To teach children with CI, it is necessary to investigate their learning abilities and deficits. This is important for the nurse who may be involved in a home care program or caring for the child in a health care setting. The nurse who understands how these children learn can teach them basic skills or prepare them for various health-related procedures effectively.

Children with CI have a marked deficit in their ability to discriminate between two or more stimuli because of difficulty in recognizing the relevance of specific cues. However, these children can learn to discriminate if the cues are presented in an exaggerated, concrete form and if all extraneous stimuli are eliminated. For example, the use of colors to emphasize visual cues or the use of singing or rhymes to stress auditory cues can help them learn. Their deficit in discrimination also implies that concrete ideas are learned much more effectively than abstract ideas. Therefore demonstration is preferable to verbal explanation, and learning should be directed toward mastering a skill rather than understanding the scientific principles underlying a procedure.

FIG 37-1 A push panel allows a child with cognitive impairment to turn a computer on and off.

Another cognitive deficit is in short-term memory. Children of average intelligence can remember several words, numbers, or directions at one time; children with CI are less able to do so. Therefore they need simple, one-step directions. Learning through a step-by-step process requires a task analysis in which each task is separated into its necessary components and each step is taught completely before proceeding to the next activity.

One critical area of learning that has had a tremendous impact on education for cognitively impaired individuals is motivation. Programs based on the motivational principles of behavior modification, using positive reinforcement for specific tasks or behaviors, have demonstrated marked improvement in children's ability to learn. Advances in technology have greatly aided in providing reinforcement, especially in children with severe disabilities and who may have physical disabilities that limit their range of capabilities. For example, with the use of specially designed switches, children are given control of some event in the environment such as turning on the television (Fig. 37-1). The television picture becomes the reinforcement for activating the switch. Repetitive use of these switches provides an early, simplistic association with a technical device that may progress to increasingly complex aids.

Early-intervention program is a systematic program of therapy, exercises, and activities designed to address developmental delays in disabled children to help achieve their full potential (American Academy of Pediatrics [AAP] Committee on Genetics, 2001; National Down Syndrome Society, 2011a; Weijerman and de Winter, 2010). Considerable evidence indicates that these programs are valuable for cognitively impaired children. Nurses working with these families need to be aware of the types of programs in their community. Under the Individuals with Disabilities Education Act (IDEA) of 1990 (Public Law 101-476), states are encouraged to provide full early-intervention services and are required to provide educational opportunities for all children with disabilities from birth to 21 years of age. Services may be provided under state Programs for Children with Special Health Needs or Head Start or by private organizations such as National Down Syndrome

Society,* Easter Seals,† or the Arc of the United States.‡ Parents should inquire about these programs by contacting the appropriate agencies. The child's education should begin as soon as possible. As children grow older, their education should be directed toward vocational training that prepares them for as independent a lifestyle as possible within their scope of abilities.

Teach Child Self-Care Skills

When a child with CI is born, parents need help in promoting normal developmental skills that are almost automatically learned by other children. These include self-care skills such as feeding, toileting, dressing, and grooming. Teaching these skills requires a basic knowledge of the developmental sequence in learning the skills demonstrated by children of average intelligence. For example, children with subaverage intelligence would not be expected to dress themselves as early as unaffected youngsters.

Teaching self-care skills also necessitates a working knowledge of the individual steps needed to master a skill. For example, before beginning a self-feeding program, the nurse performs a task analysis. After a task analysis the child is observed in a particular situation such as eating to determine what skills the child possesses and his or her developmental readiness to learn the task. Family members are included in this process because their "readiness" is as important as the child's. Numerous self-help aids are available to facilitate independence and can help eliminate some of the difficulties of learning such as using a plate with suction cups to prevent accidental spills.§

Promote Child's Optimal Development

Optimal development involves more than achieving independence. It requires appropriate guidance for establishing acceptable social behavior and personal feelings of self-esteem, worth, and security. These attributes are not simply learned through a stimulation program. Rather they must arise from the genuine love and caring that exist among family members. However, families need guidance in providing an environment that fosters optimal development. Often the nurse can provide this help.

Another important area for promoting optimal development and self-esteem is ensuring the child's physical well-being. Any congenital defects such as cardiac, gastrointestinal, or orthopedic anomalies should be repaired. Plastic surgery may be considered when the child's appearance can be improved substantially. Dental health is significant, and orthodontic and restorative procedures can improve facial appearance immensely.

Encourage Play and Exercise

Children who are cognitively impaired have the same needs for recreation and exercise as other children. However, because of the children's slower development, parents may be less aware of these needs. Therefore the nurse guides parents toward selection of suitable play and exercise activities (Fig. 37-2). Because play has been discussed for children in each age-group in earlier chapters, only the exceptions are presented here.

FIG 37-2 Placing an attractive object outside the child's reach encourages crawling movements. (Courtesy James DeLeon, Texas Children's Hospital, Houston, TX.)

The type of play is based on the child's developmental age, although the need for sensorimotor play may be prolonged for several years. Parents should use every opportunity to expose the child to as many different sounds, sights, and sensations as possible. Appropriate play includes musical mobiles, stuffed toys, water play, floating toys, a rocking chair or horse, a swing, bells, and rattles. The child should be taken on outings such as trips to the grocery store or shopping center; other people should be encouraged to visit in the home; and the child should be related to directly such as by cuddling, holding, rocking, talking to him or her in the en face (face-to-face) position, and giving "rides" on the parents' shoulders.

Toys are selected for their recreational and educational value. For example, a large inflatable beach ball is a good water toy; it encourages interactive play and can be used to learn motor skills such as balance, rocking, kicking, and throwing. A doll with removable clothes and different types of closures can help the child learn dressing skills. Musical toys that mimic animal sounds or respond with social phrases are excellent ways of encouraging speech. Toys should be simple in design so the child can learn to manipulate them without help. For children with severe cognitive and physical impairment, electronic switches can be used to allow them to operate toys (Fig. 37-3).

Suitable activities for physical activity are based on the child's size, coordination, physical fitness and maturity, motivation, and health (Fig. 37-4). Some children may have physical problems that prevent participation in certain sports such as atlantoaxial instability in children with Down syndrome (see p. 1090). These children often have greater success in individual and dual sports than in team sports and enjoy themselves most with children of the same developmental level. The Special Olympics* provides these children with a unique competitive opportunity.

Safety is a major consideration in selecting recreational and exercise activities. For example, toys that may be appropriate

FIG 37-4 A favorite toy provides stimulation for a young child.

developmentally may present dangers to a child who is strong enough to break them or use them incorrectly.

Provide Means of Communication

Verbal skills typically are delayed more than other physical skills. Speech requires hearing and interpretation (receptive skills) and facial muscle coordination (expressive skills). Because both types of skills may be impaired, these children need frequent audiometric testing and should be fitted with hearing aids if indicated. In addition, they may need help to learn to control their facial muscles. For example, some children may need tongue exercises to correct the tongue thrust or gentle reminders to keep the lips closed.

Nonverbal communication may be appropriate for some of these children, and various devices are available. For the child without associated physical disabilities a talking picture board is helpful. For children with physical limitations several adaptations or types of communication devices are available to facilitate selection of the appropriate picture or word (Fig. 37-5). Some children may be taught sign language or Blissymbols (i.e., a highly stylized system of graphic symbols representing words, ideas, and concepts). Although the symbols require education to learn their meaning, no reading skill is needed. The symbols are usually arranged on a board, and the person points or uses some type of selector to convey a message.

FIG 37-5 A child with cognitive and physical impairments can activate electronic and communication equipment by moving a device near her head.

Establish Discipline

Discipline must begin early. Limit-setting measures need to be simple, consistently applied, and appropriate for the child's mental age. Control measures are based primarily on teaching a specific behavior rather than on understanding the reasons behind it. Stressing moral lessons is of little value to a child who lacks the cognitive skills to learn from self-criticism or from a lesson based on previous wrong-doing. Behavior modification, especially reinforcement of desired actions, and time-out are appropriate forms of behavior control.

Encourage Socialization

Acquiring social skills is a complex task, as is learning self-care procedures. Active rehearsals with role-playing and practice sessions and positive reinforcement for desired behavior have been the most successful approaches. Parents should be encouraged early to teach their child socially acceptable behavior: waving goodbye, saying "hello" and "thank you," responding to his or her name, greeting visitors, and sitting modestly. The teaching of socially acceptable sexual behavior is especially important to minimize sexual exploitation. Parents also need to expose the child to strangers so he or she can practice manners because there is no automatic transfer of learning from one situation to another.

Dressing and grooming are also important aspects of socialization. A child who is dressed in age-appropriate clothing and well groomed is much more likely to be accepted and develop positive self-esteem. Clothes should be clean, up-to-date, and well fitted. Many attractive outfits can be adapted with self-adhering fasteners and elastic openings to facilitate self-dressing.

As soon as possible parents should enroll the child in appropriate preschool programs. Not only do these programs provide education and training, but they also offer an opportunity for social experiences among the children. As children grow older, they should have peer experiences similar to those of other children, including group outings, sports, and organized activities such as scouts and Special Olympics. Nurses can assess the child's abilities and encourage others (e.g., parents, teachers) to promote developmentally appropriate peer interaction (Johnson and Walker, 2006; National Down Syndrome Society, 2011a; Shapiro and Batshaw, 2007).

Provide Information on Sexuality

Adolescence may be a particularly difficult time for the family, especially in terms of the child's sexual behavior, possibility of pregnancy, future plans to marry, and ability to be independent. Frequently little anticipatory guidance has been offered parents to prepare the child for physical and sexual maturation. The nurse can help in this area by providing parents with information about sex education that is geared to the child's developmental level. For example, adolescent girls need a *simple* explanation of menstruation and instructions on personal hygiene during the menstrual cycle.

These adolescents also need practical sexual information regarding anatomy, physical development, and conception.* Because of their easy persuasion and lack of judgment, they need a well-defined, concrete code of conduct. The subtleties of social sexual behavior are less beneficial than specific instructions for handling certain situations. For example, an adolescent should be told firmly never to go alone anywhere with any person that he or she does not know well. To protect him or her from abusive sexual activities, parents must observe their teenager's activities and associates closely. The question of contraceptive protection for these adolescents is often a parental concern.

Parents of these adolescents are often concerned about the advisability of marriage between two individuals with intellectual disabilities. There is no conclusive answer; each situation must be judged individually. In some instances marriage is possible, but parenthood may not be desirable because of the complexity of childrearing and the potential problem of perpetuating mental deficiency. The nurse should discuss this topic with parents and with the prospective couple, stressing suitable living accommodations and contraceptive methods to prevent pregnancy. If children are conceived, these parents require specialized help to learn to meet the needs of their offspring (Johnson and Walker, 2006).

Help Family Adjust to Future Care

Not all families are able to cope with home care of their affected child, especially one who is severely or profoundly impaired or has multiple disabilities. Older parents may not be able to assume care responsibilities after they reach retirement or older age. For these parents the decision regarding residential placement is a difficult one, and the availability of such facilities varies widely. The nurse working with a family should help them investigate and evaluate various programs and adjust to the decision for placement.

Care for Child During Hospitalization

Caring for the child during hospitalization can be a special challenge. Frequently nurses are unfamiliar with children who are cognitively impaired, and they may cope with their feelings of insecurity and fear by ignoring or isolating the child. Not only is this approach nonsupportive, but it may also be destructive for the child's sense of self-esteem and optimal development, and it may hamper the parents' ability to cope with the stress of the experience. One method that successfully avoids this nontherapeutic approach is the use of the mutual-participation model in planning the child's care. Parents are encouraged to stay with their child but should not be made to feel as if the responsibility is theirs alone.

When the child is admitted, a detailed history is taken (see Chapter 29), especially in terms of all self-care activity. During the interview the child's developmental age is assessed. It is best to avoid asking directly about IQ levels because this may make the parents uncomfortable and often tells little about the child's actual abilities. Questions are approached positively. For example, rather than asking, "Is your child toilet trained yet?" the nurse may state, "Tell me about your child's toileting habits." The assessment should also focus on any special devices the child uses, effective measures of limit setting, unusual or favorite routines, and any behaviors that may require intervention. If the parent states that the child engages in self-injurious activities (e.g., head banging, self-biting), the nurse should inquire about events that precipitate them and techniques (e.g., distraction, medication) that the parents use to manage them (Johnson and Walker, 2006; Oliver and Richards, 2010).

The nurse also assesses the child's functional level of eating and playing; ability to express needs verbally; progress in toilet training; and relationship with objects, toys, and other children. The child is encouraged to be as independent as possible in the hospital.

Realizing that the child may be lonely in the hospital, the nurse makes certain that toys and other activities are provided. The child is placed in a room with other children of approximately the same developmental age, preferably a room with only two beds to avoid overstimulation. The nurse discusses with the other parents the child's abilities and introduces the parents and children to one another. By the nurse's example of treating the child with dignity and respect, others who may fear what they do not understand are encouraged to accept the child.

Procedures are explained to the child through methods of communication that are at the appropriate cognitive level. Generally explanations should be simple, short, and concrete, emphasizing what the child will experience *physically*. Demonstration either through actual practice or with visual aids is always preferable to verbal explanation. The nurse repeats instructions often and evaluates the child's understanding by asking questions such as, "What will it feel like?" "Show me how you must lie," or "Where will the dressing be?" Parents are included in preprocedural teaching for their own learning and to help the nurse learn effective methods of communicating with the child.

