabilitation efforts or treatments. Parents can be encouraged to view their experiences as a series of challenges that they are capable of handling, particularly with available professional feedback. The parents are assured that the nurse will be available to answer questions and provide further assistance as needed.

The preceding discussion relates primarily to the initial informing interview. However, because of the need for long-term follow-up, it is only one in a series of continuing discussions. In all interactions the family's input is solicited and incorporated into the care plan. Some situations require consideration of special problems (see Guidelines box).

Support the Family's Coping Methods

For the family to meet the stresses of optimally adjusting to the child's condition, each member must be supported individually so the family system is strong. Although the family can indefinitely support a member who is in need of assistance, its greatest strength lies in every member supporting one another. The nurse should bear in mind that the family member in greatest need is not necessarily the affected child but may be a parent or sibling who is dealing with stresses that require intervention.

Parents

The nurse can provide support by being attentive to families' responses to their children. Mothers and fathers need to experience success, joy, and pride in their children to give the support they need. Children, too, require support for their interactions, adjustments, and efforts. They must be reinforced for attempts to get to know their care providers and communicate their needs to them.

It is important for nurses to examine their attitudes to determine their ability to engage in parent-professional partnerships. An essential characteristic is the belief that parents are equal to professionals and are experts regarding their child (see Guidelines box on p. 1065).

Communication among all family members is encouraged. Parent group sessions can help parents verbalize thoughts and feelings to one another but often do not take into account siblings' or the child's viewpoint. Therefore the nurse may need to set up a family session such as during a home or clinic visit. Although the ideal situation is to have all the members present at one time, often this is not possible. Inviting members to participate at various visits is an appropriate alternative.

Parents can be encouraged to discuss their feelings toward the child, the impact of this event on their marriage, and associated stresses such as financial burdens. For most families, regardless of their income or insurance coverage, financial concerns exist. The costs of caring for a child with special needs can be overwhelming. In addition, the family wage earner may have to sacrifice job opportunities to remain close to a medical facility or avoid losing insurance benefits.*

The nurse regards fathers as able, effective parents who are competent and capable of coping with the challenges they face. Every effort is made to include the father in visits such as to the nursery, clinic, special school, and stimulation programs. He is included in the assessment process, with specific emphasis on having him describe the child's strengths and difficulties. It is not unusual to find two parents who have differing views of the child's abilities, especially in the area of developmental disabilities.

Numerous volunteer and community resources are available that provide assistance, rehabilitation, equipment, and funding for a variety of health problems.† National and local disease-oriented organizations may provide needed assistance and support to

GUIDELINES

Situations Requiring Special Consideration

Congenital Anomaly

- Tension in the delivery room conveys the sense that something is seriously wrong. Communication is often delayed while the physician is involved with the mother's care. The manner in which the infant is presented may well set the tone for the early parent-child relationship.
- Clarify role with physician in regard to revealing information to enable immediate parental support.
- Explain to parents briefly in simple language what the defect is and something concerning the immediate prognosis before showing them the infant, at which point they may be more ready to "hear" what is said.
- Be aware of nonverbal communication. Parents watch facial expressions of others for signs of revulsion or rejection.
- Present infant as something precious.
- Emphasize well-formed aspects of infant's body.
- Allow time and opportunity for parents to express their initial response.
- Encourage parents to ask questions and provide honest, straightforward answers without undue optimism or pessimism.

Cognitive Impairment

- Unless cognitive impairment is associated with other physical problems, it is often easy for parents to miss clues to its presence or make defensive excuses regarding the diagnosis.
- Plan situations that help parents become aware of the problem.
- Encourage parents to discuss their observations of child but withhold diagnostic opinions.
- Focus on what the child can do and appropriate interventions to promote progress (e.g., infant stimulation programs) to involve parents in their child's care while helping them gain an awareness of his or her condition.

Physical Disability

- If loss of motor or sensory ability occurs during childhood, the diagnosis is readily apparent. The challenge lies in helping the child and parents over the period of shock and grief and toward the phase of acceptance and reintegration.
- Institute early rehabilitation (e.g., using a prosthetic limb, learning to read braille, learning to read lips).
- Be aware that physical rehabilitation usually precedes psychologic adjustment.
- When the cause of the disability is accidental, avoid implying that parents or child was responsible for the injury but allow them the opportunity to discuss feelings of blame.
- Encourage expression of feelings (see Communication Techniques, Chapter 29).

Chronic Illness

- Realization of the true impact may take months or years. Conflict over parent's versus child's concerns may result in serious problems. When condition is inherited, parents may blame themselves, or child may blame his or her parents.
- Help each family member gain an appreciation of the others' concerns.
- Discuss hereditary aspect of condition with parents at time of diagnosis to lessen guilt and accusatory feelings.
- Encourage child to express feelings by using third-person technique (e.g., "Sometimes when a person has an illness that was passed on by the parents, that person feels angry or bitter toward them").

Multiple Disabilities

- The child or parent may require additional time for the shock phase and may be able to attend to only one diagnosis before hearing significant information regarding other disorders.
- Acknowledge parents' understanding and acceptance of all diagnoses, especially when an obvious and more hidden disability coexists.
- Appreciate the devastating consequences of more than one disability for a child, especially if they interfere with expressive-receptive abilities.

Terminal Illness

- Parents require much support to deal with their own feelings and guidance in how to tell the child the diagnosis. They may want to conceal the diagnosis from the child. They may believe that the child is too young to know, will not be able to cope with the information, or will lose hope and the will to live.
- Approach the subject of disclosure in a positive way by asking, "How will you tell your child about the diagnosis?"
- Help parents understand the disadvantages of not telling children (e.g., deprives them of the opportunity to discuss their feelings openly and ask questions, incurs the risk of their learning the truth from outside and sometimes less tactful sources, may lessen children's trust and confidence in their parents after they learn the truth).
- Guide parents to see the potential problems involved in fostering a conspiracy.
- Offer parents guidelines for how and what to tell children about their disease or the possibility of death. Explanations should be tailored to child's cognitive ability, be based on knowledge child already has, and be honest. Honesty must be tempered with concern for child's feelings.
- Assure parents that telling a child the name of the illness and the reason for treatment instills hope, provides support from others, and serves as a foundation for explaining and understanding subsequent events.
- Acknowledge that being honest is not always easy because the truth may prompt children to ask other distressing questions such as, "Am I going to die?" However, even this difficult question must be answered.

families that qualify. Many of these are discussed elsewhere in this text under the specific diagnosis. State and federal departments of health, mental health, social service, and labor may be able to help locate appropriate regional resources. For example, state programs for Children with Special Health Needs (formerly Crippled Children's Services) provide financial assistance for children with many disabling conditions. Local and national sources of respite care and medical day care may be useful to families. Nurses should become acquainted with those in their communities and with vocational programs for special groups.

Parent-to-Parent Support. Just being with another parent who has shared similar experiences is helpful. It may not need to be a parent of a child with the same diagnosis because parents in the process of adjusting to a child with special needs—or finding respite services, educational or rehabilitative services, special equipment vendors, and financial counseling—tread a common path. If the agency does not have a parent staff position, the nurse can contact parent groups who will often send a representative. Another strategy is to ask another parent to talk to the parents. The nurse should seek out a parent who is a good listener, has a nonjudgmental approach

GUIDELINES

Developing Successful Parent-Professional Partnerships

- Promote primary nursing; in nonhospital settings, designate a case manager.
- Acknowledge parents' overall competence and their unique expertise with their child.
- Respect parents' time as having value equal to that of other members of child's health care team.
- Explain or define any medical, technical, or discipline-specific terms.
- Tell families, "I am not sure" or "I don't know" when appropriate.
- Facilitate family's effectiveness in team meetings (e.g., provide parents with same information as other participants).

to differences in families, and possesses good advocacy and problem-solving skills.

The parent self-help group is another way to promote parent-to-parent support.* Group members feel less alone and have the opportunity to observe both coping and mastery role modeling from other members. Parents' groups are rich resources for information. Even if parents are unable to attend meetings, they can still benefit from group newsletters and other literature that often accompany membership. The nurse can foster parent participation in self-help groups by serving as a referral agent, a group advisory board member, a resource person, a group member, or an assistant in founding a group. Sometimes all that is required in starting a group is to identify one or two parents as leaders; share with them the names, telephone numbers, and addresses of other families who have expressed both an interest and a willingness to release their phone number and address; and guide them in how to initiate a first meeting.

Advocate for Empowerment. Nurses can advocate for methods that foster opportunities for parent empowerment. For example, they can suggest reimbursement for travel and child care plus stipends to enable parents' voices to be heard at meetings and conferences. They can encourage parent membership on committees and advisory boards. They can keep parents informed of pending legislation on child health issues or take action when parents inform them.

The Child

Through ongoing contacts with the child, the nurse (1) observes his or her responses to the disorder, ability to function, and adaptive behaviors within the environment and with significant others; (2) explores the child's own understanding of his or her illness or condition; and (3) provides support while the child learns to cope with his or her feelings. Children are encouraged to express their concerns rather than allow others to express them for them because open discussions may reduce anxiety.

One of the most important interventions is alleviating the child's feeling of being different and normalizing his or her life as much as possible (see Guidelines box). Whenever possible, the nurse helps the family assess the child's daily routine for indications of a need for normalizing practices. For example, the child who remains in a bedroom all day requires a restructured daily routine to provide

*Information about self-help groups is available from the American Self-Help Group Clearinghouse, www.selfhelpgroups.org.

GUIDELINES

Promoting Normalization

Preparation—Prepare child in advance for changes that may occur from the chronic or complex condition.
Example—Tell the child in advance the possible side effects of drug therapy.

Participation—Include child in as many decisions as possible, especially those relating to his or her care regimen.
Example—The child is responsible for taking medications or scheduling home treatments.

Sharing—Allow both family members and child's peers to be a part of the care regimen whenever possible.
Examples—Give the child his or her medication when the other siblings receive their vitamins.
The parent cooks the same menu for the whole family.
If the child is invited to another's home, the parent advises the family of the child's dietary restrictions.

Control—Identify areas in which child can be in control so feelings of uncertainty, passivity, and helplessness are decreased.
Example—The child identifies activities that are appropriate to his or her energy level and chooses to rest when fatigued.

Expectation—Apply the same family rules to the child with a complex chronic illness as to the well siblings or peers.
Example—The child is disciplined, is expected to fulfill household responsibilities, and attends school in accordance with abilities.

activities in different parts of the house such as eating in the kitchen or dining room with the family. Such children may also be deprived of social, recreational, and academic activities that can be better accommodated by applying normalization practices. For example, home and out-of-home health-related treatments should be planned at times that least interfere with normal daily activities.