During hospitalization the nurse should also focus on growth-promoting experiences for the child. For example, hospitalization may be an excellent opportunity to emphasize to parents abilities that the child does have but has not had the opportunity to practice such as self-dressing. It may also be an opportunity for social experiences with peers, group play, or new educational and recreational activities. For example, one child who had the habit of screaming and kicking demonstrated a definite decrease in these behaviors after he learned to pound pegs and use a punching bag. Through social services the parents may become aware of specialized programs for the child. Hospitalization may also offer parents a respite from everyday care responsibilities and an opportunity to discuss their feelings with a concerned professional.

Assist in Measures to Prevent Cognitive Impairment

Besides having a responsibility to families with a child with CI, nurses also need to be involved in programs aimed at preventing CI. Many of the familial, social, and environmental factors known to cause mild impairment are preventable. Counseling and education can reduce or eliminate such factors (e.g., poor nutrition, cigarette smoking, chemical abuse), which increase the risk of prematurity and intrauterine growth restriction. Interventions are directed toward improving maternal health by educating women regarding the dangers of chemicals, including prenatal alcohol exposure, which affects organogenesis; craniofacial development; and

*Sources of information on sexuality and conception are the Arc of the United States (see footnote, p. 1087) and Planned Parenthood Federation of America, 434 W. 33rd St., New York, NY 10001, 212-541-7800 or 800-230-7526, fax: 212-245-1845, www.plannedparenthood.org.

cognitive ability (Defendi, 2010; Wilton and Plane, 2006). Other preventive strategies that play an important role include adequate prenatal care; optimal medical care of high-risk newborns; rubella immunization; genetic counseling and prenatal screening, especially in terms of Down or fragile X syndrome; use of folic acid supplements to prevent neural tube defects during pregnancy and the childbearing years; newborn screening for treatable inborn errors of metabolism such as congenital hypothyroidism, phenylketonuria, and galactosemia; and early appropriate therapies and rehabilitation services for children with developmental disabilities.

Down Syndrome

Down syndrome is the most common chromosome abnormality of a generalized syndrome, occurring in one in 691 to 1000 live births (National Down Syndrome Society, 2011b; Weijerman and de Winter, 2010). It occurs in people of all races and economic levels.

Etiology

The cause of Down syndrome is not known, but evidence from cytogenetic and epidemiologic studies supports the concept of multiple causality. Approximately 95% of all cases of Down syndrome are attributable to an extra chromosome 21 (group G); thus the name nonfamilial trisomy 21 (National Down Syndrome Society, 2011b; Walker and Johnson, 2006). Although children with trisomy 21 are born to parents of all ages, there is a statistically greater risk in older women, particularly those older than 35 years of age. For example, in women 35 years of age the chance of conceiving a child with Down syndrome is about 1 in 350 live births, but in women age 40 it is approximately 1 in 100. However, the majority (≈80%) of infants with Down syndrome are born to women younger than 35 years of age because younger women have higher fertility rates (National Down Syndrome Society, 2011b). Approximately 3% to 4% of the cases may be caused by translocation of chromosomes 15 and 21 or 22. This type of genetic aberration is usually hereditary and is not associated with advanced parental age. of affected people, 1% to 2% demonstrate mosaicism, which refers to a mixture of normal and abnormal cell types. The degree of cognitive and physical impairment is related to the percentage of cells with the abnormal chromosome makeup.

Diagnostic Evaluation

Down syndrome can usually be diagnosed by the clinical manifestations alone (Box 37-3 and Fig. 37-6), but a chromosome analysis should be done to confirm the genetic abnormality.

Several physical problems are associated with Down syndrome. Many of these children have congenital heart malformations, the most common being septal defects. Respiratory tract infections are prevalent and, when combined with cardiac anomalies, are the chief causes of death, particularly during the first year of life. Hypotonicity of chest and abdominal muscles and dysfunction of the immune system probably predispose the child to the development of respiratory tract infection. Other physical problems include thyroid dysfunction, especially congenital hypothyroidism, and an increased incidence of leukemia.

Therapeutic Management

Although no cure exists for Down syndrome, a number of therapies such as surgery to correct serious congenital anomalies (e.g., heart defects, strabismus) are advocated. These children also benefit from evaluative echocardiography soon after birth and regular medical care. Evaluation of sight and hearing is essential; and treatment of otitis media is required to prevent auditory loss, which can influence cognitive function. Periodic testing of thyroid function is recommended, especially if growth is severely delayed. Children participating in sports that may involve stress on the head and neck such as gymnastics, diving, butterfly stroke in swimming, high jump, and soccer should be evaluated radiologically for atlantoaxial instability. Symptoms of the disorder include neck pain, weakness, and torticollis. Affected children are at risk for spinal cord compression.

BOX 37-3 CLINICAL MANIFESTATIONS OF DOWN SYNDROME

Head and Eyes
- Separated sagittal suture*
- Brachycephaly
- Rounded and small skull
- Flat occiput
- Enlarged anterior fontanel
- Oblique palpebral fissures (upward, outward slant)*
- Inner epicanthal folds
- Speckling of iris (Brushfield spots)

Nose and Ears
- Small nose*
- Depressed nasal bridge (saddle nose)*
- Small ears and narrow canals
- Short pinna (vertical ear length)
- Overlapping upper helices
- Conductive hearing loss

Mouth and Neck
- High, arched, narrow palate*
- Protruding tongue
- Hypoplastic mandible
- Delayed teeth eruption and microdontia
- Alignment teeth abnormalities common
- Periodontal disease
- Neck skin excess and laxity*
- Short and broad neck

Chest and Heart
- Shortened rib cage
- Twelfth-rib anomalies
- Pectus excavatum or carinatum
- Congenital heart defects common (e.g., atrial septal defect, ventricular septal defect)

Abdomen and Genitalia
- Protruding, lax, and flabby abdominal muscles
- Diastasis recti abdominis
- Umbilical hernia
- Small penis
- Cryptorchidism
- Bulbous vulva

Hands and Feet
- Broad, short hands and stubby fingers
- Incurved little finger (clinodactyly)
- Transverse palmar crease
- Wide space between big and second toes*
- Plantar crease between big and second toes*
- Broad, short feet and stubby toes

Musculoskeletal and Skin
- Short stature
- Hyperflexibility and muscle weakness*
- Hypotonia
- Atlantoaxial instability
- Dry, cracked, and frequent fissuring
- Cutis marmorata (mottling)

Other
- Reduced birth weight
- Learning difficulty (average intelligence quotient of 50)
- Hypothyroidism common
- Impaired immune function
- Increased risk of leukemia
- Early-onset dementia (in one third)

*Most common findings in modified chart (Pueschel, 1999).

! NURSING ALERT

Report immediately any child with the following signs of spinal cord compression:
- Persistent neck pain
- Loss of established motor skills and bladder or bowel control
- Changes in sensation

FIG 37-6 Down syndrome in an infant. Note the infant's small, square head with upward slant to the eyes; flat nasal bridge; protruding tongue; mottled skin; and hypotonia. (Courtesy Shannon E. Perry, San Francisco, CA.)

Prognosis. Life expectancy for those with Down syndrome has improved in recent years but remains lower than for the general population. More than 80% survive to age 60 years and beyond (National Down Syndrome Society, 2011b; Weijerman and de Winter, 2010). As the prognosis continues to improve for these individuals, it will be important to provide for their long-term health care and social and leisure needs.

CARE MANAGEMENT

Support Family at Time of Diagnosis. Because of the unique physical characteristics, infants with Down syndrome are usually diagnosed at birth, and parents should be informed of the diagnosis at this time. Parents usually prefer that both of them be present during the informing interview so they can support one another emotionally. They appreciate receiving reading material about the syndrome* and being referred to others such as parent groups or professional counseling for help or advice.

After parents are aware of the diagnosis, they are confronted with the crisis of losing their perfect or dream child and grieving for and accepting their reality child. Consequently the parents' responses to the child may greatly influence decisions regarding future care. Some families willingly take the child home, whereas others consider immediate residential placement. The nurse must carefully answer questions regarding developmental potential. Institutionalization is no longer an option. For families unable or ill prepared to choose taking the newborn home, specialized foster care and adoption are other options (see Critical Thinking Case Study).

*Sources of information include the Arc of the United States (see footnote, p. 1087); the AAIDD, 501 3rd Street NW, Suite 200, Washington, DC 20001, 800-424-3688, fax: 202-387-2193, www.aamr.org; the National Down Syndrome Society (see footnote, p. 1087); and the National Down Syndrome Congress, 30 Mansell Court, Suite 108, Roswell, GA 30076, 800-232-6372 or 770-604-9500, www.ndsccenter.org.

CRITICAL THINKING CASE STUDY

Diagnosis of Down Syndrome

The parents of Melissa, a newborn diagnosed as having Down syndrome, ask the nurse, "What are we supposed to do with her?" They further state that they already have three other children at home.

1. Evidence—Is there sufficient evidence to draw conclusions about the parents' concerns regarding their newborn daughter?
2. Assumptions—Describe an underlying assumption about each of the following:
   a. Newborn diagnosed with Down syndrome
   b. Parental care of a newborn with Down syndrome
   c. Newborn with Down syndrome and older siblings
3. What priorities for the nursing response should be established?
4. Does the evidence support your nursing intervention?

Assist Family in Preventing Physical Problems. Many of the physical characteristics of infants with Down syndrome present nursing problems. The hypotonicity of muscles and hyperextensibility of joints complicate positioning. The limp, flaccid extremities resemble the posture of a rag doll; as a result, holding the infant is difficult and cumbersome. Sometimes parents perceive this lack of molding to their bodies as evidence of inadequate parenting. The extended body position promotes heat loss because more surface area is exposed to the environment. Parents are encouraged to swaddle or wrap the infant tightly in a blanket before picking him or her up to provide security and warmth. The nurse also discusses with parents their feelings concerning attachment to the child, emphasizing that the child's lack of clinging or molding is a physical characteristic, not a sign of detachment or rejection.

Decreased muscle tone compromises respiratory expansion. In addition, the underdeveloped nasal bone causes a chronic problem of inadequate drainage of mucus. The constant stuffy nose forces the child to breathe by mouth, which dries the oropharyngeal membranes, increasing the susceptibility to upper respiratory tract infections. Measures to lessen these problems include clearing the nose with a bulb-type syringe, rinsing the mouth with water after feedings, increasing fluid intake, and using a cool-mist vaporizer to keep the mucous membranes moist and the secretions liquefied. Other helpful measures include changing the child's position frequently, performing postural drainage with percussion if necessary, practicing good hand washing, and properly disposing of soiled articles such as tissues. If antibiotics are ordered, the nurse stresses the importance of completing the full course of therapy for successful eradication of the infection and prevention of growth of resistant organisms.

Inadequate drainage resulting in pooling of mucus in the nose also interferes with feeding. Because the child breathes by mouth, sucking for any length of time is difficult. When eating solids, the child may gag on the food because of mucus in the oropharynx. Parents are advised to clear the nose before each feeding; give small, frequent feedings; and allow opportunities for rest during mealtime.

The protruding tongue also interferes with feeding, especially of solid foods. Parents need to know that the tongue thrust is not an indication of refusal to feed but a physiologic response. They are advised to use a small but long, straight-handled spoon to push the food toward the back and side of the mouth. If food is thrust out, it should be fed again.

Dietary intake needs supervision. Decreased muscle tone affects gastric motility, predisposing the child to constipation. Dietary measures such as increased fiber and fluid promote evacuation. The child's eating habits may need careful scrutiny to prevent obesity. Height and weight measurements should be obtained on a serial basis, especially during infancy. Because these children grow more slowly than the general pediatric population, special growth charts developed for them should be used (AAP, Committee on Genetics, 2001; National Down Syndrome Society, 2011c).

During infancy the child's skin is pliable and soft. However, it gradually becomes rough and dry and is prone to cracking and infection. Skin care involves the use of minimum soap and application of lubricants. Lip balm is applied to the lips, especially when the child is outdoors, to prevent excessive chapping.

Assist in Prenatal Diagnosis and Genetic Counseling. Prenatal diagnosis of Down syndrome is possible through chorionic villus sampling and amniocentesis because chromosome analysis of fetal cells can detect the presence of trisomy or translocation. However, analysis will not identify sporadic cases in young women when there is no indication for prenatal testing. Testing for low maternal serum α-fetoprotein, high chorionic gonadotropin, low unconjugated estriol levels, maternal serum fetal cell markers, and measurement of the first-trimester nuchal transparency ultrasound marker may identify an affected fetus in women, who can then undergo amniocentesis (Bahado-Singh and Argoti, 2010; Benn and Chapman, 2009; National Down Syndrome Society, 2011b).

Prenatal testing and genetic counseling should be offered to women of advanced maternal age and those who have a family history of the disorder. If prenatal testing indicates that the fetus is affected, the nurse must allow the parents to express their feelings concerning elective abortion and support their decision to terminate or proceed with the pregnancy.

Fragile X Syndrome

Fragile X syndrome is the most common inherited cause of CI and the second most common genetic cause of CI after Down syndrome. It has been described in all ethnic groups and races. The incidence of affected boys is one in 3600; the incidence of affected girls is one in 4000 to 6000; the incidence of carrier girls is one in 100 to 260; and the incidence of carrier boys is one in 250 to 800 worldwide (Hagerman, 2008; National Fragile X Foundation, 2010).