Children who are concerned that their condition detracts from their physical attractiveness need attention focused on the normal aspects of appearance and capabilities. Health professionals help strengthen and consolidate the self-image by emphasizing the normal while allowing children to express anger, isolation, fear of rejection, feelings of sadness, and loneliness. The children need positive reinforcement for compliance and any evidence of improvement. Anything that might improve attractiveness and contribute to a positive self-image is used such as makeup for a teenager with a scar, clothing that disguises a prosthesis, or a hairstyle or wig to cover a deformity or lost hair.

Siblings

The presence of a child with special needs in a family may result in parents paying less attention to the other children. Siblings may respond by developing negative attitudes toward the child or expressing anger in different forms. The nurse can help by using anticipatory guidance, questioning the parents about what they believe is the best way to have siblings respond to the child, and guiding them through ways to meet their other children's needs for attention. This questioning should take place before serious negative effects occur.

Siblings may also experience embarrassment associated with having a brother or sister with a chronic or complex condition. Parents are then faced with the difficulty of responding to this embarrassment in an understanding and appropriate manner without punishing the siblings for how they feel. They are

encouraged to talk with the siblings about how they view their affected sibling. For example, siblings of a child with developmental disabilities may express fears about their ability to bear normal children. Adolescents in particular may not be able to discuss these vital issues with their parents and may prefer to consult with the nurse. Many siblings benefit from sharing their concerns with other young people who are experiencing a similar situation. Support groups for siblings can help decrease isolation, promote expression of feelings, and provide examples of effective coping skills.

Many parents express concern about when and how to inform the other children in the family about a sibling's illness or disability. The answer depends on each child's level of sophistication and understanding. However, it is usually best to inform the siblings before a neighbor or other nonfamily member does so. Uninformed siblings may fantasize or develop apprehensions that are out of proportion to the child's actual condition. Furthermore, if parents choose to be silent or deceptive about the issue, they are setting a negative precedent for the siblings to follow rather than encouraging them to cope with the experience in a healthy and nurturing way.

The nurse is sensitive to the reactions of siblings and whenever possible intervenes to promote more positive adjustment. For example, siblings often mention that they are expected to take on additional responsibilities to help the parents care for the child. It is not unusual for them to express a positive reaction to assuming the extra duties but a negative response to feeling unappreciated for doing so. Such feelings can often be minimized by encouraging siblings to discuss this with the parents and suggesting to parents ways of showing gratitude such as an increase in allowance; special privileges; and, most significantly, verbal praise.

Educate About the Disorder and General Health Care

Educating the family about the disorder is actually an extension of revealing the diagnosis. Education involves not only supplying technical information but also discussing how the condition will affect the child. Parents may be able to digest only so much information at a time. It may be helpful to provide essential information and then follow by asking, "What else would you like to know about your child's condition?" Responding to parents' questions and concerns ensures that their information needs are met.

Activities of Daily Living

Parents also need guidance in how the condition may interfere with or alter activities of daily living such as eating, dressing, sleeping, and toileting. One area frequently affected is nutrition. Common problems are undernutrition resulting from food being inappropriately restricted or loss of appetite, vomiting, or motor deficits that interfere with feeding; overnutrition may also occur, usually because of a caloric intake in excess of energy expenditure or boredom and lack of stimulation in other areas. Although the child requires the same basic nutrients as other children, the daily requirements may differ. Special nutritional considerations are discussed as appropriate throughout this text.

Safe Transportation

Modifications may also be needed regarding car safety. Children with conditions such as low birth weight or orthopedic, neuromuscular, or respiratory impairments often cannot safely use conventional car restraints. For example, children with hip spica casts cannot sit properly in child safety seats (see Developmental Dysplasia of the Hip, Chapter 48). Modifications can be made to some commercial models, and for older children a special vest is available that secures the child to the back seat in a lying-down position.*

If a child requires a wheelchair, the family should consult the wheelchair manufacturer for specific instructions regarding safe car transportation. Considerations for wheelchairs used with vehicle transportation must address securing both the wheelchair and the occupant in the wheelchair. Wheelchairs should be secured facing forward with tie downs at four points. The tie-down system should be dynamically crash tested, as should the occupant securement system that secures the child in the wheelchair. For example, use of trays is not recommended for transportation. With children who must travel with additional medical equipment, this equipment (e.g., oxygen, monitors, or ventilators) should be anchored to the floor or underneath the vehicle seat or wheelchair. Soft padding should be added around the equipment to reduce movement. A second adult should be present to monitor the condition of a medically fragile child while traveling.

Primary Health Care

Children with special needs require all the usual health care recommended for any child. Attention to injury prevention, immunizations, dental health, and regular physical examinations is essential. Nurses can play an important role in reminding parents of these aspects of care that are so often neglected when the concern is focused on the child's chronic condition. Specific discussions of nutrition, sleep and activity, dental health, and injury prevention are presented in the chapters on health promotion for specific age-groups. Immunizations are discussed in Chapter 31.

Parents also need to be aware of the importance of communicating the child's condition in the event of a medical emergency. Young children are unable to give information about their disorders; and, although older children may be reliable sources, after an accident they may be physically unable to speak. Therefore all children with any type of chronic condition that may affect medical care should wear some type of identification such as a MedicAlert bracelet† or carry a card in their wallet that lists the medical condition and a phone number for emergency medical records and other personal information.

Promote Normal Development

Aside from knowledge of the condition and its effect on the child's abilities, the family must be guided toward fostering appropriate development in their child. Although each stage may take longer to achieve, parents are guided toward helping the child fully realize his or her potential in preparation for the next developmental stage. Table 36-1 outlines developmental aspects of complex conditions and supportive interventions. With appropriate planning and knowledge of strategies to improve the child's functional abilities, most children can live fulfilling and productive lives.

One important aspect of promoting normal development is to encourage the child's self-care abilities in both activities of daily living and the medical regimen. An assessment of the child's age and physical, emotional, and mental capacities together with the support and structure provided by the family should be considered in determining the appropriate level of self-care in the medical regimen.

BOX 36-7 CHARACTERISTICS OF PARENTAL OVERPROTECTION

- Sacrifices self and rest of family for child
- Continually helps child even when child is capable
- Is inconsistent with regard to discipline or uses no discipline; frequently applies different rules to siblings
- Is dictatorial and arbitrary, making decisions without considering child's wishes such as keeping child from attending school
- Hovers and offers suggestions; calls attention to every activity; overdoes praise
- Protects child from every possible discomfort
- Restricts play, often because of fear that child will be injured
- Denies child opportunities for growing up and assuming responsibility such as learning to give own medications or perform treatments
- Does not understand child's capabilities and sets goals too high or too low
- Monopolizes child's time such as sleeping with child, permitting few friends, or refusing participation in social or educational activities

FIG 36-4 A modified tricycle with block pedals, self-adhesive straps for support, and a modified seat and handle bars can help a child with disabilities gain mobility.

Even toddlers can be involved in their own care by holding supplies for the parent during a procedure. Over time children should be encouraged toward greater autonomy in the self-care arena.

Early Childhood

During infancy the child is achieving basic trust through a satisfying, intimate, consistent relationship with his or her parents. However, affected children's early existence may be stressful, chaotic, and unsatisfying. Consequently they may need more parental support and expressions of affection to achieve trust. Likewise the parents require assistance in finding ways to meet the infant's needs such as how to hold a rigid or flaccid infant, how to feed a child with tongue thrust or episodes of dyspnea, and how to stimulate a child who seems incapable of achieving any skills. If hospitalizations are frequent or prolonged, every effort is made to preserve the parent-child relationship (see also Chapter 38). Hospital policies should promote visitation by and involvement of families.

During early childhood the goal is to achieve separation from parents, autonomy, and initiative. However, the natural parental response to having a sick child is overprotection (Box 36-7). Parents need help in realizing the importance of the child's brief separations from them and others involved in his or her care and of providing social experiences outside the home whenever possible. Respite care, which provides temporary relief for family members, can be essential in allowing caregivers time away from the daily burdens.

Young children also need the opportunity to develop independence. Frequently the child is able to learn self-help skills such as holding a bottle, finger feeding, and removing simple articles of clothing; but the parent continues to perform the act. The nurse can guide parents to the usual milestones expected from the child. When a child is unable to perform a skill independently, functional aids should be used. With innovation many adaptations can be implemented in children's environments to increase their mobility and independence and allow them to play like other children their age. For example, with slight modifications a child with physical limitations may be able to ride a tricycle (Fig. 36-4).

Another critical component for normal child development is discipline. Discipline and guidance serve several purposes (e.g., providing children with boundaries on which to test their behavior and teaching them socially acceptable behavior). Resentment and hostility can arise among siblings if different standards are applied to each child. The nurse's responsibility is to help parents learn successful methods of managing a child's behaviors before they become problems.

School Age

For school-age children the major tasks are entry into school and achieving a sense of industry. Although the importance of school in the life of all children is well known, school absences are significantly higher among children with chronic illnesses than among their healthy peers. The more school absences the child experiences, the more difficult it is to resume attendance, and school phobia may result. The child should return to school as soon as possible after diagnosis or treatments.

Preparation for entry into or resumption of school is best accomplished through a team approach with the parents, child, teacher, school nurse, and primary nurse in the hospital. Ideally this planning should begin before hospital discharge, provided that the child is well enough to resume usual activities. A structured plan should be developed, with attention to aspects of care that must be continued during school hours such as administration of medication or other treatments.

Children also need preparation before entering or resuming school. Having a tutor in the hospital or home as soon as children are physically able helps them realize that school will continue and gives them time to consider this prospect (Fig. 36-5). They need to investigate possible answers to the many questions others will ask. One method of anticipatory preparation is to role-play, with the child as the "returned pupil" and the nurse or parent as "other schoolmates." If the child returns to school with some obvious physical change such as hair loss, amputation, or a visible scar, the nurse might also ask questions about these alterations to prompt preparatory responses from the child.

Classroom peers also need preparation; a joint plan of the teacher, nurse, and child is best. At a minimum classmates should be given a description of the child's condition, prepared for any visible changes in the child, and allowed an opportunity to ask questions. The child should have the option of attending this session. As the child's condition changes, particularly if the illness is potentially

FIG 36-5 Children with disabilities should continue their schooling as soon as their condition permits.

fatal, school personnel, including the students, need periodic appraisal of his or her status and preparation for what to expect.

Children with special needs are encouraged to maintain or reestablish relationships with peers and participate according to their capabilities in any age-appropriate activities. Alternative activities may be substituted for those that are impossible or place a strain on the child's condition. Programs such as the Special Olympics* offer children an opportunity to compete with their peers and achieve athletic skill. Summer camps† allow children to associate with peers and develop a wide variety of skills. Children with special needs can derive enormous benefits from expressive activities such as art, music, poetry, dance, and drama. With adaptive equipment and imagination children can participate in a variety of activities. Organizations such as VSA Arts allow children to celebrate and share their accomplishments.‡ They need the opportunity to interact with healthy peers and engage in activities with groups or clubs composed of similarly affected age-mates. Such organizations as ostomy clubs, diabetes clubs, and cerebral palsy groups share information and provide support related to the special problems the members face.

Adolescence

Adolescence can be a particularly difficult period for the teenager and family. All of the needs discussed previously apply to this age-group as well. However, developing independence or autonomy is a major task for the adolescent as planning for the future becomes a prominent concern. Although the emphasis in the past has been on achieving independence from physical assistance, recent developments in the fields of special education, adolescent development, and family systems suggest redefining autonomy in terms of individuals' capacities to take responsibility for their own behavior, make decisions regarding their own lives, and maintain supportive social relationships. Given this understanding, even individuals with severe impairments can be viewed as autonomous if they perceive their own needs and take responsibility for meeting them, either directly or by engaging the assistance of others. As adolescents become more autonomous, the nurse can help them articulate their needs, participate in developing their own care plans, and discover and express how others can be of greatest assistance.

Physical symptoms are high on teenagers' list of health-related concerns. Because adolescence is a time of enormous physical and emotional changes, it is important for the nurse to distinguish between body changes that are related to the child's complex condition and those that are a result of normal body development. It can be a great comfort for teenagers with disabling conditions to know that many of the changes they experience are normal developmental outcomes.

A sense of feeling different from peers can lead to loneliness, isolation, and depression. Participation in groups of teenagers with chronic conditions or disabilities can alleviate feelings of isolation and smooth the transition to a meaningful relationship with one person in adulthood.

Establish Realistic Future Goals

One of the most difficult adjustments is setting realistic future goals for the child that are based on the child's own goals and values. Sometimes the impact of this decision does not surface until the child finishes school or the parents approach retirement, when a crisis can arise because of disruption of all of the family roles and relationships that maintained stability.

Planning for the future should be a gradual process. All along the parents should cultivate realistic vocations for the child. For example, if children have physical disabilities, they are directed to intellectual, artistic, or musical pursuits. Children with developmental disabilities are taught manual skills. In this way the child's development proceeds in the direction of self-support through gainful employment.

With prolonged survival young people with chronic illnesses must deal with new decisions and problems such as marriage, employment, and insurance coverage. With appropriate guidance individuals with disabilities can attain gainful employment, marriage, and a family. For those whose conditions are genetic, counseling is needed regarding future offspring. Prospective spouses often benefit from an opportunity to discuss their feelings regarding marriage to an individual with continued health needs and possibly a limited life span. Health insurance coverage is a critical issue for chronically ill children because of their enormous health care costs over time. The Affordable Care Act allows young adults to remain on their parents' insurance until 26 years of age and prevents private insurance carriers from denying them coverage. Life insurance is another dilemma, especially when children have serious conditions such as congenital heart anomalies.

PERSPECTIVES ON THE CARE OF CHILDREN AT THE END OF LIFE

Although most childhood illnesses and many injuries and other trauma respond favorably to treatment, some do not. When a child and family face a prolonged and life-limiting illness, health

professionals must confront the challenge of providing the best possible care to meet the physical, psychologic, spiritual, and emotional needs of the child and family during the uncertain course of the illness and at the time of death. When death is sudden and unexpected, nurses are challenged to respond to grief and shock in families and provide comfort and support in the absence of a prior relationship.

Many factors affect the causes of death that nurses are likely to encounter in children, including developmental factors, medical advances and technology, and changing social patterns. In infants the leading causes of death are congenital anomalies, respiratory distress syndrome, disorders related to short gestation and low birth weight, and sudden infant death syndrome (Arias, MacDorman, Strobino, et al., 2003) (see Chapter 26). The leading causes of death in children 5 to 9 years of age include injuries (accidents), malignant neoplasms, congenital anomalies, assault (homicide), and heart disease. In children 10 to 14 years of age suicide is the third leading cause of death after injuries (accidents) and malignant neoplasms. In youths 15 to 19 years of age assault (homicide), suicide, malignant neoplasms, and heart disease follow accidents as the most prevalent causes of death (Anderson and Smith, 2005).

A child who is diagnosed with a life-threatening illness or suffering serious, life-threatening trauma needs medical diagnosis and intervention and nursing assessment and care—sometimes for a short time and sometimes over a lengthy period. When cure is no longer possible and life-prolonging measures result in pain and distress to the child, parents need information about care options that are available to help them decide how they want the remaining time with their child to be managed by the health care team. It is important that families be reassured that, although their child cannot be cured, active care will continue to be provided to maintain his or her comfort. Support is provided to assist the child and family during the dying process. As a result nurses may care for children and families who are making the difficult transition from curative or restorative treatments to palliative care.

Principles of Palliative Care

Palliative care involves a multidisciplinary approach to the care of children living with or dying from chronic, complex or potentially life-limiting conditions with a primary focus on symptom control, supportive care, and quality of life rather than on cure or life prolongation in the absence of the possibility of a cure (Field and Behrman, 2004). The World Health Organization (WHO) (1996) defines **palliative care** as the "active total care of patients whose disease is not responsive to curative treatment. Control of pain; other symptoms; and psychologic, social, and spiritual problems is paramount. The goal of palliative care is the achievement of the best possible quality of life for patients and their families." This goal is certainly compatible with care for patients who are pursuing curative or life-prolonging therapy. Therefore there should be a distinction between palliative and end-of-life care: end-of-life care is a part of palliative care, but the goals of palliative care extend to all aspects of a patient's quality of life and can be established early in the trajectory of a patient's disease. The WHO (1998) amended the definition of palliative care for children to include:

- Palliative care for children is the active total care of the child's body, mind, and spirit and involves giving support to the family.
- It begins when illness is diagnosed and continues regardless of whether or not a child receives treatment directed at the disease.
- Health providers must evaluate and alleviate the child's physical, psychologic, and social distress.
- Effective palliative care requires a broad multidisciplinary approach that includes the family and makes use of available community resources; it can be implemented successfully even if resources are limited.
- It can be provided in tertiary care facilities, in community health centers, and even in children's homes.

Palliative care interventions do not serve to hasten death; rather they provide pain and symptom management, attention to issues faced by the child and family with regard to death and dying, and promotion of optimal functioning and quality of life during the time the child has remaining. The implementation of neonatal and pediatric palliative care consulting services within hospitals has led to enhanced quality of life and end-of-life care for children and their families and support for their care providers (Jennings, 2005; Pierucci, Kirby, and Leuthner, 2001). Several principles are hallmarks of palliative care.

The child and family are considered the unit of care. The death of a child is an extremely stressful event for a family because it is out of the natural order of things. Children represent health and hope, and their death calls into question the understanding of life. A multidisciplinary team of health care professionals consisting of social workers, chaplains, nurses, personal care aides, and health care providers skilled in caring for dying patients assist the family by focusing care on the complex interactions among physical, emotional, social, and spiritual issues.

Palliative care seeks to create a therapeutic environment as homelike as possible, if not in the child's own home. Through education and support of family members, an atmosphere of open communication is provided regarding the child's dying process and its impact on all members of the family (see Evidence-Based Practice box).

Decision Making at the End of Life

Discussions concerning the possibility that a child's illness or condition is not curable and that death is an inevitable outcome cause everyone involved a great deal of stress. Physicians, other members of the health care team, and families must consider all information regarding the child's situation and make decisions to which all parties agree and that will have a profound impact on the child and family.

Ethical Considerations in End-of-Life Decision Making

A number of ethical concerns arise when parents and health care professionals are deciding on the best course of care for the dying child. Many parents and health care providers are concerned that not offering treatment that would cause potential pain and suffering but might extend life would be considered euthanasia or assisted suicide. To eliminate such concerns it is necessary to understand the various terms. Euthanasia involves an action carried out by a person other than the patient to end the life of the patient suffering from a terminal condition. The intent of this action is based on the belief that the act is "putting the person out of his or her misery"; this action has also been called mercy killing. Assisted suicide occurs when someone provides the patient with the means to end his or her life and the patient uses that means to do so. The important distinction between these two actions involves who is actually acting to end the person's life.

The American Nurses Association *Code of Ethics for Nurses* (2001) does not support the active intent on the part of a nurse to end a person's life. However, it does permit the nurse to provide

EVIDENCE-BASED PRACTICE

Pediatric Pain and Symptom Management at the End of Life

Ask the Question

In children, what is the pain and symptom experience at the end of life?

Search for Evidence

Search Strategies

Published studies from 2000 to 2005 using the subject terms *child, palliative care, pain,* and *symptoms* were identified and examined. Retrospective descriptive studies dominated the findings describing infants' and children's end-of-life experiences through the use of medical record reviews and provider and parental surveys.

Databases Used

PubMed, CINAHL

Critically Analyze the Evidence

Children experienced an average of 11 symptoms during their last week of life (Drake, Frost, and Collins, 2003). Pain, dyspnea, and fatigue were the most frequently documented symptoms experienced by most children at the end of life (Bradshaw, Hinds, Lensing, et al., 2005; Carter, Howenstein, Gilmer, et al., 2004; Drake, Frost, and Collins, 2003; Hongo, Chieko, Okada, et al., 2003). Children and their parents report high distress with pain and symptoms at the end of life. Parents reported pain and suffering as one of the most important factors in deciding to withhold or withdraw life support from their child in the pediatric intensive care unit (Meert, Thurston, and Sarnaik, 2000).

Documentation was scarce related to symptom management. Morphine was the most commonly prescribed pain medication (Drake, Frost, and Collins, 2003; Hongo, Chieko, Okada, et al., 2003). Parents reported their children as experiencing high levels of pain near the end of life (Contro, Larson, Scofield, et al., 2002). Physicians were more likely than nurses or parents to report that a child's pain and symptoms were well managed at the end of life, but the majority of both provider groups believed that the child's physical management was difficult (Andresen, Seecharan, and Toce, 2004; Wolfe, Grier, Klar, et al., 2000).

Barriers to the adequate provision of pediatric palliative care include developmental issues specific to infants and children; symptoms, their causes, how they are related, and effective treatment strategies; lack of education; and reimbursement issues (Harris, 2004). Physicians report reliance on trial and error as they learn to care for children at the end of life and the need for specialty consultations with palliative care service providers (Hilden, Emanuel, Fairclough, et al., 2001).