The syndrome is caused by an abnormal gene on the lower end of the long arm of the X chromosome. Chromosome analysis may demonstrate a fragile site (a region that fails to condense during mitosis and is characterized by a nonstaining gap or narrowing) in the cells of affected males and females and in carrier females. This fragile site is caused by a gene mutation that results in excessive repeats of nucleotide in a specific deoxyribonucleic acid (DNA) segment of the X chromosome. The number of repeats in a normal individual is between 6 and 50. An individual with 50 to 200 base-pair repeats is said to have a permutation and therefore is a carrier. When passed from a parent to a child, these base-pair repeats can expand from 200 or more, which is termed a full mutation. This expansion occurs only when a carrier mother passes the mutation to her offspring; it does not occur when a carrier father passes the mutation to his daughters.

The inheritance pattern has been termed X-linked dominant with reduced penetrance. This is in distinct contrast to the classic X-linked recessive pattern in which all carrier females are normal, all affected males have symptoms of the disorder, and no males are carriers. Consequently genetic counseling of affected families is more complex than that for families with a classic X-linked disorder such as hemophilia. Prenatal diagnosis of the fragile X gene mutation is now possible with direct DNA testing in a family with an established history using amniocentesis or chorionic villus sampling (National Fragile X Foundation, 2010). Both affected sexes are capable of transmitting the fragile X disorder.

BOX 37-4 CLINICAL MANIFESTATIONS OF FRAGILE X SYNDROME

Physical Features

- Increased head circumference
- Long, wide, or protruding ears
- Long, narrow face with prominent jaw
- Strabismus
- Mitral valve prolapse, aortic root dilation
- Hypotonia
- Enlarged testicles (postpubertally)

Behavioral Features

- Mild-to-severe cognitive impairment
- Speech delay; may be rapid speech with stuttering and word repetition
- Short attention span, hyperactivity
- Hypersensitivity to taste, sounds, touch
- Intolerance to change in routine
- Autistic-like behaviors such as social anxiety and gaze aversion

Clinical Manifestations

The classic trend of physical findings in adult men with fragile X syndrome consists of a long face with a prominent jaw (prognathism); large, protruding ears; and large testes (macroorchidism). However, in prepubertal children these features may be less obvious, and behavioral manifestations may initially suggest the diagnosis (Box 37-4). In carrier females the clinical manifestations vary greatly.

Therapeutic Management

Fragile X syndrome has no cure. Medical treatment may include the use of serotonin agents such as carbamazepine (Tegretol) or fluoxetine (Prozac) to control violent temper outbursts and central nervous system stimulants or clonidine (Catapres) to improve attention span and decrease hyperactivity. Protein replacement and gene therapy are treatment options that are being investigated (Kuehn, 2011).

All affected children require referral to early-intervention program (speech and language therapy, occupational therapy, and special education assistance) and multidisciplinary assessment, including cardiology, neurology, and orthopedic anomalies.

Prognosis. Individuals with fragile X syndrome are expected to live a normal life span. Their CI may be improved by behavioral and educational interventions that usually begin in preschool age children.

CARE MANAGEMENT

Because CI is a fairly consistent finding in individuals with fragile X syndrome, the care given to these families is the same as for any child with CI. Because the disorder is hereditary, genetic counseling is necessary to inform parents and siblings of the risks of transmission. In addition, any male or female with unexplained or nonspecific mental impairment should be referred for genetic testing and, if needed, counseling. Families with a member affected

by the disorder should be referred to the National Fragile X Foundation.*

SENSORY IMPAIRMENT

Hearing Impairment

Hearing impairment is one of the most common disabilities in the United States. An estimated one to six per 1000 well infants have hearing loss of varying degrees (AAP Task Force on Newborn and Infant Hearing, 1999; Gifford, Holmes, and Bernstein, 2009). For infants admitted to neonatal intensive care units, the incidence rises sharply to approximately 2 to 4 per 100 neonates (AAP Task Force on Newborn and Infant Hearing, 1999). In the United States there are about 1 million children with hearing impairment ranging in age from birth to 21 years, and almost one third of these children have other disabilities such as visual or cognitive deficits.

Definition and Classification

Hearing impairment is a general term indicating disability that may range in severity from slight to profound hearing loss. *Slight-to–moderately severe hearing loss* describes a person who has residual hearing sufficient to enable successful processing of linguistic information through audition, generally with the use of a hearing aid. *Severe-to–profound hearing loss* describes a person whose hearing disability precludes successful processing of linguistic information through audition with or without a hearing aid. Hearing-impaired persons who are speech impaired tend not to have a physical speech defect other than that caused by the inability to hear.

Hearing defects may be classified according to etiology, pathology, or symptom severity. Each is important in terms of treatment, possible prevention, and rehabilitation.

Etiology

Hearing loss may be caused by a number of prenatal and postnatal conditions. These include a family history of childhood hearing impairment, anatomic malformations of the head or neck, low birth weight, severe perinatal asphyxia, perinatal infection (cytomegalovirus, rubella, herpes, syphilis, toxoplasmosis, bacterial meningitis), chronic ear infection, cerebral palsy, Down syndrome, prolonged neonatal oxygen supplementation or administration of ototoxic drugs (Botelho, Bouzada, de Resende, et al., 2010; Haddad, 2007; Robertson, Howarth, Bork, et al., 2009; Weijerman and de Winter, 2010).

In addition, high-risk neonates who survive formerly fatal prenatal or perinatal conditions may be susceptible to hearing loss from the disorder or its treatment. For example, sensorineural hearing loss may be a result of continuous humming noises or high noise levels associated with incubators, oxygen hoods, or intensive care units, especially when combined with the use of potentially ototoxic antibiotics.

Environmental noise is a special concern. Sounds loud enough to damage sensitive hair cells of the inner ear can produce irreversible hearing loss. Very loud, brief noise such as gunfire can cause immediate, severe, and permanent loss of hearing. Longer exposure to less intense but still hazardous sounds such as loud persistent music via headphones, sound systems, concerts, or industrial noises may also produce hearing loss (Daniel, 2007; Henderson, Testa, and Hartnick, 2011). Loud noises combined with toxic substances such as smoking or secondhand smoke produce a synergistic effect on hearing that causes hearing loss (Fabry, Davila, Arheart, et al., 2011; Mohammadi, Mazhari, Mehrparvar, et al., 2009).

Pathology

Disorders of hearing are divided according to the location of the defect. Conductive or middle-ear hearing loss results from interference of transmission of sound to the middle ear. It is the most common of all types of hearing loss and most frequently a result of recurrent serous otitis media. Conductive hearing impairment mainly involves interference with loudness of sound.

Sensorineural hearing loss involves damage to the inner ear structures or the auditory nerve. The most common causes are congenital defects of inner ear structures or consequences of acquired conditions such as kernicterus, infection, administration of ototoxic drugs, or exposure to excessive noise. Sensorineural hearing loss results in distortion of sound and problems in discrimination. Although the child hears some of everything going on around him or her, the sounds are distorted, severely affecting discrimination and comprehension.

Mixed conductive-sensorineural hearing loss results from interference with transmission of sound in the middle ear and along neural pathways. It frequently results from recurrent otitis media and its complications.

Central auditory imperception includes all hearing losses that are not linked to defects in the conductive or sensorineural structures. They are usually divided into organic or functional losses. In the organic type of central auditory imperception, the defect involves the reception of auditory stimuli along the central pathways and the expression of the message into meaningful communication. Examples are aphasia, the inability to express ideas in any form, either written or verbal; agnosia, the inability to interpret sound correctly; and dysacusis, difficulty in processing details or discriminating among sounds. In the functional type of hearing loss no organic lesion exists to explain a central auditory loss. Examples of functional hearing loss are conversion hysteria (an unconscious withdrawal from hearing to block remembrance of a traumatic event), infantile autism, and childhood schizophrenia.

Symptom Severity. Hearing impairment is expressed in terms of a decibel (dB), a unit of loudness; hearing is measured at various frequencies such as 500, 1000, and 2000 cycles/sec (i.e., the critical listening speech range). Hearing impairment can be classified according to hearing threshold level (the measurement of an individual's hearing threshold by means of an audiometer) and the degree of symptom severity as it affects speech (Table 37-2). These classifications offer only general guidelines regarding the effect of the impairment on any individual child because children differ greatly in their ability to use residual hearing.

Therapeutic Management

Conductive Hearing Loss. Treatment of hearing loss depends on the cause and type of hearing impairment. Many conductive hearing defects respond to medical or surgical treatment such as antibiotic therapy for acute otitis media or insertion of tympanostomy tubes for chronic otitis media. When the **conductive loss** is permanent, hearing can be improved with the use of a hearing aid to amplify sound.

The nurse should be familiar with the types, basic care, and handling of hearing aids, especially when the child is hospitalized.*

*Information about hearing aids is available from the International Hearing Society, 16880 Middlebelt Road, Suite 4, Livonia, MI 48154, 800-521-5247 or 734-522-7200, fax: 734-522-0200, ihsinfo.org.

TABLE 37-2 CLASSIFICATION OF HEARING IMPAIRMENT BASED ON SYMPTOM SEVERITY

HEARING LEVEL (DB)	EFFECT
Slight—16-25	Has difficulty hearing faint or distant speech Usually is unaware of hearing difficulty Likely to achieve in school but may have problems No speech defects
Mild to moderate—26-55	May have speech difficulties Understands face-to-face conversational speech at 0.9-1.5 m (3-5 ft)
Moderately severe—56-70	Unable to understand conversational speech unless loud Considerable difficulty with group or classroom discussion Requires special speech training
Severe—71-90	May hear a loud voice if nearby May be able to identify loud environmental noises Can distinguish vowels but not most consonants Requires speech training
Profound—91	May hear only loud sounds Requires extensive speech training

FIG 37-7 On-the-body hearing aids are convenient for young children such as this child with severe bilateral hearing loss. Note eye patching for strabismus.

Types of aids include those worn in or behind the ear, models incorporated into an eyeglass frame, and types worn on the body with a wire connection to the ear (Fig. 37-7). One of the most common problems with a hearing aid is acoustic feedback, an annoying whistling sound usually caused by improper fit of the ear mold. Sometimes the whistling may be at a frequency that the child cannot hear but that is annoying to others. In this case, if children are old enough, they are told of the noise and asked to readjust the aid.

As children grow older they may be self-conscious about the device. Effort may be made to make the aid inconspicuous such as styling the hair to cover behind-the-ear or in-the-ear models and encourage the use of attractive frames for glasses with connected hearing aids. Give children responsibility for the care of the device as soon as they are able because fostering independence is a primary goal of rehabilitation.

! NURSING ALERT

Stress to parents the importance of storing batteries for hearing aids in a safe location out of reach of children and teaching children not to remove the battery from the hearing aid (or supervising young children when they do so). Battery ingestion requires immediate emergency management.

Sensorineural Hearing Loss. Treatment for sensorineural hearing loss is much less satisfactory. Because the defect is not one of intensity of sound, hearing aids are of less value in this type of defect. The use of cochlear implants* (a surgically implanted prosthetic device) provides a sensation of hearing for individuals who have severe or profound hearing loss (Gifford, Holmes, and Bernstein, 2009; Zeng and Liu, 2006). Children with sensorineural hearing loss have lost or damaged some or all of their hair cells or auditory nerve fibers. Often these children cannot benefit from conventional hearing aids because they only amplify sound that cannot be processed by a damaged inner ear. A cochlear implant bypasses the hair cells to directly stimulate surviving auditory nerve fibers so they can send signals to the brain. These signals can be interpreted by the brain to produce sound and sensations (Baldassari, Schmidt, Schubert, et al., 2009; Gifford, Holmes, and Bernstein, 2009).

Multichanneled implants are now available. This more sophisticated device stimulates the auditory nerve at a number of locations with differently processed signals. It allows a person to use the pitch information present in speech signals, leading to better understanding of speech. The trend is toward early use of cochlear implants, usually by 18 months of age, to give the child maximum opportunity to develop listening, language, and speaking skills.

CARE MANAGEMENT

Assessment of children for hearing impairment is a critical nursing responsibility. Identification of hearing loss within the first 3 to 6 months of life is essential to improve the language and educational outcomes for children with hearing impairments (Gifford, Holmes, and Bernstein, 2009; Tierney and Brown, 2008). The Joint Committee on Infant Hearing (2000) issued guidelines on auditory screening of newborns and infants to detect early hearing loss and implement intervention programs. Auditory testing is presented in Chapter 29.

Infancy. At birth the nurse can observe the neonate's response to auditory stimuli, as evidenced by the startle reflex, head turning, eye blinking, and cessation of body movement. The infant may vary in the intensity of the response, depending on the state of alertness.

*Hearing Enrichment Language Program of the Hough Ear Institute, 3434 N.W. 56th St., Oklahoma City, Ok 73112, 405-945-7186, fax: 405-947-6266, www.integris-health.com/INTEGRIS/en-US/Specialties/EarInstitute/HELP.