Apply the Evidence: Nursing Implications

There is *moderate quality evidence with strong recommendations* for better pain management at the end of life (Guyatt, Oxman, Vist, et al., 2008). Although the philosophy of palliative care encompasses pain and symptom management for infants and children who may not outlive their disease, making that care available to ease suffering and provide comfort to those who will die continues to lag. Studies show that children experience significant pain and other distressing symptoms at the end of life that are not well managed. Discrepancies in perceptions of infants' and children's pain and suffering continue to exist between providers and parents. Barriers to providing pediatric palliative care exist. Improvements are needed in the management of pain and symptoms at the end of life for infants and children.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe common symptoms experienced at the end of life.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by carefully assessing pain and other symptoms in children at the end of life.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate strengths and weakness of evidence for symptom assessment and management at the end of life.

interventions to relieve symptoms in the dying patient even when the interventions involve substantial risks of hastening death. When the prognosis for a patient is poor and death is the expected outcome, it is ethically acceptable to withhold or withdraw treatments that may cause pain and suffering and provide interventions that promote comfort and quality of life. Therefore providing palliative care for patients is the ethically correct choice in such a circumstance.

Physician–Health Care Team Decision Making

Decisions by health care providers regarding care are often made on the basis of the progression of the disease or amount of trauma, the availability of treatment options that would provide cure from disease or restoration of health, the impact of such treatments on the child, and the child's overall prognosis (Davis and Eng, 1998). Often the main determinants prompting health care providers to discuss end-of-life issues and options for children with critical illnesses include the child's age, premorbid cognitive condition and functional status, pain or discomfort, probability of survival, and quality of life (Masri, Farrell, Lacroix, et al., 2000). When the health care provider discusses this information openly with families, a shared decision-making process can occur regarding do not resuscitate (DNR) orders and care that is focused on the comfort of the child and family during the dying process.

Unfortunately many families are not given the option of terminating treatment and pursuing care that is focused on comfort and quality of life when cure is unlikely, and staff may be reluctant to raise the question of DNR orders. This occurs for a number of reasons, including the belief that not being able to "save" a child is a "failure." In addition, the physician and other members of the health care team may lack knowledge of and experience with the principles of palliative care (Field and Behrman, 2004; Sahler, Frager, Levetown, et al., 2000; Sumner, 2003).

Parental Decision Making

Rarely are families prepared to cope with the numerous decisions that must be made when a child is dying. When the death is unexpected, as in the case of an accident or trauma, the confusion of emergency services and possibly an intensive care setting presents challenges to parents as they are asked to make difficult choices. If the child has either experienced a life-threatening illness such as cancer or lived with a chronic illness that has now reached its terminal phase, parents are often unprepared for the reality of their child's impending death (see Family-Centered Care box). Numerous studies have found that families facing the impending death of a child depend on information provided to them by the health care team, particularly an honest appraisal of the child's prognosis, to make difficult decisions regarding care options for their children (Hinds, Oakes, Furman, et al., 2001; James and Johnson, 1997; Wolfe, Friebert, and Hilden, 2002).

As the group of health professionals that is most involved with families, nurses are in an excellent position to ensure that families are presented with the options available to them. The nurse's first responsibility is to explore the family's wishes. This is best done in concert with the physician but at times may need to be initiated by the nurse. Statements such as, "Tell me about your thoughts for the type of care you want your child to receive when he is dying." or "Have you considered the types of interventions you would like us to use when your child is near death?" can begin discussion of this sensitive but critical aspect of terminal care.

FAMILY-CENTERED CARE

Family of the Dying Child

No matter whether you have a PhD or many children, when your child dies it is a new experience, and nothing can prepare you for it. Like so many things in life, experience is the best teacher.

Three of our children have died, and by the time the third was dying, we handled many things differently. We learned a lot about dignity and the rights of the child and family. For example, at first we didn't know that we had a right to have our child die at home. We also didn't understand pain medications and that, if children are taking these medicines and are still in agony, they have not overdosed on the medication.

We learned a lot about case management. With our first two children, lots of different people were making decisions and disagreeing about what was best and what should be done. No one had primary authority. With our third child, one doctor took a primary role. Any questions and problems were handled by one person. I could call him 24 hours a day. It made a lot of difference, and I felt our concerns and needs were better heard and respected.

The nurses caring for our third child at home enabled me to step back and just be his mommy. When I could do this, I realized that we were fighting so hard for his life that we weren't really letting him die. His nurses had worked with him for a long time and really loved him. It was hard for them when we decided to let him die. In his last several days we wanted a lot of family time with our son, and I think the nurses felt left out. Something about their reaction to our increased time with him in the last few days made us feel guilty. If we had all been able to communicate a little more openly, I would have understood that they needed more time with him at the end, too. Everyone's needs could have been met.

Jeni Stepanek
Mother
Upper Marlboro, MD

The Dying Child

Children need honest and accurate information about their illness, treatments, and prognosis; this information needs to be given in clear, simple language. In most situations this best occurs as a gradual process over time characterized by increasingly open dialog among parents, professionals, and the child (Young, Dixon-Woods, Windridge, et al., 2003). Providing an atmosphere of open communication early in the course of an illness facilitates answering difficult questions as the child's condition worsens. Providing appropriate literature about the disease and the experience of illness and possible death is also helpful. Exactly how and when to involve children in decisions regarding care during their dying process and death is an individual matter. The child's age or developmental level is an important consideration in the process (Table 36-3). In general parents should be asked how they would like their child to be told of his or her prognosis, and they should be included in his or her care. Some parents may request that their child not be told that he or she is dying even if the child asks. This often places health care providers in a difficult situation. Children, even at a young age, are perceptive. Even if they are not told outright that they are dying, they realize that something is seriously wrong and that it involves them. Often helping parents understand that honesty and shared decision making between them and their child are important to the child's and family's emotional health encourages parents to allow discussion of dying with their child. Parents may require

professional support and guidance in this process from a nurse, social worker, or child life specialist who has a good relationship with the child and family.

If given the opportunity, children will tell others how much they want to know. Asking questions such as, "If the disease came back, would you want to know?" "Do you want others to tell you everything even if the news isn't good?" or "If someone were not getting better [or more directly, "were dying"], do you think he would want to know?" helps children set the limits of how much truth they can cope with and accept. Children need time to process many feelings and much information so they can assimilate and ideally accept the inevitable fact of mortality.

Care of dying adolescents requires the nurse to become knowledgeable about any possible delays or alterations in normal growth and development. Legal and ethical issues also come to the forefront with respect to the age at which an adolescent should have autonomy in decision making with regard to care and treatment. Effective communication among the patient, family, and health care team is an important part of optimal care for dying adolescents (Freyer, 2004).

Treatment Options for Terminally Ill Children

Based on the child and family's decision regarding their wishes for terminal care, they have several options from which to choose.

Hospital. Families may choose to remain in the hospital to receive care if the child's illness or condition is unstable and home care is not an option or the family is uncomfortable with providing care at home. If a family chooses to remain at the hospital for terminal care, the setting should be made as homelike as possible. Families are encouraged to bring familiar items from the child's

TABLE 36-3 CHILDREN'S UNDERSTANDING OF AND REACTIONS TO DEATH

CONCEPTS OF DEATH	REACTIONS TO DEATH	NURSING CARE MANAGEMENT
Infants and Toddlers		
Death has least significance to children younger than 6 months of age. After parent-child attachment and trust are established, the loss, even if temporary, of the significant person is profound. Prolonged separation during the first several years is thought to be more significant in terms of future physical, social, and emotional growth than at any subsequent age. Toddlers are egocentric and can only think about events in terms of their own frame of reference—living. Their egocentricity and vague separation of fact and fantasy make it impossible for them to comprehend absence of life. Instead of understanding death, this age-group is affected more by any change in lifestyle.	With the death of someone else, they may continue to act as though the person is alive. As children grow older, they are increasingly able and willing to let go of the dead person. Ritualism is important; a change in lifestyle could be anxiety producing. This age-group reacts more to the pain and discomfort of a serious illness than to the probable fatal prognosis. They also react to parental anxiety and sadness.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Encourage parents to remain as near to child as possible yet be sensitive to parents' needs. Maintain as normal an environment as possible to retain ritualism. If a parent has died, encourage having consistent caregiver for child. Promote primary nursing.
Preschool Children		
Preschoolers believe that their thoughts are sufficient to cause death; the consequence is the burden of guilt, shame, and punishment. Their egocentricity implies a tremendous sense of self-power and omnipotence. They usually have some understanding of the meaning of death. Death is seen as a departure, a kind of sleep. They may recognize the fact of physical death but do not separate it from living abilities. Death is seen as temporary and gradual; life and death can change places with one another. They have no understanding of the universality and inevitability of death.	If they become seriously ill, they conceive of the illness as a punishment for their thoughts or actions. They may feel guilty and responsible for the death of a sibling. Greatest fear concerning death is separation from parents. They may engage in activities that seem strange or abnormal to adults. Because they have fewer defense mechanisms to deal with loss, young children may react to a less significant loss with more outward grief than to the loss of a very significant person. The loss is so deep, painful, and threatening that the child must deny it for a time to survive its overwhelming impact. Behavior reactions such as giggling, joking, attracting attention, or regressing to earlier developmental skills indicate children's need to distance themselves from tremendous loss.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Help parents understand behavioral reactions of their children. Encourage parents to remain near the child as much as possible to minimize the child's great fear of separation from parents. If a parent has died, encourage having a consistent caregiver for the child. Promote primary nursing.

TABLE 36-3 CHILDREN'S UNDERSTANDING OF AND REACTIONS TO DEATH—cont'd

CONCEPTS OF DEATH	REACTIONS TO DEATH	NURSING CARE MANAGEMENT
School-Age Children		
Children still associate misdeeds or bad thoughts with causing death and feel intense guilt and responsibility for the event. Because of their higher cognitive abilities, they respond well to logical explanations and comprehend the figurative meaning of words. They have a deeper understanding of death in a concrete sense. They particularly fear the mutilation and punishment they associate with death. They personify death as the devil, a monster, or the bogeyman. They may have naturalistic or physiologic explanations of death. By age 9 or 10 years, children have an adult concept of death, realizing that it is inevitable, universal, and irreversible.	Because of their increased ability to comprehend, they may have more fears, for example: The reason for the illness Communicability of the disease to themselves or others Consequences of the disease The process of dying and death itself Their fear of the unknown is greater than their fear of the known. The realization of impending death is a tremendous threat to their sense of security and ego strength. They are likely to exhibit fear through verbal uncooperativeness rather than actual physical aggression. They are interested in postdeath services. They may be inquisitive about what happens to the body.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Encourage parents to remain near child as much as possible yet be sensitive to parents' needs. Because of children's fear of the unknown, anticipatory preparation is important. Because the developmental task of this age is industry, interventions of helping children maintain control over their bodies and increasing their understanding allow them to achieve independence, self-worth, and self-esteem and avoid a sense of inferiority. Encourage children to talk about their feelings and provide aggressive outlets. Encourage parents to honestly answer questions about dying rather than avoiding the subject or fabricating euphemisms. Encourage parents to share their moments of sorrow with their children. Provide preparation for postdeath services.
Adolescents		
Adolescents have a mature understanding of death. They are still influenced by remnants of magical thinking and are subject to guilt and shame. They are likely to see deviations from accepted behavior as reasons for their illness.	Adolescents straddle transition from childhood to adulthood. They have the most difficulty in coping with death. They are least likely to accept cessation of life, particularly if it is their own. Concern is for the present much more than for the past or the future. They may consider themselves alienated from their peers and unable to communicate with their parents for emotional support, feeling alone in their struggle. Adolescents' orientation to the present compels them to worry about physical changes even more than the prognosis. Because of their idealistic view of the world, they may criticize funeral rites as barbaric, money making, and unnecessary.	Help parents deal with their feelings, allowing them greater emotional reserves to meet the needs of their children. Avoid alliances with either parent or child. Structure hospital admission to allow for maximum self-control and independence. Answer adolescents' questions honestly, treating them as mature individuals and respecting their needs for privacy, solitude, and personal expressions of emotions. Help parents understand their child's reactions to death and dying, especially that concern for present crises, such as loss of hair, may be much greater than for future ones, including possible death.

room at home. In addition, there should be a consistent and coordinated care plan for the child's and family's comfort.

Home Care. Some families prefer to take their child home and receive services from a home care agency. Generally these services entail periodic nursing visits to administer a treatment or provide medications, equipment, or supplies. The child's care continues to be directed by the primary health care provider. Home care is often the option chosen by health care providers and families because of the traditional view that a child must be considered to have a life expectancy of less than 6 months to be referred to hospice care. Fortunately a number of hospice organizations are expanding their services to children based on the presence of a life-limiting disease process for which cure is not possible rather than on the sole criteria of a limited-time projected prognosis.

Hospice Care. Parents should be offered the option of caring for their child at home during the final phases of an illness with the assistance of a hospice organization. **Hospice** is a community health care organization that specializes in the care of dying patients by combining the hospice philosophy with the principles of palliative care. Hospice philosophy regards dying as a natural process and care of dying patients as including management of the physical, psychosocial, and spiritual needs of the patient and family. Care is provided by a multidisciplinary group of professionals in the patient's home or an inpatient facility that uses the hospice philosophy. Hospice care for children was introduced in the 1970s, and a number of community hospice organizations now accept children into their care (Davies, Davis, and Sibert, 2003; Faulkner and Armstrong-Dailey, 1997; Forrester, 2003; Winkler and Mardegian,

2001). Collaboration between the child's primary treatment team and the hospice care team is essential to the success of hospice care. Families may continue to see their primary care physicians as they choose.*

Hospice care is based on a number of important concepts that significantly set it apart from hospital care:

- Family members are usually the principal caregivers and are supported by a team of professional and volunteer staff.
- The priority of care is comfort. The child's physical, psychosocial, and spiritual needs are considered. Pain and symptom control are primary concerns, and no extraordinary efforts are used to attempt a cure or prolong life.
- The family's needs are considered to be as important as those of the patient.
- Hospice is concerned with the family's postdeath adjustment, and care may continue for a year or more.

The goal of hospice care is for children to live life to the fullest without pain, with choices and dignity, in the familiar environment of their home, and with the support of their family. Hospice care is covered under state Medicaid programs and by most insurance plans. The service provides home visits from nurses, social workers, chaplains, and in some cases physicians. Medications, medical equipment, and any necessary medical supplies are all provided by the hospice organization providing care.

With children the home has been the more common environment for implementing the hospice concept; it benefits the family in a variety of ways. Children who are dying are allowed to remain with those they love and with whom they feel secure. Many children who were thought to be in imminent danger of death have gone home and lived longer than expected. Siblings can feel more involved in the care and often have more positive perceptions of the death. Parental adaptation is often more favorable, demonstrated by their perceptions of how the experience at home affected their marriage, social reorientation, religious beliefs, and views on the meaning of life and death.

If the home is chosen for hospice care, the child may or may not die in the home. Reasons for final admission to a hospital vary but may be related to the parents' or siblings' wish to have the child die outside the home; exhaustion on the part of the caregivers; and physical problems such as sudden, acute pain or respiratory distress.

NURSING CARE OF THE CHILD AND FAMILY AT THE END OF LIFE

Regardless of where the child is cared for during the terminal stage of illness, both the child and family usually experience fear of (1) pain and suffering, (2) dying alone (child) or not being present when the child dies (parent), and (3) actual death. Nurses can help families by lessening their fears through attention to the care needs of the child and family (see Nursing Care Plan).

Fear of Pain and Suffering

The presence of unrelieved pain in a terminally ill child can have detrimental effects on the quality of life experienced by the child and family. Parents feel that having their child in pain is unendurable and results in feelings of helplessness and a sense that they must be present and vigilant to get the necessary pain medications. Persistent pain also has an impact on the family as a whole. Nurses can alleviate the fear of pain and suffering by providing interventions aimed at treating the pain and symptoms associated with the terminal process in children.

Pain and Symptom Management

Pain control for children in the terminal stages of illness or injury must be given the highest priority. Despite ongoing efforts to educate physicians and nurses on pain-management strategies in children, studies have reported that children continue to be undermedicated for their pain (Wolfe, Grier, Klar, et al., 2000). Nearly all children experience some amount of pain in the terminal phase of their illness. The current standard for treating children's pain follows the WHO analgesic stepladder (1996), which promotes tailoring the pain interventions to the child's level of reported pain. Children's pain should be assessed frequently, and medications adjusted as necessary. Pain medications should be given on a regular schedule, and extra doses for breakthrough pain should be available to maintain comfort. Opioid drugs such as morphine should be given for severe pain, and the dose should be increased as necessary to maintain optimal pain relief. Techniques such as distraction, relaxation techniques, and guided imagery should be combined with drug therapy to provide the child and family strategies to control pain (see Chapter 30 for further discussion of pain-management strategies) (Lambert, 1999).

In addition to pain, children experience a variety of symptoms during their terminal course as a result of their disease process or as a side effect of medicines used to manage pain or other symptoms. These symptoms include fatigue, nausea and vomiting, constipation, anorexia, dyspnea, congestion, seizures, anxiety, depression, restlessness, agitation, and confusion (Hellsten, Hockenberry, Lamb, et al., 2000; Wolfe, Friebert, and Hilden, 2002). Each of these symptoms should be managed aggressively with appropriate medications or treatments and interventions such as repositioning, relaxation, massage, and other measures to maintain the child's comfort and quality of life.

Occasionally children require very high doses of opioids to control pain. This may occur for several reasons. Children on long-term opioid pain management can become tolerant of the drug, meaning that it is necessary to give more drugs to maintain the same level of pain relief. This should not be confused with addiction, which is a psychologic dependence on the side effects of opioids. Addiction is not a factor in managing terminal pain in children. Other obvious reasons for requiring increased doses of opioids include progression of disease and other physiologic experiences of pain. It is important to understand that there is no maximum dose that can be given to control pain. However, nurses often express concern that administering doses of opioids that exceed that which they are familiar will hasten the child's death. The principle of double effect (Box 36-8) addresses such concerns. It provides an ethical standard that supports the use of interventions intended to relieve pain and suffering, even though there is a foreseeable possibility that death may be hastened (Rousseau, 2001). In cases in which the child is terminally ill and in severe pain, using large doses of opioids and sedatives to manage pain is justified when no other treatment options are available that would relieve the pain but make the risk of death less likely (Hawryluck and Harvey, 2000). See Chapter 30 for an extensive discussion of pain assessment and management.

NURSING CARE PLAN

The Child Who Is Terminally Ill or Dying

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALE
Anxiety related to fear or worry about dying **Child's or Family's Defining Characteristics *(Subjective and Objective Data)*** Unstable emotions Aggressive behavior Withdrawn behavior Depression	Child and family will receive appropriate emotional support during terminal phase of child's illness. Child will express fears and anxiety related to dying. Family will support child's ability to express fears and anxiety. Child and family will be informed of symptoms to expect as child nears end of life. Child and family will be informed of procedures and therapies necessary to promote comfort. Child and family will be able to cope with dying process.	Encourage family to remain near child as much as possible. Encourage child to talk about feelings; help family as they encourage child to express feelings. Provide safe, acceptable outlets for aggression and for grieving. Answer questions as honestly as possible while maintaining positive, hopeful approach. Explain progression of physical symptoms as child nears end of life. Explain all procedures and therapies, especially physical effects child will experience. Help child distinguish between consequences of treatment and manifestations of the disease. Structure hospital or home environment to allow for maximum self-control and independence within limitations imposed by child's developmental level and physical condition. The following NIC concepts apply to these interventions: Active Listening Coping Enhancement Simple Relaxation Touch	To provide support through presence of loved one To provide sense of closeness and understanding among family members To establish that anger and sadness are normal reactions To promote trust as major strength for therapeutic relationships To promote trust and decrease anxiety To decrease fear of unknown, which may be more of concern than actual procedure or therapy To focus on interventions that can minimize discomfort To minimize fear and loss of control
Chronic Pain related to disease process **Characteristics *(Subjective and Objective Data)*** Crying Withdrawal Aggression Fear of touch Fear of movement	Child will exhibit minimal or no evidence of physical discomfort. Family will be able to participate in child's care without causing discomfort. Family will be able to provide comfort measures for child.	Assess child's level of comfort. Provide pain management around the clock. Assess child for symptoms associated with pain or its treatment. Provide stool softener, laxative, or diphenhydramine as needed. Provide nonpharmacologic interventions that child prefers. Administer anticholinergic drugs as needed. Encourage family to provide comfort measures that child prefers. Provide soothing surroundings for child. Avoid excessive noise and light. Ensure pleasant smell, touch, temperature. Place all commodities within easy reach of child. Use gentle touch when required to perform physical procedures. Avoid pressure on painful areas. Avoid pressure on bony prominences and painful sites. Use pillows and other supports to prop child in comfortable position. Place absorbent pads under hips if child is incontinent. Limit care to essential needs.	To ensure that child is treated for changes in pain To prevent recurrence or escalation of pain To ensure that child is treated for symptoms accompanying pain or its management To prevent or treat symptoms related to pain or its management To aid pharmacologic management of pain, helping to prevent recurrence or escalation of pain and accompanying symptoms To reduce secretions and lessen "death rattle," which can be distressing to family To provide comfort To minimize irritation and maximize comfort To minimize discomfort from movement To minimize pain when possible To make it easier for child to breathe To prevent skin breakdown To minimize fatigue