BOX 37-5 CLINICAL MANIFESTATIONS OF HEARING IMPAIRMENT

Infants

- Lack of startle or blink reflex to a loud sound
- Failure to be awakened by loud environmental noises
- Failure to localize a source of sound by 6 months of age
- Absence of babble or voice inflections by age 7 months
- Lack of response to the spoken word; failure to follow verbal directions
- Response to loud noises as opposed to the voice

Children

- Using gestures rather than verbalization to express desires, especially after age 15 months
- Failure to develop intelligible speech by age 24 months
- Monotone and unintelligible speech; lessened laughter
- Vocal play, head banging, or foot stomping for vibratory sensation
- Yelling or screeching to express pleasure, needs, or annoyance
- Asking to have statements repeated or answering them incorrectly
- Greater response to facial expression and gestures than to verbal explanation
- Avoiding social interaction; preferring to play alone
- Inquiring, sometimes confused facial expression
- Suspicious alertness alternating with cooperation
- Frequently stubbornness because of lack of comprehension
- Irritability at not making themselves understood
- Shy, timid, and withdrawn behavior
- Frequently appearing "dreamy" or "in a world of their own" or exhibiting inattentiveness

However, a consistent absence of a reaction should lead to suspicion of hearing loss. Box 37-5 summarizes other clinical manifestations of hearing impairment in infants.

Childhood. Children who are profoundly hearing impaired are much more likely to be diagnosed during infancy than less severely affected ones. If the defect is not detected during early childhood, it likely becomes evident during entry into school, when the child has difficulty learning. Unfortunately some of these children are mistakenly placed in special classes for students with learning disabilities or CI. Therefore it is essential that the nurse suspect a hearing impairment in any child who demonstrates the behaviors listed in Box 37-5.

! NURSING ALERT

When parents express concern about their child's hearing and speech development, refer the child for a hearing evaluation. Absence of well-formed syllables *(da, na, yaya)* by 11 months of age should result in immediate referral.

Of primary importance is the effect of hearing impairment on speech development.* A child with a mild conductive hearing loss may speak fairly clearly but in a loud, monotone voice. A child with a sensorineural defect usually has difficulty in articulation. For example, an inability to hear higher frequencies may result in the word *spoon* being pronounced "poon." Children with articulation problems need to have their hearing tested.

GUIDELINES

Facilitating Lipreading

- Attract child's attention before speaking; use light touch to signal speaker's presence.
- Stand close to child.
- Face child directly or move to a 45-degree angle.
- Stand still; do not walk back and forth or turn away to point or look elsewhere.
- Establish eye contact and show interest.
- Speak at eye level and with good lighting on speaker's face.
- Be certain that nothing interferes with speech patterns such as chewing food or gum.
- Speak clearly and at a slow and even rate.
- Use facial expression to help convey messages.
- Keep sentences short.
- Rephrase message if child does not understand the words.

Lipreading. Even though the child may become an expert at lipreading, only about 40% of the spoken word is understood, less if the speaker has an accent, mustache, or beard. Exaggerating pronunciation or speaking in an altered rhythm further reduces comprehension. Parents can help the child understand the spoken word by using the suggestions in the Guidelines box. The child learns to supplement the spoken word with sensitivity to visual cues, primarily body language and facial expression (e.g., tightening the lips, muscle tension, eye contact).

Cued Speech. This method of communication is an adjunct to straight lipreading. It uses hand signals to help the child with a hearing impairment distinguish between words that look alike when formed by the lips (e.g., mat, bat). It is most often used by children with hearing impairments who are using speech rather than those who are nonverbal.

Sign Language. Sign language such as American Sign Language (ASL) or British Sign Language (BSL) is a visual gestural language that uses hand signals that roughly correspond to specific words and concepts in the English language. Family members are encouraged to learn signing because using or watching hands requires much less concentration than lipreading or talking. In addition, a symbol method enables some children to learn more faster.

Speech Language Therapy. The most formidable task in the education of a child who is profoundly hearing impaired is learning to speak. Speech is learned through a multisensory approach using visual, tactile, kinesthetic, and auditory stimulation. Parents are encouraged to participate fully in the learning process.

Additional Aids. Everyday activities present problems for older children with hearing impairment. For example, they may not be able to hear the telephone, doorbell, or alarm clock. Several commercial devices are available to help them adjust to these dilemmas. Flashing lights can be attached to a telephone or doorbell to signal its ringing. Trained hearing-ear dogs can provide great assistance because they alert the person to sounds such as someone approaching, a moving car, a signal to wake up, or a child's cry. Special teletypewriters or telecommunications devices for the deaf (TTY or TDD) help people with impaired hearing communicate

with one another over the telephone; the typed message is conveyed via the telephone lines and displayed on a small screen.*

Any audiovisual medium presents dilemmas for these children, who can see the picture but cannot hear the message. However, with closed captioning a special decoding device is attached to the television, and the audio portion of a program is translated into subtitles that appear on the screen.†

Socialization. As children learn to compensate for their lack of hearing, they become extremely perceptive to visual and vibratory changes. They often know when another person wants to talk to them because the person walks close by but does not pass. They learn to be alert to other people approaching them by seeing their shadows or feeling the vibrations of their footsteps. They are acutely aware of facial expressions and may comprehend unspoken messages more quickly than the spoken word.

Socialization is extremely important to children's development. If they attend a special school for the hearing impaired, they are able to socialize with peers in that setting. Classmates become a potential source of close friendships because they communicate more easily among themselves. Encourage parents to promote these relationships whenever possible.

Children with a hearing impairment may need special help with school or social activities. For children wearing hearing aids, background noise should be kept to a minimum. Because many of these children are able to attend regular classes, the teacher may need help to adapt methods of teaching for the child's benefit. The school nurse is often in an optimal position to emphasize methods of facilitated communication such as lipreading (see Guidelines box on p. 1095). Because group projects and audiovisual teaching aids may hinder the child's learning, these educational methods should be evaluated carefully.

In a group setting it is helpful for the other members to sit in a semicircle in front of the child. Because one of the difficulties in following a group discussion is that the child is unaware of who will speak next, someone should point out each speaker. Speakers can also be given numbers, or their names can be written down as each person talks. If one person writes down the main topic of the discussion, the child is able to follow lipreading more closely. Such suggestions can increase the child's ability to participate in sports, organizations such as scouts, and group projects.

Supporting the Child and Family. After the diagnosis of hearing impairment is made, parents need extensive support to adjust to the shock of learning about their child's disability and an opportunity to realize the extent of the hearing loss. If the hearing loss occurs during childhood, the child also requires sensitive, supportive care during the long and often difficult adjustment to this sensory loss. Early rehabilitation is one of the best strategies for fostering adjustment. However, progress in learning communication may not always coincide with emotional adjustment. Depression or anger is common, and such feelings are a normal part of the grieving process. (See also Chapter 38 for an extensive discussion of the emotional support of the child and family.)

CRITICAL THINKING CASE STUDY

Hearing Impairment

Four-year-old Jason has a severe congenital hearing impairment. Jason has been admitted to the outpatient surgery PACU after a herniorrhaphy and regional block. As he emerges from anesthesia, he becomes more and more agitated.

1. Evidence—Is there sufficient evidence to draw conclusions about Jason's increasing agitation after surgery?
2. Assumptions—Describe an underlying assumption about each of the following:
   a. Severe congenital hearing impairment in a preschool child
   b. Preschooler with severe congenital hearing impairment awakening in the PACU after surgery
   c. Preschooler with severe congenital hearing impairment awakening from herniorrhaphy and after regional block
3. What priorities for nursing care should be established for Jason?
4. Does the evidence support your nursing intervention?

PACU, Postanesthesia care unit.

Caring for the Child During Hospitalization. The needs of the hospitalized child with impaired hearing are the same as those of any other child, but the disability presents special challenges to the nurse (see Critical Thinking Case Study). For example, verbal explanations must be supplemented by tactile and visual aids such as books or actual demonstration and practice. Children's understanding of the explanation needs to be reassessed constantly. If their verbal skills are poorly developed, they can answer questions through drawing, writing, or gesturing. For example, if the nurse is attempting to clarify where a spinal tap is done, the child is asked to point to where the procedure will be done on the body. Because these children often need more time to grasp the full meaning of an explanation, the nurse needs to be patient, allowing ample time for understanding.

When communicating with the child, the nurse should use the same principles as those outlined for facilitating lipreading. Ideally nurses without foreign accents should be assigned to the child. The child's hearing aid is checked to ensure that it is working properly. If it is necessary to awaken the child at night, the nurse should gently shake him or her or turn on the hearing aid before arousing him or her. The nurse should always make certain that the child can see him or her before any procedures, even routine ones such as changing a diaper or regulating an infusion. It is important to remember that the child may not be aware of one's presence until alerted through visual or tactile cues.

Ideally parents are encouraged to room with the child. However, it must be conveyed to them that this is not to serve as a convenience to the nurse but as a benefit to the child. Although the parents' aid can be enlisted in familiarizing the child with the hospital and explaining procedures, the nurse also talks directly to the youngster, encouraging expression of feelings about the experience. If the child's speech is difficult to understand, the nurse makes an effort to become familiar with his or her pronunciation of words. Parents often can be helpful by explaining the child's usual speech habits. Nonverbal communication devices that use pictures or words to which the child can point are also available. Such boards can also be made by drawing pictures or writing the words of common needs on cardboard such as *parent, food, water,* or *toilet*.

The nurse has a special role as child advocate and is in a strategic position to alert other health team members and patients to the

child's special needs regarding communication. For example, the nurse should accompany other practitioners on visits to the child's room to ensure that they speak to the child and that he or she understands what is said. Caregivers sometimes forget that the child has the abilities to perceive and learn despite a hearing loss; consequently they communicate only with the parents. As a result, the child's needs and feelings remain unrecognized and unmet.

Because children with impaired hearing may have difficulty forming social relationships with other children, the child is introduced to roommates and encouraged to engage in play activities. The hospital setting can provide growth-promoting opportunities for social relationships. With the assistance of a child life specialist, the child can learn new recreational activities, experiment with group games, and engage in therapeutic play. The use of puppets, dollhouses, role-playing with dress-up clothes, building with a hammer and nails, finger painting, and water play can help the child express feelings that previously were suppressed.

Assisting in Measures to Prevent Hearing Impairment. A primary nursing role is prevention of hearing loss. Because the most common cause of impaired hearing is chronic otitis media, it is essential that appropriate measures be instituted to treat existing infections and prevent recurrences (see Chapter 40). Children with a history of ear or respiratory infections or any other condition known to increase the risk of hearing impairment should receive periodic auditory testing.

To prevent the causes of hearing loss that begin prenatally and perinatally, pregnant women need counseling regarding the necessity of early prenatal care, including genetic counseling for known familial disorders; avoidance of all ototoxic drugs, especially during the first trimester; tests to rule out syphilis, rubella, or blood incompatibility; medical management of maternal diabetes; strict control of alcohol intake; adequate dietary intake; and avoidance of smoke exposure. The necessity of routine immunization during childhood to eliminate the possibility of acquired sensorineural hearing loss from rubella, mumps, or measles (encephalitis) is stressed.

Excessive noise pollution is a well-established cause of sensorineural hearing loss. The nurse should assess the possibility of environmental noise pollution routinely and advise children and parents of the potential danger. When individuals engage in activities associated with high-intensity noise such as flying model airplanes, target shooting, or snowmobiling, they should wear ear protection such as earmuffs or earplugs. Even common household equipment such as lawn mowers, vacuum cleaners, and cordless telephones can be harmful.

! NURSING ALERT

Suspect hazardous noise if the listener experiences (1) difficulty in communication while hearing the sound, (2) ringing in the ears (tinnitus) after exposure to the sound, or (3) muffled hearing after leaving the sound.

Visual Impairment

Visual impairment is a common problem during childhood. In the United States the prevalence of serious visual impairment in the pediatric population is estimated at 30 to 64 children per 100,000 population. Vision impairment such as refractive error, strabismus, and **amblyopia** occur in 5% to 10% of all preschoolers, who are usually identified through vision screening programs (Rahi, Cumberland, Perkham, et al., 2010; Tingley, 2007; U.S. Preventive Services Task Force, 2011). The nurse's role is one of assessment, detection, prevention, referral, and in some instances rehabilitation.

Definition and Classification

Visual impairment is a general term that encompasses both partial sight and legal blindness. Partial sight or partial visual impairment is defined as a visual acuity between 20/70 and 20/200. The child can generally use normal-size print because near vision is almost always better than distance vision. Legal blindness or severe permanent visual impairment is defined as a visual acuity of 20/200 or lower or a visual field of 20 degrees or less in the better eye. It is important to keep in mind that legal blindness is not a medical diagnosis but a legal definition. Educational and governmental agencies in the United States use the legal definition of blindness to determine tax status, eligibility for entrance into special schools, eligibility for financial aid, and other benefits.

Etiology

Visual impairment can be caused by a number of genetic and prenatal or postnatal conditions. These include perinatal infections (herpes, Chlamydia, gonococci, rubella, syphilis, toxoplasmosis); retinopathy of prematurity; trauma; postnatal infections (meningitis); and disorders such as sickle cell disease, juvenile rheumatoid arthritis, Tay-Sachs disease, albinism, and retinoblastoma. In many instances such as with refractive errors the cause of the defect is unknown.

Refractive errors are the most common types of visual disorders in children. The term refraction means bending and refers to the bending of light rays as they pass through the lens of the eye. Normally light rays enter the lens and fall directly on the retina. However, in refractive disorders the light rays either fall in front of the retina **(myopia)** or beyond it **(hyperopia).** Other eye problems such as strabismus may or may not include refractive errors, but they are important because, if untreated, they result in severe permanent visual impairment from amblyopia. These, along with other less frequent visual disorders, are summarized in Box 37-6. In addition to these disorders, other visual problems can be a result of trauma or infection.