NURSING CARE PLAN

The Child Who Is Terminally Ill or Dying—cont'd

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALE
Anticipatory Grieving related to impending loss of child	Family will express fears, concerns, and any special desires for terminal care.	Discuss with family and child the grieving process and differences in grieving among men, women, and children.	To facilitate understanding of what family members are feeling and experiencing
Child's or Family's Defining Characteristics *(Subjective and Objective Data)*	Family will demonstrate an understanding of their children's needs.	Provide opportunities for family members to express emotions independently or together as desired.	To provide an outlet for their emotions
Parents' feelings and physical responses of loss and depression	Family members will be actively involved in their child's care.	Facilitate child's or sibling's expression of emotions through art or play activities.	To facilitate expression of their emotions
Parents' feelings of loss of control and uncertainty	Family members will seek resources needed to help them during grieving process.	Help parents and siblings deal with their feelings about child's death.	To provide support
Child's or sibling's feelings and physical responses of loss and depression		Encourage parents to remain as near to child as possible.	To allow parents to feel they are doing something for their child
Child's or sibling's feelings of loss of control and uncertainty		Provide family with information regarding child's status.	To promote understanding and communication
		Provide family with information on common behavioral reactions.	To promote understanding of their children's behaviors
		Encourage family's assistance with child's care.	To assist with coping and minimize loss of control
		Provide information to family on how to maintain own health care needs.	To give families approval to take care of themselves
		Provide as much privacy as possible without isolating family from nurse's care.	To provide dignity for grieving process
		Help family assess their needs for referral services.	To facilitate support for families
		Encourage parents to honestly answer children's questions about dying.	To decrease children's fear and anxiety
		Provide resources for family to facilitate discussions with children about dying.	To provide support and facilitate parents' discussion
		Encourage parents to share their moments of sorrow with their children.	To promote grief expression of children
		Assist family and child with memory-making opportunities.	To facilitate emotions and sharing between family and child
		Assist child as needed to complete any unfinished business.	To facilitate support of child
		Discuss with parents appropriate involvement of siblings.	To prevent siblings from feeling excluded
		Identify family's religious and cultural beliefs related to death.	To provide support and spiritual care
		Provide preparation for postdeath services.	To provide support and guidance
		Discuss with parents the frequent need of children to be given permission to die.	To provide support and guidance
		Discuss with family their preferences for care if death is imminent.	To allow families to be in control
		Facilitate appropriate spiritual care in accordance with family's beliefs or affiliations.	To provide support
		Provide support for families who choose home care for their child.	To allow families to choose where the child is to die and provide guidance for this to occur

Parents' and Siblings' Need for Education and Support

Parents are the primary caregivers when the child is at home, and nurses providing care to the child and family need to teach the family about the medications being given to the child, how to administer them, and the use of nonpharmacologic techniques. Parents are kept informed of all medications and treatments given to a child in the hospital, and they are encouraged to participate in the child's care to the extent that they desire. This empowers parents and provides a sense of control over the child's comfort and well-being, reducing their fear that their child will be in pain or suffering as he or she is dying. In addition, better bereavement outcomes (e.g., adaptive coping; family cohesion; less anxiety, stress, and

BOX 36-8 ETHICAL PRINCIPLE OF DOUBLE EFFECT

- An action that has one good (intended) and one bad (unintended but foreseeable) effect is permissible if the following conditions are met:
- The action itself must be good or indifferent. Only the good consequences of the action must be sincerely intended.
- The good effect must not be produced by the bad effect.
- There must be a compelling or proportionate reason for permitting the foreseeable bad effect to occur.

depression) have been reported by parents who were actively involved in the care of their child (Goodenough, Drew, Higgins, et al., 2004; Lauer, Mulhern, Schell, et al., 1989). The grief work of fathers in particular seems to be facilitated when their child dies in the home setting. This finding may be related to the increased opportunity of working fathers to provide care to and spend time with their child at home versus in the hospital setting.

Siblings may feel isolated and displaced during the time that their brother or sister is dying. Parents devote the majority of their time to the care and comfort of the dying child, causing siblings to feel left out of the parent–sick child relationship. Siblings may become resentful of their sick sibling and begin to feel guilty or ashamed about such feelings (Murray, 1999). Nurses can assist the family by helping the parents identify ways to involve siblings in the caring process, perhaps by bringing some supplies or favorite toy, game, or food item. Parents should also be encouraged to schedule time to spend with the other children during which their focus is on them. Helping parents identify a trusted friend or family member who can sit with the ill child for a short period allows them to attend to their own needs or those of their other children.

Fear of Dying Alone or of Not Being Present When the Child Dies

When a child is being cared for at home, the burden of care on parents and family members can be great. Often, as the child's condition declines, family members begin the "death vigil." Rarely is a child left alone for any length of time. This can be exhausting for family members, and nurses can assist the family by helping them arrange shifts so friends or family members can be present with the child and allow others to rest. If the family has limited resources, community organizations such as hospice or churches often have volunteers who are willing to visit and sit with children. It is important that whoever is sitting with the child be aware of when the parent(s) would like to be notified to return to his or her bedside (Fig. 36-6).

When a child is dying in the hospital, the parents should be given full access to him or her at all times. If the parents need to leave they should be provided with a pager or other means of immediate communication and alerted if staff members note any change in the child that may indicate imminent death. Nurses should advocate for parents' presence in intensive care and emergency departments and attend to the parents' needs for food, drinks, comfortable chairs, blankets, and pillows.

Fear of Actual Death

Home Deaths

Most children receiving hospice care die at home, often in their own room with family, pets, and loved possessions around them. The physical process of dying can be distressing to parents because often

FIG 36-6 For a dying child there is no greater comfort than the security and closeness of a parent.

BOX 36-9 PHYSICAL SIGNS OF APPROACHING DEATH

- Loss of sensation and movement in lower extremities, progressing toward upper body
- Sensation of heat, although body feels cool
- Loss of senses:
  - Tactile sensation decreasing
  - Sensitivity to light
  - Hearing the last sense to fail
- Confusion, loss of consciousness, slurred speech
- Muscle weakness
- Loss of bowel and bladder control
- Decreased appetite and thirst
- Difficulty swallowing
- Change in respiratory pattern:
  - Cheyne-Stokes respirations (waxing and waning of depth of breathing with regular periods of apnea)
  - "Death rattle" (noisy chest sounds from accumulation of pulmonary and pharyngeal secretions)
  - Weak, slow pulse; decreased blood pressure

the child slowly becomes less alert in the days before the actual death. The nurse can help the family by providing them with information about what changes will occur as the child progresses through the dying process (Box 36-9). During this time nursing visits often become more frequent and longer in duration to provide the family with additional support as the death nears. The most distressing change for parents to observe is the change in the respiratory pattern. In the final hours of life the dying patient's respirations may become labored, with deep breaths and long periods of apnea referred to as *Cheyne-Stokes respirations.* Families are reassured that this is not distressing to the child and that it is a normal part of the dying process. However, the use of opioids can slow the respirations to make the child breathe more easily; and scopolamine, usually applied as a topical patch, can help reduce noisy respirations known as the "death rattle." Noisy respirations are more likely to occur if the child is overhydrated.

All families have the option of admitting their child to the hospital if they feel unable to deal with the death. The child who dies at home must be pronounced dead; hospice programs typically have provisions so this proceeds smoothly. In some circumstances the police may be notified, with an explanation of the circumstances to prevent unnecessary concern regarding abuse. Providing the police with the number of the responsible practitioner is usually all that is necessary to confirm the cause of death.

Hospital Deaths

Children dying in the hospital of terminal illnesses who are receiving supportive care interventions experience a similar process. Again increased nursing presence and attendance to the child's and family's needs provide comfort and support for many families.

Death resulting from accident or trauma or acute illness in settings such as the emergency department or intensive care unit often requires the active withdrawal of some form of life-supporting intervention such as a ventilator or bypass machine. These situations often raise difficult ethical issues (Sine, Sumner, Gracy, et al., 2001), and parents are often less prepared for the actual moment of death. Nurses can help these parents by providing detailed information about what will happen as supportive equipment is withdrawn, ensuring that appropriate pain medications are administered to prevent pain during the dying process and allowing the parents time before the start of the withdrawal to be with and speak to their child. It is important that the nurse attempt to control the environment around the family at this time by providing privacy, asking if they would like to play music, softening lights and monitor noises, and arranging for any religious or cultural rituals that the family may want performed.

After the child's death the family should be allowed to remain with the body and hold or rock the child if they desire. After the nurse has removed all tubes and equipment from the body, the parents should be given the option of helping with the preparation of the body such as bathing and dressing. It is important for the nurse to determine whether the family has any specific needs because many cultures have adopted specific methods for coping with and mourning death, and impeding these practices may interfere with the grieving process (Clements, Vigil, Manno, et al., 2003).

At some point the nurse discusses whether the family has made preparations for the burial service and whether the staff can help in any way. Parents often have concerns about the funeral such as siblings' involvement in the death rituals. Although no absolute answers exist regarding the question of siblings attending the funeral or burial services, the consensus is that the surviving children benefit from being involved in these events. However, children need preparation for postdeath services. They should be told what to expect, particularly how the deceased person will look if the coffin is open; allowed their private time to say good-bye; and permitted to stay as long as they wish. Ideally the parents should prepare the siblings. If the parents' grief prevents this communication, a significant family member or friend should substitute (see Family-Centered Care box).

Organ or Tissue Donation and Autopsy

For some families organ or tissue donation may be a meaningful act (i.e., one that benefits another human being despite the loss of their child). Unfortunately initiating a discussion about tissue donation is often stressful for staff, and there may be confusion regarding whose responsibility this is. In centers in which transplants are performed, a full-time transplant coordinator is usually available to inform the family about organ donation and take care of details. If such services are not available, the staff needs to determine which members should discuss this topic with the family. Ideally the person who knows the family best, knows when the death is expected, or has the opportunity to spend time with the family when the death is unexpected takes the role. Often nurses are in an optimal position to suggest tissue donation after consultation with the attending physician. When possible the topic should be raised before death occurs. The request should be made in a private and quiet area of the hospital and should be simple and direct, with questions such as, "Are you a donor family?" or "Have you ever considered organ donation?"

Many states have legislated a mandatory request for organ or tissue donation when a child dies, especially if the patient is brain dead. Written consent from the family is required before donation can proceed. When requests for organ donation are made, health care practitioners must address common misunderstandings that families have about brain death and organ donation (Franz, DeJong, Wolfe, et al., 1997). Training health care professionals about sensitive approaches to requests for organ donation has been shown to increase families' willingness to consent to organ donation (American Academy of Pediatrics, 2002; Evanisko, Beasley, Brigham, et al., 1998). The option to donate organs should always be separate from the communication of impending or actual death.

Nurses need to be aware of common questions about organ donation to help families make an informed decision. Healthy children who die unexpectedly are excellent candidates for organ donation. Children with cancer, chronic disease, or infection and those who have suffered prolonged cardiac arrest may not be suitable candidates, although this is determined individually. The nurse should ask whether organ donation was discussed with the child or whether the child ever expressed such a wish. Any number of body tissues or organs can be donated (skin, corneas, bone, kidney, heart, liver, pancreas), and their removal does not mutilate or desecrate the body or cause any suffering. The family may have an open casket,

FAMILY-CENTERED CARE

Children Need to Say Good-Bye

As a nurse and grief counselor, I conduct grief workshops with children who have experienced the death of someone special. Children often communicate their feelings of being excluded through drawings. They may draw a picture of the dying person in a hospital bed that is raised too high for them to see the person's face clearly. Sometimes children reveal that they did not get to say good-bye because a family member told them, for example, "You don't want to see your grandma this way. She is too sick for you to visit." If the special person died at home, the children had to stay in their room when the funeral home staff took away the body.

I have learned never to underestimate the importance of allowing children to be involved with the dying person and the significance of a child's loss. Once, when I asked a 6-year-old girl to draw a picture with the theme "This is what I was doing when my _____ died," she drew a picture and completed the sentence with "when my home died." Her grandmother had been like her mother; to the child, her home was gone. We need to give children the choice of being included in the family's activities of saying good-bye.

Barbara Bilderback, MS, MA, RN
Bereavement Supervisor, Saint Francis Hospice
Tulsa, OK

and there is no delay in the funeral. There is no cost to the donor family, but organ donation does not eliminate funeral or cremation responsibilities. Most religions permit organ donation as long as the recipient benefits from the transplant, although Orthodox Judaism forbids it.

In cases of unexplained death, violent death, or suspected suicide, autopsy is required by law. In other instances it may be optional, and parents should be informed of this choice. The procedure and the forms that require signing should be explained. The family should know that the child can be in an open casket after an autopsy.

Grief and Mourning

Grief is a process, not an event, of experiencing physiologic, psychologic, behavioral, social, and spiritual reactions to the loss of a child. It is highly individualized, encompassing a broad range of manifestations from person to person. It is a natural and expected reaction to loss. It is neither orderly nor predictable. Grieving in any form is necessary for healing to occur. When death is the expected or a possible outcome of a disorder, the child and family members may experience anticipatory grief. Anticipatory grief may be manifested in varying behaviors and intensities and may include denial, anger, depression, and other psychologic and physical symptoms.

Anticipatory guidance may help grieving family members. Health care professionals should emphasize that grief reactions such as hearing the dead person's voice, feeling distant from others, or seeking reassurance that they did everything possible for the lost person are normal, necessary, and expected. They in no way signify poor coping, insanity, or an approaching mental breakdown. On the contrary such behaviors signify that the survivor is working through the acute grief. They are a necessary part of grief work. Anticipatory guidance regarding the mourning process may help families recognize the normalcy of their experiences.

It is important to recognize that some family members may experience complicated grief. Complicated grief reactions (>1 year after the loss) include such symptoms as intense intrusive thoughts, pangs of severe emotion, distressing yearnings, feelings of excessive loneliness and emptiness, unusual sleep disturbance, and maladaptive levels of loss of interest in personal activities (Meert, Shear, Newth, et al., 2011). Bereaved persons experiencing such prolonged and complicated grief should be referred to an expert in grief and bereavement counseling.

Another important aspect of grief is the individual nature of the grief experience. Each member of the family experiences the grief of the child's death in his or her own way based on the particular relationship with that child. This can create potential conflict for families because each family member has expectations that the other family members should feel and grieve as they do. Nurses caring for families experiencing grief should be aware of the different grieving styles and help the family learn to recognize and support the uniqueness of one another's grief.

Parental Grief

Parental grief after the death of a child has been found to be the most intense, complex, long-lasting, and fluctuating grief experience compared with that of other bereaved individuals. Although parents experience the primary loss of their child, many secondary losses are felt such as the loss of part of one's self, hopes and dreams for the child's future, the family unit, prior social and emotional community supports, and often spousal support. It is common for parents of the same child to experience different grief reactions.

Studies with bereaved parents have shown that grieving does not end with the severing of the bond with the deceased child but rather involves a continuing bond between the parent and that child (Klass, 2001). Parental resolution of grief is a process of integrating the dead child into daily life in which the pain of losing a child is never completely gone but lessens. There are occasions of brief relapse but not to the degree experienced when the loss initially occurred. Thus parental grief work is never completed and is a timeless process of accommodating the new reality of being without a child as it changes over time (Davies, 2004). A child's death can also challenge the marital relationship in several ways. Maternal and paternal reactions often differ (Birenbaum, Stewart, and Phillips, 1996; Moriarty, Carroll, and Cotroneo, 1996; Vance, Najman, Thearle, et al., 1995). Different grieving styles between the couple may hinder communication and support for one another. Differing needs and expectations can place a strain on the marriage.

Sibling Grief

Each child grieves in his or her own way and on his or her own timeline. Children, even adolescents, grieve differently than adults. Adults and children differ more widely in their reactions to death than in their reactions to any other phenomenon. Children of all ages grieve the loss of a loved one, and their understanding and reactions to death depend on their age and developmental level. Children grieve for a longer duration, revisiting their grief as they grow and develop new understandings of death. However, they do not grieve 100% of the time. They grieve in spurts and can be emotional and sad in one instance and then, just as quickly, off and playing. Children express their grief through play and behavior. They can be exquisitely attuned to their parents' grief and try to protect them by not asking questions or trying not to upset them. This can set the stage for the sibling to try to become the "perfect child." Children exhibit many of the grief reactions of adults, including physical sensations and illnesses, anger, guilt, sadness, loneliness, withdrawal, acting out, sleep disturbances, isolation, and search for meaning. Again nurses should be attentive for signs that siblings are struggling with their grief and provide guidance to parents when possible.

At times family members may need assistance in their grieving (see Guidelines box). Communication with the bereaved family is essential, but often nurses do not know what to say and feel helpless in offering words of comfort. The most supportive approach is to avoid judging the family's reactions or offering advice or rationalizations and to focus on feelings. Perhaps the most valuable supportive measure the nurse can perform for families is to listen. Families understand that no words will relieve their pain; all they want is acceptance, understanding, and respect for their grief.

It is important for families to understand that mourning takes a long time. Acute grief may last only weeks or months, but resolving the loss is measured in years. Holidays and anniversaries can be particularly difficult, and people who previously had been supportive may now expect the family to have "adjusted." Consequently prolonged mourning is often silent and lonely.

Many families never receive the support and guidance that could help them resolve the loss. A plan for regular follow-up with bereaved families can be beneficial. At minimum one follow-up phone call or meeting with the family should be arranged. Families can also be referred to self-help groups. When such groups are not available, nurses can be instrumental in bringing families together or facilitating parent and sibling groups. Formal bereavement programs or bereavement counseling can be helpful as well.

GUIDELINES

*Supporting Grieving Families**

General

- Stay with the family; sit quietly if they prefer not to talk; cry with them if desired.
- Accept the family's grief reactions; avoid judgmental statements (e.g., "You should be feeling better by now").
- Avoid offering rationalizations for the child's death (e.g., "Your child isn't suffering anymore").
- Avoid artificial consolation (e.g., "I know how you feel," or "You're still young enough to have another baby").
- Deal openly with feelings such as guilt, anger, and loss of self-esteem.
- Focus on feelings by using a feeling word in the statement (e.g., "You're still feeling all the pain of losing a child").
- Refer the family to an appropriate self-help group or for professional help if needed.

At the Time of Death

- Reassure the family that everything possible is being done for the child if they want lifesaving interventions.
- Do everything possible to ensure the child's comfort, especially relieving pain.
- Provide the child and family with the opportunity to review special experiences or memories in their lives.
- Express personal feelings of loss or frustrations (e.g., "We'll miss him so much," "We tried everything; we feel so sorry that we couldn't save her").
- Provide information that the family requests and be honest.
- Respect the emotional needs of family members such as siblings, who may need brief respites from the dying child.
- Make every effort to arrange for family members, especially the parents, to be with the child at the moment of death if they want to be present.
- Allow the family to stay with the dead child for as long as they wish and to rock, hold, or bathe the child.
- Provide practical help when possible such as collecting the child's belongings.
- Arrange for spiritual support based on the family's religious beliefs; pray with the family if no one else can stay with them.

Postdeath

- Attend the funeral or visitation if there was a special closeness with the family.
- Initiate and maintain contact (e.g., sending cards, telephoning, inviting them back to the unit, making a home visit).
- Refer to the dead child by name; discuss shared memories with the family.
- Discourage the use of drugs and alcohol as a method of escaping grief.
- Encourage all family members to communicate their feelings rather than remain silent to avoid upsetting another member.
- Emphasize that grieving is a painful process that often takes years to resolve.

**Family* refers to all significant persons involved in the child's life such as the parents, siblings, grandparents, and other close relatives or friends.

Nurses' Reactions to Caring for Dying Children

The death of a patient is one of the most stressful aspects of critical care and oncology nursing (see Family-Centered Care box).* Nurses experience reactions to a fatal illness that are very similar to the responses of family members, including denial, anger, depression, guilt, and ambivalent feelings.

Strategies that can help nurses maintain the ability to work effectively in these settings include maintaining good general health, developing well-rounded interests, using distancing techniques such as taking time off when needed, developing and using professional and personal support systems, cultivating the capacity for empathy, focusing on the positive aspects of the caregiver role, and basing nursing interventions on sound theory and empiric observations. Attending shared-remembrance rituals helps some nurses resolve grief (Davis and Eng, 1998). Similarly, attending the funeral services can be a supportive act for both the family and the nurse and in no way detracts from the professionalism of care.

FAMILY-CENTERED CARE

A Dying Child: A Nurse's Perspective

Claire was unresponsive with slow, gasping breathing. Her mother asked me what I thought was happening. I replied honestly, "Your baby is dying because of her brain tumor." The mother put her arms around me and cried. We arranged for Claire to be baptized.

Honesty. As painful as the loss of a child is, my job is to assist the family through this experience. Although I usually wait until a private moment such as driving home, I found tears streaming down my face as family and friends gathered for Claire's baptism. I went into the kitchen to compose myself, only to find several of my colleagues crying as well. Saying goodbye to a dying child will always be a difficult but shared experience.

Jeanne O'Connor Egan, RN, MSN
Pediatric Clinical Specialist, Children's Hospital
Washington, DC

KEY POINTS

- Trends in the treatment of children with chronic illnesses and disabilities have focused on developmental age, the child's strengths and uniqueness, family-centered care, normalization, early discharge, home care, mainstreaming, and early intervention.
- In response to the child with chronic conditions, parents may be affected by feelings of inadequacy and failure; excessive demands on time, energy, and financial resources; and strain on the marital relationship.