Trauma. Trauma is a common cause of visual impairment in children. Injuries to the eyeball and adnexa (supporting or accessory structures such as eyelids, conjunctiva, or lacrimal glands) can be classified as penetrating or nonpenetrating. Penetrating wounds are most often a result of sharp instruments such as sticks, knives, or scissors or propulsive objects such as firecrackers, guns, arrows, or slingshots. Nonpenetrating injuries may be a result of foreign objects in the eyes, lacerations, a blow from a blunt object such as a ball (baseball, softball, basketball, racquet sports) or fist, or thermal or chemical burns.

Treatment is aimed at preventing further ocular damage and is primarily the responsibility of the ophthalmologist. It involves adequate examination of the injured eye (with the child sedated or anesthetized in severe injuries); appropriate immediate intervention such as removal of the foreign body or suturing of the laceration; and prevention of complications such as administration of antibiotics or steroids and complete bed rest to allow the eye to heal and blood to resorb (see Emergency box). The prognosis varies according to the type of injury. It is usually guarded in all cases of penetrating wounds because of the high risk of serious complications.

Infections. Infections of the adnexa and structures of the eyeball or globe may occur in children. The most common eye infection is conjunctivitis. Treatment is usually with ophthalmic antibiotics. Severe infections may require systemic antibiotic therapy. Steroids are used cautiously because they exacerbate viral infections such

BOX 37-6 TYPES OF VISUAL IMPAIRMENT

Refractive Errors

Myopia

- *Nearsightedness*—Ability to see objects clearly at close range but not at a distance

Pathophysiology

- Results from eyeball that is too long, causing images to fall in front of the retina

Clinical Manifestations

- Headaches
- Dizziness
- Excessive eye rubbing
- Head tilt or forward head thrusts
- Difficulty reading or doing other close work
- Clumsiness; walking into objects
- Blinking more than usual or irritability when doing close work
- Inability to see objects clearly
- Poor school performance, especially in subjects that require demonstration such as arithmetic

Treatment

- Corrected with biconcave lenses that focus rays on retina
- May be corrected with laser surgery

Hyperopia

Farsightedness—Ability to see objects at a distance

Pathophysiology

- Results from eyeball that is too short, causing image to focus beyond retina

Clinical Manifestations

- Because of accommodative ability, child can usually see objects at all ranges
- Most children normally hyperopic until about 7 years of age

Treatment

- When required, corrected with convex lenses that focus rays on retina
- May be corrected with laser surgery

Astigmatism

- Unequal curvatures in refractive apparatus

Pathophysiology

- Results from unequal curvatures in cornea or lens that cause light rays to bend in different directions

Clinical Manifestations

- Depend on severity of refractive error in each eye
- Possible clinical manifestations of myopia

Treatment

- Corrected with special lenses that compensate for refractive errors
- May be corrected with laser surgery

Anisometropia

- Different refractive strength in each eye

Pathophysiology

- May develop amblyopia because weaker eye is used less

Clinical Manifestations

- Depend on severity of refractive error in each eye
- Possible clinical manifestations of myopia

Treatment

- Treated with corrective lenses, preferably contact lenses, to improve vision in each eye so they work as a unit
- May be corrected with laser surgery

Amblyopia

- Lazy eye—Reduced visual acuity in one eye

Pathophysiology

- Results when one eye does not receive sufficient stimulation
- Each retina receives different images, resulting in diplopia (double vision)
- Brain accommodates by suppressing less intense image
- Visual cortex eventually does not respond to visual stimulation, with resultant loss of vision in that eye

Clinical Manifestations

- Poor vision in affected eye

Treatment

- Preventable if treatment of primary visual defect such as anisometropia or strabismus begins before 6 years of age

Strabismus

- *"Squint"* or malalignment of eyes
- *Esotropia*—Inward deviation of eye
- *Exotropia*—Outward deviation of eye

Pathophysiology

- May result from muscle imbalance or paralysis, poor vision, or congenital defect
- Because visual axes are not parallel, brain receives two images, and amblyopia can result

Clinical Manifestations

- Squints eyelids together or frowns
- Difficulty in focusing from one distance to another
- Inaccurate judgment in picking up objects
- Unable to see print or moving objects clearly
- Closing one eye to see
- Tilting head to one side
- If combined with refractive errors, may see any of the manifestations listed for refractive errors
  - Diplopia
  - Photophobia
  - Dizziness
  - Headaches

Treatment

- Depends on cause of strabismus
- May involve occlusion therapy (patching stronger eye) or surgery to increase visual stimulation to weaker eye
- Early diagnosis essential to prevent vision loss

BOX 37-6 TYPES OF VISUAL IMPAIRMENT—cont'd

Cataracts

- Opacity of crystalline lens

Pathophysiology

- Prevents light rays from entering eye and refracting on retina

Clinical Manifestations

- Gradual decrease in ability to see objects clearly
- Possible loss of peripheral vision
- Nystagmus (with severe permanent visual impairment)
- Gray opacities of lens
- Strabismus
- Absence of red reflex

Treatment

- Requires surgery to remove cloudy lens and replace lens (with intraocular lens implant, removable contact lens, prescription glasses)
- Must be treated early to prevent severe permanent visual impairment from amblyopia

Glaucoma

- Increased intraocular pressure

Pathophysiology

- Congenital type results from defective development of some component related to flow of aqueous humor
- Increased pressure on optic nerve causes eventual atrophy and severe permanent visual impairment

Clinical Manifestations

- Loss of peripheral vision—mostly seen in acquired types
- Possible bumping into objects
- Perception of halos around objects
- Possible complaint of pain or discomfort (pain, nausea, or vomiting if sudden rise in pressure)
- Eye redness
- Excessive tearing (epiphora)
- Photophobia
- Spasmodic winking (blepharospasm)
- Corneal haziness
- Enlargement of eyeball (buphthalmos)

Treatment

- Requires surgical treatment (goniotomy) to open outflow tracts
- May require more than one procedure

EMERGENCY

Eye Injuries

Foreign Object

- Examine eye for presence of a foreign body (evert upper eyelid to examine upper eye).
- Remove a freely movable object with pointed corner of gauze pad lightly moistened with water.
- Do not irrigate eye or attempt to remove a penetrating object (see Penetrating Injury).
- Caution child against rubbing eye.

Chemical Burns

- Irrigate eye copiously with tap water for 20 minutes.
- Evert upper eyelid to flush thoroughly.
- Hold child's head with eye under a tap of running lukewarm water.
- Take child to emergency department.
- Have child rest with eyes closed.
- Keep room darkened.

Ultraviolet Burns

- If skin is burned, patch both eyes (make certain that eyelids are completely closed); secure dressing with Kling bandages wrapped around head rather than with tape.
- Have child rest with eyes closed.
- Refer to an ophthalmologist.

Hematoma ("Black Eye")

- Use a flashlight to check for gross hyphema (hemorrhage into anterior chamber; visible fluid meniscus across iris; more easily seen in light-colored than in brown eyes).
- Apply ice for first 24 hours to reduce swelling if no hyphema is present.
- Refer to an ophthalmologist immediately if hyphema is present.
- Have child rest with eyes closed.

Penetrating Injuries

- Take child to emergency department.
- Never remove an object that has penetrated eye.
- Follow strict aseptic technique in examining eye.
- Observe for:
  - Aqueous or vitreous leaks (fluid leaking from point of penetration).
  - Hyphema.
  - Shape and equality of pupils, reaction to light, prolapsed iris (not perfectly circular).
- Apply a Fox shield if available (not a regular eye patch) and apply patch over unaffected eye to prevent bilateral movement.
- Maintain bed rest with child in a 30-degree Fowler position.
- Caution child against rubbing eye.
- Refer to an ophthalmologist.

as herpes simplex, increasing the risk of damage to the involved structures.

CARE MANAGEMENT

Assessment of children for visual impairment is a critical nursing responsibility. Discovery of a visual impairment as early as possible is essential to prevent social, physical, and psychologic damage to the child. Assessment involves (1) identifying children who by virtue of their history are at risk, (2) observing for behaviors that indicate a vision loss, and (3) screening all children for visual acuity and signs of other ocular disorders such as strabismus. This discussion focuses on clinical manifestations of various types of visual problems (see Box 37-6). Vision testing is discussed in Chapter 29.

Infancy. At birth the nurse should observe the neonate's response to visual stimuli such as following a light or object and cessation of

body movement. The infant may vary in the intensity of the response, depending on the state of alertness.

Of special importance in detecting visual impairment during infancy are the parents' concerns regarding visual responsiveness in their child. Their concerns such as lack of eye contact from the infant must be taken seriously. During infancy the child should be tested for strabismus. Lack of binocularity after 4 months of age is considered abnormal and must be treated to prevent amblyopia.

! NURSING ALERT

Suspect visual impairment in an infant who does not react to light and in a child of any age if the parents express concern.

Childhood. Because the most common visual impairment during childhood is refractive errors, testing for visual acuity is essential. The school nurse usually assumes major responsibility for vision testing in schoolchildren. Besides refractive errors, the nurse should be aware of signs and symptoms that indicate other ocular problems. If a referral is made to the family requesting further eye testing, the nurse is responsible for follow-up concerning the recommendation.

The shock of learning that their child has severe permanent visual impairment precipitates an immense crisis for families. The family is encouraged to investigate appropriate stimulation and educational programs for their child as soon as possible. Sources of information include state commissions for the visually impaired, local schools for children with visual impairments, the American Foundation for the Blind,* the National Federation of the Blind,† the National Association for Parents of Children with Visual Impairments,‡ the National Association for Visually Handicapped,§ the American Council of the Blind,‖ and CNIB.¶

Promoting Parent-Child Attachment. A crucial time in the life of visual impaired infants is when they and their parents are getting acquainted with one another. Pleasurable patterns of interaction between the infant and parents may be lacking if there is not enough reciprocity. For example, if the parent gazes fondly at the infant's face and seeks eye contact but the infant fails to respond because he or she cannot see the parent, a troubled cycle of responses may occur. The nurse can help parents learn to look for other cues that indicate that the infant is responding to them such as whether the eyelids blink, whether the activity level accelerates or slows, whether respiratory patterns change such as faster or slower breathing when the parents come near, and whether the infant makes throaty sounds when they speak to him or her. In time parents learn that the infant has unique ways of relating to them. They are encouraged to show affection using nonvisual methods such as talking or reading, cuddling, and walking the child.

Promoting Child's Optimal Development. Promoting the child's optimal development requires rehabilitation in a number of important areas, including learning self-help skills and appropriate communication techniques to become independent. Although nurses may not be directly involved in such programs, they can provide direction and guidance to families regarding the availability of programs and the need to promote these activities in their child.

Development and Independence. Motor development depends on sight almost as much as verbal communication depends on hearing. From earliest infancy parents are encouraged to expose the infant to as many visual-motor experiences as possible such as sitting supported in an infant seat or swing and being given opportunities for holding up the head, sitting unsupported, reaching for objects, and crawling.

Despite visual impairment the child can become independent in all aspects of self-care. The same principles used for promoting independence in sighted children apply, with additional emphasis on nonvisual cues. For example, the child may need help in dressing such as special arrangement of clothing for style coordination and braille tags to distinguish colors and prints.

The severe permanent visually impaired child also must learn to become independent in navigational skills. The two main techniques are the tapping method (use of a cane to survey the environment for direction and avoid obstacles) and guides such as a sighted human guide or a dog guide such as a seeing-eye dog. Children who are partially sighted may benefit from ocular aids such as a monocular telescope.

Play and Socialization. Children with severe permanent visual impairments do not learn to play automatically. Because they cannot imitate others or actively explore the environment as sighted children do, they depend much more on others to stimulate and teach them how to play. Parents need help in selecting appropriate play materials, especially those that encourage fine and gross motor development and stimulate the senses of hearing, touch, and smell. Toys with educational value such as dolls with various clothing closures are especially useful.

Children with severe permanent visual impairments have the same needs for socialization as sighted children. Because they have little difficulty learning verbal skills, they are able to communicate with age mates and participate in suitable activities. The nurse should discuss with parents opportunities for socialization outside the home, especially regular preschools. The trend is to include these children with sighted children to help them adjust to the outside world for eventual independence.

To compensate for inadequate stimulation, these children may develop self-stimulatory activities such as body rocking, finger flicking, or arm twirling. Discourage such habits because they delay the child's social acceptance. Behavior modification is often successful in reducing or eliminating self-stimulatory activities.

Education. The main obstacle to learning is the child's total dependence on nonvisual cues. Although the child can learn via verbal lecturing, he or she is unable to read the written word or write without special education. Therefore the child must rely on braille, a system that uses raised dots to represent letters and numbers. He or she can then read braille with the fingers and write messages using a braille writer. However, unless others read braille, this system is not useful for communicating with others. A more portable system for written communication is the use of a braille slate and stylus or a microcassette tape recorder. A recorder is especially helpful for leaving messages for others and taking notes during classroom

lectures. For mathematic calculations, portable calculators with voice synthesizers are available.*

Records and tapes are significant sources of reading material other than braille books, which are large and cumbersome. The Library of Congress† has talking books, braille books, and a special records program, which are available at many local and state libraries and directly from the Library of Congress. The talking book machine and tape player are provided at no cost to families, and there is no postage fee for returning the materials. Learning Ally‡ also provides texts and tapes of books, which are helpful for secondary and college students who are blind. A means of writing is learning to use a home computer with a voice synthesizer that can be adapted to speak each letter or word typed.