- Families' reactions to chronic conditions are manifested in the following stages: shock and denial, adjustment, reintegration, and acknowledgment.
- The child's reaction to chronic conditions depends on his or her developmental level and coping mechanisms, others' reactions, and the illness itself.
- Assessment of the family's adjustment to a child's chronic illness, disability, or death includes the availability of a support system, their perception of the event, their coping mechanisms, concurrent stressors, and their response to the child.
- To help parents cope with their child's chronic and complex conditions, nurses must offer attentiveness, humanistic support, solicitation of suggestions for care, facilitation of communication, verbalization of feelings, and referral to volunteer and community agencies.
- Supporting the child involves encouraging self-expression, alleviating feelings of being different, and strengthening the child's self-image.
- Children's concept of death is determined by their cognitive ability and experience with life-threatening illness.
- Young children see death as temporary and reversible and mainly fear separation.
- School-age children view death as irreversible but not necessarily inevitable and may fear mutilation.
- Children beyond 9 to 10 years of age realize that death is irreversible, universal, and inevitable but may resist the thought of their own death.
- Siblings have special needs, including the need for information, reassurance about their own health status, assurance that they are not responsible for the illness or death, and support for their own grieving process.
- Special needs of the family facing the unexpected death of a child include support while awaiting news of the child's status; a sensitive pronouncement of death; acknowledgment of feelings of denial, guilt, and anger; an opportunity to view the body; and referrals for support.
- Special decisions at the time of dying and death may involve hospital or hospice care, visualization of the body, tissue donation and autopsy, and siblings' attendance at the funeral.
- Acute grief is a syndrome with intense and distressing psychologic and somatic symptoms that appear at the time of death.
- In dealing with stress related to the dying patient, the nurse can cope successfully through self-awareness, consciousness raising, knowledge and practice, an available support system, and maintenance of general good health and by focusing on the positive rewards of involvement with dying children and their families.

CHAPTER

37

Impact of Cognitive or Sensory Impairment on the Child and Family

Marilyn J. Hockenberry

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Define the classifications of intellectual disability.
- Define developmental delay.
- Outline nursing interventions for the child with cognitive impairment that promote optimal development, including during hospitalization.
- Identify the major biologic and cognitive characteristics of children with Down syndrome.
- Outline nursing interventions for children with Down syndrome.
- Identify the major characteristics associated with fragile X syndrome.
- List the general classifications of hearing impairment and the effect on speech.
- Outline nursing interventions for children with hearing impairment, including during hospitalization.
- List the common types of visual impairments in children.
- Outline nursing interventions for children with visual impairment, including during hospitalization.
- Outline nursing interventions for children with retinoblastoma.
- Outline nursing interventions for children with an autism spectrum disorder.

COGNITIVE IMPAIRMENT

General Concepts

Cognitive impairment (CI) is a general term that encompasses any type of mental difficulty or deficiency. In this chapter the term is used synonymously with intellectual disability and replaces the term mental retardation (MR), defined by the American Association on Intellectual and Developmental Disabilities (AAIDD, 2010). Although the needs and concerns of the family are a primary focus throughout the chapter, readers are encouraged to review Chapter 36, which details the family's adjustment to disabilities in general.

The definition of intellectual disability in children consists of three components: intellectual functioning, functional strengths and weaknesses, and age younger than 18 years at time of diagnosis. Intellectual functioning is measured by the intelligence quotient (IQ) of 70 to 75 or below. The child with an intellectual disability must demonstrate functional impairment in at least 2 of 10 different adaptive skill areas: communication, self-care, home living, social skills, leisure, health and safety, self-direction, functional academics, community use, and work (American Psychiatric Association, 2013) or have deficits in one or more adaptive domains (AAIDD, 2010). The classification system by the AAIDD allows for identification of the individual's specific needs in four established dimensions of care (Box 37-1). Careful evaluation to identify the needs of individuals with CI is focused on promoting habilitation for each person. It is anticipated that the functional capabilities of children with CI will improve over time when support is provided.

Diagnosis and Classification

The diagnosis of CI is usually made after a period of suspicion, by professionals or the family, that the child's developmental progress is delayed. In some cases it is confirmed at birth because of recognition of distinct syndromes such as Down syndrome and fetal alcohol syndrome. At the other extreme the diagnosis is made when problems such as speech delays arouse concern. In all cases a high index of suspicion for developmental delay and behavioral signs (Box 37-2) is necessary for early diagnosis; routine developmental screening can help in early identification (see Chapter 29). Delays are typically seen in gross and fine motor and speech development, although the latter is most predictive. Developmental delay can be described as any significant lag in a child's physical, cognitive, behavioral, emotional, or social development when compared against developmental norms. CI is a permanent impairment encompassing cognitive ability and adaptive behavior that are

BOX 37-1 DIMENSIONS OF CARE FOR INTELLECTUALLY DISABLED PATIENTS

- *Dimension I*—Intellectual functioning and adaptive skills
- *Dimension II*—Psychologic and emotional considerations
- *Dimension III*—Physical, health, and etiology considerations
- *Dimension IV*—Environmental considerations

BOX 37-2 EARLY BEHAVIORAL SIGNS SUGGESTIVE OF COGNITIVE IMPAIRMENT

- Dysmorphic features (e.g., Down syndrome, fragile X syndrome)
- Irritability or unresponsiveness to contact
- Abnormal eye contact
- Gross motor delay
- Decreased alertness to voice or movement
- Language difficulties or delay
- Feeding difficulties

Modified from Shapiro B, Batshaw M: Mental retardation (intellectual disability). In Kliegman RM, Behrman RE, Jenson HB, editors: *Nelson textbook of pediatrics,* ed 18, Philadelphia, 2007, Saunders; Wilks T, Gerber J, Erdie-Lalena C: Developmental milestones: cognitive development, *Pediatr Rev* 31(9):364–367, 2010.

functioning significantly below average (see Box 37-2). In the absence of clear-cut evidence of CI, it is more appropriate to use a diagnosis of developmental delay.

Results of standardized tests are used in making the diagnosis of intellectual disability based on cognitive deficits. Tests for assessing adaptive behaviors include the Vineland Social Maturity Scale and the American Association of Mental Retardation (AAMR) Adaptive Behavior Scale. Informal appraisal of adaptive behavior may be made by those fully acquainted with the child (e.g., teachers, parents, other care providers). Frequently these observations lead parents to seek evaluation of the child's development.

A more useful approach for clinical application is classification based on educational potential or symptom severity. For educational purposes the mildly impaired group (educable MR) constitutes about 85% of all people with CI, and the group with moderate levels of CI (trainable MR) accounts for about 10% of the intellectually disabled population (American Psychiatric Association, 2000; Katz and Lazcano-Ponce, 2008; Walker and Johnson, 2006) (Table 37-1). Although nurses may be familiar with the approximate range of IQ for classifying severity, they should refrain from using numbers as the criterion for assessing or evaluating the child's abilities because numbers are of little value in counseling parents or training these children.

Etiology

The causes of severe CI are primarily genetic, biochemical, and infectious. Although the etiology is unknown in most cases,

TABLE 37-1 CLASSIFICATION OF COGNITIVE IMPAIRMENT

LEVEL (IQ)*	PRESCHOOL (BIRTH–5 YEARS)—MATURATION AND DEVELOPMENT	SCHOOL AGE (6-21 YEARS)—TRAINING AND EDUCATION	ADULT (≥21 YEARS)—SOCIAL AND VOCATIONAL ADEQUACY
Mild—50-55 to ≈70-75	Often not noticed as delayed by casual observer but is slower to walk, feed self, and talk than most children; follows same sequence in development as normal children	Can acquire practical skills and useful reading and arithmetic to a third- to sixth-grade level with special education; can be guided toward social conformity; achieves mental age of 8-12 years	Can usually achieve social and vocational skills adequate to self-maintenance; may need occasional guidance and support when under unusual social or economic stress; can adjust to marriage but not childrearing
Moderate—35-40 to 50-55	Noticeable delays in motor development, especially in speech; responds to training in various self-help activities	Can learn simple communication, elementary health and safety habits, and simple manual skills; does not progress in functional reading or arithmetic; achieves mental age of 3-7 years	Can perform simple tasks under sheltered conditions; participates in simple recreation; travels alone in familiar places; usually incapable of self-maintenance
Severe—20-25 to 35-40	Marked delay in motor development; little or no communication skills; may respond to training in elementary self-care (e.g., self-feeding)	Usually walks, barring specific disability; has some understanding of speech and some response; can profit from systematic habit training; achieves mental age of toddler	Can conform to daily routines and repetitive activities; needs continuing direction and supervision in protective environment
Profound—below 20-25	Gross delay; minimum capacity for functioning in sensorimotor areas; needs total care	Obvious delays in all areas of development; shows basic emotional responses; may respond to skillful training in use of legs, hands, and jaws; needs close supervision; achieves mental age of young infant	May walk; needs complete custodial care; has primitive speech; usually benefits from regular physical activity

*Data from American Psychiatric Association: *Diagnostic and statistical manual of mental disorders (DSM-5),* ed 5, Washington, DC, 2013, The Association; and Rittey CD: Learning difficulties: what the neurologist needs to know, *J Neurol Neurosurg Psychiatry* 74(suppl 1): 30–36, 2005.
IQ, intelligence quotient.

familial, social, environmental, and organic causes may predominate. Among individuals with CI, a sizable proportion of the cases are linked to Down syndrome, fragile X syndrome, or fetal alcohol syndrome. General categories of events that may lead to CI include the following (Katz and Lazcano-Ponce, 2008; Walker and Johnson, 2006):

- Infection and intoxication such as congenital rubella, syphilis, maternal drug consumption (e.g., fetal alcohol syndrome), chronic lead ingestion, or kernicterus
- Trauma or physical agent (i.e., injury to the brain experienced during the prenatal, perinatal, or postnatal period)
- Inadequate nutrition and metabolic disorders such as phenylketonuria or congenital hypothyroidism
- Gross postnatal brain disease such as neurofibromatosis and tuberous sclerosis
- Unknown prenatal influence, including cerebral and cranial malformations such as microcephaly and hydrocephalus
- Chromosome abnormalities resulting from radiation, viruses, chemicals, parental age, and genetic mutations such as Down syndrome and fragile X syndrome
- Gestational disorders, including prematurity, low birth weight, and postmaturity
- Psychiatric disorders that have their onset during the child's developmental period up to age 18 years such as autism spectrum disorders (ASDs)
- Environmental influences, including evidence of a deprived environment associated with a history of intellectual disability among parents and siblings

Nursing Care of Children with Impaired Cognitive Function

Nurses play a major role in identifying children with CI. In the newborn and early infancy periods few signs are present, with the exception of Down syndrome (see p. 1090). However, after this age delayed developmental milestones are the major clues to CI. In addition, nurses must have a high index of suspicion for early behavior patterns that may suggest CI (see Box 37-2). Parental concerns such as delayed development compared with siblings need to be taken seriously. All children should receive regular developmental assessment, and the nurse is often the person responsible for performing such assessments (see Chapter 29). When delays are found, the nurse must use sensitivity and discretion in revealing this finding to parents.