Children with partial sight benefit from specialized visual aids that produce a magnified retinal image. The basic devices are accommodation (e.g., bringing the object closer), special plus lenses, handheld and stand magnifiers, telescopes, video projection systems, and large print. Special equipment is available to enlarge print. Information about services for the partially sighted is available from the National Association for Visually Handicapped and American Foundation for the Blind. Children with diminished vision often prefer to do close work without their glasses and compensate by bringing the object very near to their eyes. This should be allowed. The exception is children with vision in only one eye, who should always wear glasses for protection.

Caring for the Child During Hospitalization. Because nurses are more likely to care for children who are hospitalized for procedures that involve temporary loss of vision than for children who have severe permanent visual impairments, the following discussion concentrates primarily on the needs of such children. The nursing care objectives in either situation are to (1) reassure the child and family throughout every phase of treatment, (2) orient the child to the surroundings, (3) provide a safe environment, and (4) encourage independence. Whenever possible, the same nurse should care for the child to ensure consistency in the approach.

When sighted children temporarily lose their vision, almost every aspect of the environment becomes bewildering and frightening. They are forced to rely on nonvisual senses for help in adjusting to the visual impairment without the benefit of any special training. Nurses have a major role in minimizing the effects of temporary loss of vision. They need to talk to the child about everything that is occurring, emphasizing aspects of procedures that are felt or heard. They should approach the child by always identifying themselves as soon as they enter the room. Because unfamiliar sounds are especially frightening, these are explained. Parents are encouraged to room with their child and participate in the care. Familiar objects such as a teddy bear or doll should be brought from home to help lessen the strangeness of the hospital. As soon as the child is able to be out of bed, he or she is oriented to the immediate surroundings. If the child is able to see on admission, this opportunity is taken to point out significant aspects of the room. He or she is encouraged to practice ambulating with the eyes closed to become accustomed to this experience.

The room is arranged with safety in mind. For example, a stool or chair is placed next to the bed to help the child climb in and out of bed. The furniture is always placed in the same position to prevent collisions. Cleaning personnel are reminded of the need to keep the room in order. If the child has difficulty navigating by feeling the walls, a rope can be attached from the bed to the point of destination such as the bathroom. Attention to details such as well-fitting slippers and robes that do not drag on the floor is important in preventing tripping. Unlike children who have permanent visual impairments, children with temporary visual impairments are not familiar with navigating with a cane.

The child is encouraged to be independent in self-care activities, especially if the visual loss may be prolonged or potentially permanent. For example, during bathing the nurse sets up all of the equipment and encourages the child to participate. At mealtimes the nurse explains where each food item is on the tray, opens any special containers, prepares cereal or toast, and encourages the child to self-feed. Favorite finger foods such as sandwiches, hamburgers, hot dogs, or pizza may be good selections. The child is praised for efforts at being cooperative and independent. Any improvements made in self-care, no matter how small, are stressed.

Appropriate recreational activities are provided; if a child life specialist is available, such planning is done jointly. Because children with temporary visual impairment have a wide variety of play experiences on which to draw, they are encouraged to select activities. For example, if they like to read, they may enjoy having someone read to them. If they prefer manual activity, they may appreciate playing with clay or building blocks or feeling different textures and naming them. If they need an outlet for aggression, activities such as pounding or banging on a drum can be helpful. Simple board and card games can be played with a "seeing partner" or an opponent who helps with the game. They should have familiar toys from home with which to play because familiar items are more easily manipulated than new ones. If parents want to bring presents, they should be objects that stimulate hearing and touch such as a radio, music box, or stuffed animal.

Occasionally children who are visually impaired come to the hospital for procedures to restore their vision. Although this is an extremely happy time, it also requires intervention to help them adjust to sight. They need an opportunity to take in all that they see. They should not be bombarded with visual stimuli. They may need to concentrate on people's faces or their own to become accustomed to this experience. They often need to talk about what they see and to compare the visual images with their mental ones. The children may also go through a period of depression, which must be respected and supported. The nurse or parents should encourage the child to discuss how it feels to see, especially in terms of seeing themselves.

Newly sighted children also need time to adjust and engage in activities that were impossible before. For example, they may prefer to use braille to read rather than learning a new "visual approach" because of familiarity with the touch system. Eventually, as they learn to recognize letters and numbers, they will integrate these new skills into reading and writing. However, parents and teachers must be careful not to push them before they are ready. This applies to social relationships, physical activities, and learning situations.

Assisting in Measures to Prevent Visual Impairment. An essential nursing goal is to prevent visual impairment. This involves many of the same interventions discussed for hearing impairments:

- Prenatal screening for pregnant women at risk such as those with rubella or syphilis infection and family histories of genetic disorders associated with visual loss
- Adequate prenatal and perinatal care to prevent prematurity
- Periodic screening of all children, especially newborns through preschoolers, for congenital and acquired visual impairments caused by refractive errors, strabismus, and other disorders
- Rubella immunization of all children
- Safety counseling regarding the common causes of ocular trauma, including safe practices when working with, playing with, and carrying objects such as scissors, knives, and balls

! NURSING ALERT

A helmet with a face mask should be required for children playing football, hockey, and baseball.

After detection of eye problems, the nurse has a responsibility to prevent further ocular damage by ensuring that corrective treatment is used. For children with strabismus, this often necessitates occlusion patching of the stronger eye. Compliance with the procedure is greatest during the early preschool years. It is more difficult to encourage school-age children to wear the occlusive patch because the poor visual acuity of the uncovered weaker eye interferes with school work and the patch sets them apart from their peers. In school they benefit from being positioned favorably (closer to the white board or other visual media) and allowed extra time to read or complete an assignment. If treatment of the eye disorder requires instillation of ophthalmic medication, the family is taught the correct procedure (see Chapter 39).

The nurse helps children with refractive errors adjust to wearing glasses. Young children who often pull off glasses benefit from temporal pieces that wrap around the ears or an elastic strap attached to the frames and around the back of the head to hold the glasses on securely. After children appreciate the value of clear vision, they are more likely to wear the corrective lenses.

Glasses should not interfere with any activity. Special protective guards are available during contact sports to prevent accidental injury; and all corrective lenses should be made from safety glass, which is shatterproof. Often corrective lenses improve visual acuity so dramatically that children are able to compete more effectively in sports. This in itself is a tremendous inducement to continue wearing glasses.

Contact lenses are a popular alternative, especially for adolescents. Several types are available such as hard lenses, including gas-permeable ones, and soft lenses, which may be designed for daily or extended wear. Contact lenses offer several advantages over glasses such as greater visual acuity, total corrected field of vision, convenience (especially with the extended-wear type), and optimal cosmetic benefit. Unfortunately they are usually more expensive and require much more care than glasses, including considerable practice to learn techniques for insertion and removal. If they are prescribed, the nurse can help to teach parents or older children how to care for them.

Because trauma is the leading cause of visual impairment, the nurse has the major responsibility of preventing further eye injury until specific treatment is instituted. The major principles to follow when caring for an eye injury are outlined in the Emergency box on p. 1099. Because patients with a serious eye injury fear visual impairment, the nurse should stay with the child and family to provide support and reassurance.

Hearing-Visual Impairment

The most traumatic sensory impairment is loss of both vision and hearing, which may have profound effects on the child's development. They interfere with the normal sequence of physical, intellectual, and psychosocial growth. Although such children often achieve the usual motor milestones, their rate of development is slower. They learn communication only with specialized training. Finger spelling is one desirable method often taught. Words are spelled letter by letter into the child's hand, and the child spells into the other person's hand. Some children with hearing-visual impairment, especially those with residual hearing or sight, can learn to speak. Whenever possible, speech is encouraged because it allows communication with other individuals.

The future prospects for children with hearing-visual impairment are at best unpredictable. Congenital hearing-visual impairment may be accompanied by other physical or neurologic problems, which further diminish the child's learning potential. The most favorable prognosis is for children who have acquired hearing-visual impairment with few, if any, associated disabilities. Their learning capacity is greatly potentiated by their developmental progress before the sensory impairments. Although total independence, including gainful vocational training, is the goal, some children with hearing-visual impairment are unable to develop to this level. They may require lifelong parental or residential care. The nurse working with such families helps them deal with future goals for the child, including possible alternatives to home care during the parents' advancing years.

Retinoblastoma

Retinoblastoma, which arises from the retina, is the most common congenital malignant intraocular tumor of childhood. Approximately 11 cases per million occur annually, primarily in children younger than 5 years of age. Retinoblastoma is caused by a mutation in a gene and may occur sporadically or be inherited (Hurwitz, Shields, Shields, et al., 2011; Parulekar, 2010). It develops when the mutated gene is unable to produce the natural signals to stop the growth of retinal cells. Of all cases, the majority are nonhereditary and unilateral, with the remainder divided between hereditary and unilateral and hereditary and bilateral. Hereditary retinoblastomas are transmitted with few exceptions as an autosomal dominant trait with high but incomplete penetrance (Hurwitz, Shields, Shields, et al., 2011; Parulekar, 2010).

Diagnostic Evaluation

Retinoblastoma has few grossly obvious signs (Box 37-7). Typically the most common sign is observed by the parent as a whitish "glow" in the pupil, known as the white reflex or leukocoria. Leukocoria

BOX 37-7 CLINICAL MANIFESTATIONS OF RETINOBLASTOMA

- White eye reflex (most common sign)
- Strabismus (second most common sign)
- Red, painful eye, often with glaucoma
- Severe permanent visual impairment (late sign)

FIG 37-8 White reflex. Whitish appearance of lens is produced as light falls on tumor mass in left eye.

FIG 37-9 The same infant with a left prosthetic eye.

represents visualization of the tumor as the light momentarily falls on the mass (Fig. 37-8). The second most common sign of retinoblastoma is acquired strabismus (Hurwitz, Shields, Shields, et al., 2011; Phan and Stout, 2010).

The first step in diagnosis is carefully listening to and recognizing the significance of reports from family members regarding suspected abnormalities within the eye. Eye abnormalities, including white reflex, strabismus, decreased vision, and persistent painful erythematous eyes, are referred to an ophthalmologist. Definitive diagnosis is usually based on ophthalmoscopic examination with the patient under general anesthesia. Imaging studies, including ultrasonography and computed tomography of the orbit, are done to determine the extent of the disease.

Therapeutic Management

Treatment of retinoblastoma is complex. Enucleation may be used to treat advanced disease with optic nerve invasion in which there is no hope for salvage of vision. Irradiation can be used when there is vitreous seeding; and chemotherapy has been used more recently to decrease the size of the tumor, which would then allow treatment with local therapies such as plaque brachytherapy (surgical implantation of an iodine-125 applicator on the sclera until the maximum radiation dose has been delivered to the tumor), photocoagulation (use of a laser beam to destroy retinal blood vessels that supply nutrition to the tumor), and cryotherapy (freezing of the tumor, which destroys the microcirculation to the tumor and the cells themselves through microcrystal formation). Vincristine, carboplatin, and etoposide are the agents most commonly used.

The use of chemotherapy in advanced disease is controversial and has not shown improved survival. Drugs that may be used in the treatment of metastatic disease include vincristine, cyclophosphamide, doxorubicin, cisplatin, carboplatin, and etoposide. In the case of central nervous system disease, intrathecal chemotherapy may be administered (Hurwitz, Shields, Shields, et al., 2011; Lanzkowsky, 2005).

Prognosis

The overall prognosis for retinoblastoma is favorable; with early appropriate treatment the survival rate is nearly 95% for both unilateral and bilateral tumors. Retinoblastoma is one of the tumors that may spontaneously regress. Of major concern in long-term survivors is the development of decreased visual acuity; facial disfiguration; and secondary tumors, especially osteogenic sarcoma, other sarcomas, and melanoma. Children with bilateral disease (hereditary form) are more likely to develop secondary cancers than are children with unilateral disease. It is thought that these individuals are predisposed to developing cancer and that radiation increases their risk.

CARE MANAGEMENT

One of the most important nursing goals is to have a high index of suspicion for this rare malignancy. If parents report noticing a strange light in the eye or expression, these concerns must be taken seriously. Families with a history of retinoblastoma require follow-up, and the nurse can be instrumental in reminding parents of appointments and the importance of genetic counseling

Because the tumor is usually diagnosed in infants or very young children, most of the preparation for diagnostic tests and treatment involves parents. After indirect ophthalmoscopy the child may not see clearly, or the eyes may be sensitive to light because of pupillary dilation. The parents are made aware of these normal reactions before the procedure.

The treatment plan may include focal intraocular therapy with or without chemotherapy; external-beam radiation; and, if necessary, enucleation. Enucleation is the treatment of choice if there is extensive disease threatening metastasis or no chance for useful vision. The enucleation procedure and the positive benefits of a prosthesis are explained to the parents. Showing them pictures of another child with an artificial eye may help them adjust to the thought of disfigurement (Fig. 37-9).

After surgery the parents are prepared for the child's facial appearance. An eye patch is in place, and the child's face may be edematous or ecchymotic. Parents often fear seeing the surgical site because they imagine a cavity in the skull. A surgically implanted sphere maintains the shape of the eyeball, and the implant is covered with conjunctiva. When the eyelids are open, the exposed area resembles the mucosal lining of the mouth. After the child is fitted for a prosthesis, usually within 3 weeks, the facial appearance returns to normal. Initial instructions for care of the prosthesis are given by the ocularist who manufactures and fits the device.

Care of the socket is minimal and easily accomplished. The wound itself is clean and has little or no drainage. If an antibiotic ointment is prescribed, it is applied in a thin line on the surface of the tissues of the socket. To cleanse the site, an irrigating solution

may be ordered and is instilled daily or more frequently *before* application of the antibiotic ointment. The dressing, consisting of an eye pad taped over the surgical site, is changed daily. After the socket has healed completely, a dressing is no longer necessary, although it is a preventive measure against infection.

Autism Spectrum Disorders

Autism spectrum disorders (ASDs) are complex neurodevelopmental disorders of unknown etiology composed of qualitative alterations in social interaction and verbal impairment with repetitive, restricted, and stereotype behavioral patterns (American Psychiatric Association, 2013; Amin, Smith, and Wang, 2011; Grynszpan, Nadel, Constant, et al., 2011).

ASD impairments range from mild to severe (Johnson, 2008). ASD is manifested during early childhood, primarily from 18 to 36 months of age. It occurs in one in 100 to 150 children in United States; is about 4 times more common in boys than in girls (although girls are more severely affected); and is not related to socioeconomic level, race, or parenting style (Centers for Disease Control and Prevention, 2009; Johnson, 2008; Shah, Dalton, and Boris, 2007).

Etiology

The cause of ASD is unknown. Researchers are investigating a number of theories, including a link between hereditary, genetics, and medical problems. Immune and environmental factors (e.g., viral infections) may interact with the genetic susceptibility to increase the incidence of ASD (Bloom-DiCicco, Lord, Zwaigenbaum, et al., 2006). Individuals with ASD may have abnormal electroencephalograms, epileptic seizures, delayed development of hand dominance, persistence of primitive reflexes, metabolic abnormalities (elevated blood serotonin), cerebellar vermal hypoplasia (part of the brain involved in regulating motion and some aspects of memory), and infantile abnormal head enlargement (Dawson, 2007; Rutter, 2011).

The strong evidence for a genetic basis in twins is consistent with an autosomal recessive pattern of inheritance. Twin studies demonstrate a high concordance (60% to 96%) for monozygotic (identical) twins and less than 5% concordance for dizygotic (nonidentical) twins. In addition, between 5% and 16% of boys with ASD are positive for the fragile X chromosome (Clifford, Dissanayake, Bui, et al., 2007).

There is a relatively high risk of recurrence of ASD in families with one affected child (Rutter, 2011; Schaefer and Lutz, 2006; Yoder, Stone, and Walden, 2009). Several genes have been suggested as possible causative factors in ASD (Dawson, 2007; Kolevzon, Gross, and Reichenberg, 2007).

The scientific evidence to date supports that there is no link between measles, mumps, and rubella (MMR) and thimerosal-containing vaccines and ASDs (Price, Thompson, Goodson, et al., 2010; Schultz, 2010) (see Evidence-Based Practice box). ASD has been reported in association with a number of conditions such as fragile X syndrome, tuberous sclerosis, metabolic disorders, fetal rubella syndrome, *Haemophilus influenzae* meningitis, and structural brain anomalies (Dawson, 2007). Recent reports have retrospectively tied ASD to prenatal and perinatal events such as maternal and paternal ages over 40 years (for fathers, one in 116 births; for mothers, one in 123 births), uterine bleeding during pregnancy, low Apgar score, fetal distress, and neonatal hyperbilirubinemia (Amin, Smith, and Wang, 2011; Croen, Najjar, Fireman, et al., 2007; Kolevzon, Gross, and Reichenberg, 2007; Rutter, 2011). However, these same researchers urge caution in interpreting these findings.

Clinical Manifestations and Diagnostic Evaluation

Children with ASD demonstrate several peculiar and often seemingly bizarre characteristics, primarily in social interactions, communication, and behavior. One hallmark characteristic is the inability to maintain eye contact with another person. Parents of autistic children have noted that their infants had difficulties with eye contact, avoidance of body contact, and language delay at a very early age (Belschner, 2007; Golnik and Maccabee-Ryaboy, 2010; Kirchner, Hatri, Heekeren, et al., 2011). Children with ASD also display limited functional play and may interact with toys in an unusual or odd manner (Belschner, 2007). They may have significant gastrointestinal symptoms. Constipation is a common symptom and can be associated with acquired megarectum in children with ASD (Buie, Campbell, Fuchs, et al., 2010). Other clinical manifestations typically seen in children with autism are described in Box 37-8.

Children with autism do not always have the same manifestations, from mild forms requiring minimal supervision to severe forms in which self-abusive behavior is common. The majority (50% to 70%) of children with autism have some degree of CI, with scores typically in the moderate-to-severe range. More girls than boys tend to have very low intelligence scores. Despite their relatively moderate-to-severe disability, some children with autism (known as savants) excel in particular areas such as art, music, memory, mathematics, or perceptual skills such as puzzle building.

Speech and language delays are also common in children with ASD. Any child who does not display such language skills as babbling or gesturing by 12 months, single words by 16 months, and two-word phrases by 24 months is recommended for immediate hearing and language evaluation. A sudden deterioration in extant expressive speech is also a red-flag event for further evaluation.

Early recognition, referral, diagnosis, and intensive early intervention tend to improve outcomes for children with ASD (Dawson, Rogers, Munson, et al., 2009; Golnik and Maccabee-Ryaboy, 2010; Zwaigenbaum, 2010). Unfortunately diagnosis is often not made until 2 to 3 years after symptoms are first recognized, which is based on the diagnostic criteria of *Diagnostic and Statistical Manual of Mental Disorders (DSM-5-TR)* (see Box 37-8).

! NURSING ALERT

Claims of beneficial results from the use of secretin, a peptide hormone that stimulates pancreatic secretion, have not been substantiated by scientific study (Shah, Dalton, and Boris, 2007; Welch, Ludwig, Opler, et al., 2006).*

Prognosis

ASD is usually a severely disabling condition. However, some children improve with acquisition of language skills and communication with others (Golnik and Maccabee-Ryaboy, 2010; Zwaigenbaum, 2010). Some ultimately achieve independence, but most require lifelong adult supervision. Aggravation of psychiatric symptoms occurs in about half of the children during adolescence, with girls having a tendency for continued deterioration.

Early recognition of behaviors associated with ASD is critical to implement appropriate interventions and family involvement. The prognosis is most favorable for children with higher intelligence, functional speech, and less behavioral impairment (Shah, Dalton, and Boris, 2007; Solomon, Buaminger, and Rogers, 2011).

*Additional information on secretin may be found by contacting the Autism Society, 4340 East-West Hwy., Suite 350, Bethesda, MD 20814-3067, 800-3AUTISM or 301-657-0881, www.autism-society.org.

EVIDENCE-BASED PRACTICE

Thimerosal-Containing Vaccines and Autism Spectrum Disorders

Ask the Question

Is the incidence of ASDs increased in children receiving vaccines containing thimerosal?

Search for Evidence

Search Strategies

Search selection criteria included English language, publication within the past 8 years, research-based articles, and infant and child populations.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Vaccine Adverse Events Reporting System (VAERS) database, American Academy of Pediatrics, Autism Research Institute

Critically Analyze the Evidence

- Evidence does not support an association between autism and mercury exposure from the pharmaceutical preservative thimerosal use in vaccinations until 2001.
- A Cochrane systematic review of 31 studies evaluating trivalent MMR in healthy individuals up to 15 years of age found no evidence that MMR is associated with autism (Demicheli, Jefferson, Rivetti, et al., 2005). Two other reviews reached similar conclusions. An additional two reviews found no evidence to support an association between autism disorders and thimerosal-containing vaccines (Parker, Schwartz, Todd, et al., 2004; Schultz, 2010).
- Two large studies in Europe found no evidence that childhood vaccination with thimerosal-containing vaccines was associated with the development of ASDs. One longitudinal study evaluated more than 14,000 children in the United Kingdom. The mercury exposure from thimerosal-containing vaccines was recorded and calculated at ages 3, 4, and 6 months and compared with cognitive and behavioral-developmental assessments performed from 6 to 91 months of age (Heron, Golding, and the ALSPAC study team, 2004). The second study, a cohort of 467,450 children in Denmark, compared the incidence of ASDs in children vaccinated with thimerosal-containing vaccines with that of ASDs in children vaccinated with a thimerosal-free formulation of the same vaccine.
- Smaller case-control studies have also found no relationships between childhood vaccination with thimerosal-containing vaccines and the development of ASDs (Baird, Pickles, Simonoff, et al., 2007; Hviid, Stellfeld, Wohlfahrt, et al., 2003; Price, Thompson, Goodson, et al., 2010).
- In 2004 the Institute of Medicine (2004) completed an update to the review of the evidence and concluded that the epidemiologic evidence supports the rejection of a causal relationship between thimerosal exposure from childhood vaccines and the onset of autism. Based on guidelines established by the U.S. Food and Drug Administration (2010) and other government monitoring agencies, no children will be exposed to excessive mercury from childhood vaccines.

Apply the Evidence: Nursing Implications

There is *good evidence with strong recommendations* (Guyatt, Oxman, Vist, et al., 2008) published that there is no link between vaccines containing thimerosal and autism or other neurodevelopmental disorders.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Compare research summaries that provide evidence of the lack of association between vaccines containing thimerosal and autism or other neurodevelopmental disorders.

Skills

Integrate evidence into practice by sharing results with parents regarding the benefits of vaccinating their children and the evidence regarding lack of association between immunizations and autism disorders.

Attitudes

Appreciate strengths and weakness of the evidence that confirms the lack of a link between vaccines containing thimerosal and autism or other neurodevelopmental disorders.

CARE MANAGEMENT

Therapeutic intervention for children with ASD is a specialized area involving professionals with advanced training. Although there is no cure for ASD, numerous therapies have been used. The most promising results have been through highly structured and intensive behavior modification programs. In general the objective in treatment is to promote positive reinforcement, increase social awareness of others, teach verbal communication skills, and decrease unacceptable behavior. Providing a structured routine for the child to follow is a key in the management of ASD.

BOX 37-8 DIAGNOSTIC CRITERIA FOR AUTISM SPECTRUM DISORDERS

A. A total of six (or more) items from 1, 2, and 3, with at least two from 1 and one each from 2 and 3:
   1. Qualitative impairment in social interaction as manifested by at least two of the following:
      (a) Marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction
      (b) Failure to develop peer relationships appropriate to developmental level
      (c) Lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, pointing out objects of interest)
      (d) Lack of social or emotional reciprocity
   2. Qualitative impairments in communication as manifested by at least one of the following:
      (a) Delay in or total lack of the development of spoken language (not accompanied by an attempt to compensate through alternative modes of communication such as gestures or mime)
      (b) In individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others
      (c) Stereotyped and repetitive use of language or idiosyncratic language
      (d) Lack of varied, spontaneous make-believe play or social imitative play appropriate to developmental level
   3. Restricted repetitive and stereotyped patterns of behavior, interests, and activities as manifested by at least one of the following:
      (a) Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus
      (b) Apparently inflexible adherence to specific, nonfunctional routines or rituals
      (c) Stereotyped and repetitive motor mannerisms (e.g., hand or finger flapping or twisting, complex whole-body movements)
      (d) Persistent preoccupation with parts of objects

B. Delays or abnormal functioning in at least one of the following areas, with onset before age 3 years: (1) social interaction, (2) language as used in social communication, or (3) symbolic or imaginative play.

C. The disturbance is not better accounted for by Rett disorder or childhood disintegrative disorder.

When these children are hospitalized, the parents are essential to planning care and ideally should stay with the child as much as possible. Nurses should recognize that not all children with ASD are the same and require individual assessment and treatment. Decreasing stimulation by using a private room, avoiding extraneous auditory and visual distractions, and encouraging the parents to bring in possessions to which the child is attached may lessen the disruptiveness of hospitalization. Because physical contact often upsets these children, minimum holding and eye contact may be necessary to avoid behavioral outbursts. Care must be taken when performing procedures on, administering medicine to, and feeding these children because they may be either fussy eaters who willfully starve themselves or gag to prevent eating or indiscriminate hoarders, swallowing any available edible or inedible items such as a thermometer. Eating habits of ASD children may be particularly problematic for families and may involve food refusal accompanied by mineral deficiencies, mouthing objects, eating nonedibles, and smelling and throwing food (Belschner, 2007; Caronna, Augustyn, and Zuckerman, 2007; Herndon, DiGuiseppi, Johnson et al., 2009).

Children with ASD need to be introduced to new situations slowly, with visits with staff caregivers kept short whenever possible. Because these children have difficulty organizing their behavior and redirecting their energy, they need to be told directly what to do. Communication should be at the child's developmental level, brief, and concrete.

Family Support

As with so many other chronic conditions, ASD involves the entire family and often becomes "a family disease." Nurses can help alleviate the guilt and shame often associated with this disorder by stressing what is known from a biologic standpoint and providing family support. It is imperative to help parents understand that they are not the cause of the child's condition.

Parents need expert counseling early in the course of the disorder and should be referred to the Autism Society website.* The society provides information about education, treatment programs and techniques, and facilities such as camps and group homes. Other helpful resources for parents of children with ASD are the local and state departments of mental health and developmental disabilities; these organizations provide important programs and in-school programs throughout the United States for children with ASD.

As much as possible the family is encouraged to care for the child in the home. With the help of family support programs in many states, families are often able to provide home care and assist with the educational services the child needs. As the child approaches adulthood and the parents become older, the family may require assistance in locating a long-term placement facility.

*See footnote on p. 1104.

KEY POINTS

- The AAIDD defines *intellectual disability* as significantly subaverage general intellectual functioning existing concurrently with deficits in adaptive behavior and manifested during the developmental period.
- Causes of severe CI are primarily genetic, biochemical, and infectious. Mild CI is associated primarily with familial, social, and environmental causes; severe CI is more likely to be associated with specific syndromes.
- Education of children with CI emphasizes sensory and verbal discrimination, improvement of short-term memory, motivation, and technologic support.
- Optimal development may be promoted through family guidance regarding play, communication, discipline, socialization, and sexuality.
- Prevention of CI focuses on support for preterm neonates and other high-risk newborns, rubella immunization, genetic

counseling, and maternal education regarding the risks of chemical use (e.g., alcohol ingestion) and the importance of adequate nutrition.
- Down syndrome, a chromosome abnormality, is characterized by mild-to-moderate range of CI (most often), physical characteristics, slowed language development, congenital anomalies, sensory problems, and diminished growth and sexual development.
- Fragile X syndrome is characterized by CI and phenotypic findings in affected boys. It is considered the most common hereditary cause and the second leading chromosomal cause of CI after Down syndrome.
- Hearing disorders may be classified according to the location of the defect: conductive, sensorineural, mixed conductive-sensorineural, and central auditory imperception.
- Rehabilitation for hearing loss involves parent education and support, hearing aids, lipreading, sign language, speech therapy, and promotion of socialization.
- Prevention of hearing loss includes treatment of infection, universal newborn screening and child auditory testing, immunization, pregnancy and genetic counseling, and reduction of noise pollution.
- Common visual impairments in childhood include refractive errors, amblyopia, strabismus, cataracts, glaucoma, trauma, and infections.
- Prevention of visual impairment focuses on prenatal screening, prenatal and perinatal care, periodic vision screening, immunization, and safety counseling.
- Nursing goals in visual rehabilitation include helping the family and child adjust to the child's visual impairment, promoting parent-child attachment, fostering optimal development and independence, providing for play and socialization, and being aware of educational facilities.
- For a child undergoing ocular surgery, nursing care is aimed at reassuring the child and family throughout treatment, orienting the child to the surroundings, providing a safe environment, and encouraging independence.
- Retinoblastoma is a rare congenital malignant tumor; its most common clinical manifestations are white pupil reflex and strabismus.
- ASDs are a complex neurodevelopmental disorder of brain function accompanied by a broad range and severity of intellectual and behavioral deficits.

CHAPTER

38

Family-Centered Care of the Child During Illness and Hospitalization

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify the stressors of illness and hospitalization for children during each developmental stage.
- List essential priorities of nursing care on a child's admission to the hospital.
- Review nursing interventions that prevent or minimize the stress of separation during hospitalization.
- Discuss nursing interventions that minimize the stress of loss of control during hospitalization.
- Describe nursing interventions that minimize the fear of bodily injury during hospitalization.
- Outline nursing interventions that support parents, siblings, and family during a child's illness and hospitalization.
- Describe nursing interventions needed when children are admitted to special units such as the emergency department.

STRESSORS OF HOSPITALIZATION AND CHILDREN'S REACTIONS

Often illness and hospitalization are the first crises children must face. Especially during the early years, children are particularly vulnerable to these stressors because (1) stress represents a change from the usual state of health and environmental routine, and (2) children have a limited number of coping mechanisms to resolve stressors. Major stressors of hospitalization include separation, loss of control, bodily injury, and pain. Children's reactions to these crises are influenced by their developmental age; their previous experience with illness, separation, or hospitalization; their innate and acquired coping skills; the seriousness of the diagnosis; and the support system available. Children also expressed fears caused by the unfamiliar environment or lack of information; child-staff relations; and the physical, social, and symbolic environment (Samela, Salanterä, and Aronen, 2009).

Separation Anxiety

The major stress from middle infancy throughout the preschool years, especially for children ages 6 to 30 months, is separation anxiety, also called anaclitic depression. The principal behavioral responses to this stressor during early childhood are summarized in Box 38-1. During the stage of protest, children react aggressively to the separation from the parent. They cry and scream for their parents, refuse the attention of anyone else, and are inconsolable in their grief (Fig. 38-1). In contrast, through the stage of despair, the crying stops, and depression is evident. The child is much less active, is uninterested in play or food, and withdraws from others (Fig. 38-2).

The third stage is detachment, also called denial. Superficially it appears that the child has finally adjusted to the loss. He or she becomes more interested in the surroundings, plays with others, and seems to form new relationships. However, this behavior is the result of resignation and is not a sign of contentment. The child detaches from the parent in an effort to escape the emotional pain of desiring the parent's presence and copes by forming shallow relationships with others, becoming increasingly self-centered, and attaching primary importance to material objects. This is the most serious stage because reversal of the potential adverse effects is less likely to occur after detachment is established. However, in most situations the temporary separations imposed by hospitalization do not cause such prolonged parental absences that the child enters into detachment. In addition, considerable evidence suggests that, even with stressors such as separation, children are remarkably adaptable, and permanent ill effects are rare.

Although progression to the stage of detachment is uncommon, the initial stages are observed frequently, even with brief separations from either parent. Unless health team members understand the meaning of each stage of behavior, they may erroneously label the

BOX 38-1 MANIFESTATIONS OF SEPARATION ANXIETY IN YOUNG CHILDREN

Stage of Protest

- Behaviors observed during later infancy include the following:
  - Cries
  - Screams
  - Searches for parent with eyes
  - Clings to parent
  - Avoids and rejects contact with strangers
- Additional behaviors observed during toddlerhood include the following:
  - Verbally attacks strangers (e.g., "Go away")
  - Physically attacks strangers (e.g., kicks, bites, hits, pinches)
  - Attempts to escape to find parent
  - Attempts to physically force parent to stay
- Behaviors may last from hours to days.
- Protest such as crying may be continuous, ceasing only with physical exhaustion.
- Approach of stranger may precipitate increased protest.

Stage of Despair

- Observed behaviors include the following:
  - Is inactive
  - Withdraws from others
  - Is depressed, sad
  - Lacks interest in environment
  - Is uncommunicative
  - Regresses to earlier behavior (e.g., thumb sucking, bed-wetting, use of pacifier, use of bottle)
- Behaviors may last for variable length of time.
- Child's physical condition may deteriorate from refusal to eat, drink, or move.

Stage of Detachment

- Observed behaviors include the following:
  - Shows increased interest in surroundings
  - Interacts with strangers or familiar caregivers
  - Forms new but superficial relationships
  - Appears happy
- Detachment usually occurs after prolonged separation from parent; it is rarely seen in hospitalized children.
- Behaviors represent a superficial adjustment to loss.

FIG 38-1 In the protest phase of separation anxiety, children cry loudly and are inconsolable in their grief for the parent. (Courtesy James DeLeon, Texas Children's Hospital, Houston, TX.)

FIG 38-2 During the despair phase of separation anxiety, children are sad, lonely, and uninterested in food and play.

behaviors as positive or negative. For example, they may see the loud crying of the protest phase as "bad" behavior. Because the protests increase when a stranger approaches the child, they may interpret that reaction as meaning they should stay away. During the quiet, withdrawn phase of despair, health team members may think that the child is finally "settling in" to the new surroundings, and they may see the detachment behaviors as proof of a "positive adjustment." The faster this stage is reached, the more likely it is that the child will be regarded as the "ideal patient."

Because children seem to react "negatively" to visits by their parents, uninformed observers feel justified in restricting parental visiting privileges. For example, during the protest stage children outwardly do not appear happy to see their parents (Fig. 38-3). In fact, they may even cry louder. If they are depressed, they may reject their parents or begin to protest again. Often they cling to their parents in an effort to ensure their continued presence. Consequently such reactions may be regarded as "disturbing" the child's adjustment to the new surroundings. If the separation has progressed to the phase of detachment, children respond no differently to their parents than they would to any other person.

Such reactions are distressing to parents, who are unaware of their meaning. If parents are regarded as intruders, they see their absence as "beneficial" to the child's adjustment and recovery. They may respond to the child's behavior by staying for only short periods, visiting less frequently, or deceiving the child when it is time to leave. The result is a destructive cycle of misunderstanding and unmet needs.

Early Childhood

Separation anxiety is the greatest stress imposed by hospitalization during early childhood. If separation is avoided, young children have a tremendous capacity to withstand any other stress. During this age

FIG 38-3 Young children may appear withdrawn and sad even in the presence of a parent. (Courtesy E. Jacob, Texas Children's Hospital, Houston, TX.)

period the typical reactions just described are seen. However, children in the toddler stage demonstrate more goal-directed behaviors. For example, they may plead with the parents to stay and physically try to keep the parents with them or try to find parents who have left. They may demonstrate displeasure on the parents' return or departure by having temper tantrums; refusing to comply with the usual routines of mealtime, bedtime, or toileting; or regressing to more primitive levels of development. However, temper tantrums, bed-wetting, or other behaviors may also be expressions of anger, a physiologic response to stress, or symptoms of illness.

Because preschoolers are more secure interpersonally than toddlers, they can tolerate brief periods of separation from their parents and are more inclined to develop substitute trust in other significant adults. However, the stress of illness usually renders preschoolers less able to cope with separation; as a result they manifest many of the stage behaviors of separation anxiety, although in general the protest behaviors are more subtle and passive than those seen in younger children. Preschoolers may demonstrate separation anxiety by refusing to eat, experiencing difficulty in sleeping, crying quietly for their parents, continually asking when the parents will visit, or withdrawing from others. They may express anger indirectly by breaking their toys, hitting other children, or refusing to cooperate during usual self-care activities. Nurses need to be sensitive to these less obvious signs of separation anxiety to intervene appropriately.

Later Childhood and Adolescence

Previous research, usually based on adult recollections, indicated that the family does not play as important a role for school-age children as it does during the toddler and preschool years. However, in a recent study that asked children about their fears when hospitalized, children listed their greatest fears regarding hospitalization as being separated from family and friends, being in an unfamiliar environment, receiving investigations or treatments, and losing self-determination or choices (Coyne, 2006). In a qualitative study of children ages 5 to 9 years, children described hospitalization in stories that focused on being alone and feeling scared, angry, or sad. These children also described the need for protection and companionship while hospitalized (Wilson, Megel, Enenbach, et al., 2010).

Although school-age children are better able to cope with separation in general, the stress and often accompanying regression imposed by illness or hospitalization may increase their need for parental security and guidance. This is particularly true for young school-age children who have only recently left the safety of the home and are struggling with the crisis of school adjustment. Middle and late school-age children may react more to the separation from their usual activities and peers than to the absence of their parents. These children have a high level of physical and mental activity that frequently finds no suitable outlets in the hospital environment; and, even when they dislike school, they admit to missing its routine and worry that they will not be able to compete or "fit in" with their classmates when they return. Feelings of loneliness, boredom, isolation, and depression are common. Such reactions may occur more as a result of separation than of concern over the illness, treatment, or hospital setting.

School-age children may need and desire parental guidance or support from other adult figures but may be unable or unwilling to ask for it. Because the goal of attaining independence is so important to them, they are reluctant to seek help directly, fearing that they will appear weak, childish, or dependent. Cultural expectations to "act like a man" or "be brave and strong" weigh heavily on these children, especially boys, who tend to react to stress with stoicism, withdrawal, or passive acceptance. Often the need to express hostile, angry, or other negative feelings finds outlets in alternate ways such as irritability and aggression toward parents, withdrawal from hospital personnel, inability to relate to peers, rejection of siblings, or subsequent behavioral problems in school.

For adolescents separation from home and parents may produce varied emotions, ranging from difficulty coping to welcoming the event. However, loss of peer-group contact may pose a severe emotional threat because of loss of group status, inability to exert group control or leadership, and loss of group acceptance. Deviations within peer groups are poorly tolerated; and, although group members may express concern for the adolescent's illness or need for hospitalization, they continue their group activities, quickly filling the gap of the absent member. During the temporary separation from their usual group, ill adolescents may benefit from group associations with other hospitalized teens.

Effects of Hospitalization on the Child

Children may react to the stresses of hospitalization before admission, during hospitalization, and after discharge. A child's concept of illness is even more important than age and intellectual maturity in predicting the level of anxiety before hospitalization (Clatworthy, Simon, and Tiedeman, 1999). This may or may not be affected by the duration of the condition or prior hospitalizations; therefore nurses should avoid overestimating the illness concepts of children with prior medical experience (Box 38-2).

Individual Risk Factors

A number of risk factors make certain children more vulnerable than others to the stresses of hospitalization (Box 38-3). Rural children may exhibit significantly greater degrees of psychologic upset than urban children, possibly because urban children have opportunities to become familiar with a local hospital. Because separation is such an important issue surrounding hospitalization for young children, children who are active and strong willed tend to fare better when hospitalized than youngsters who are passive. Consequently nurses should be alert to children who passively accept all changes

BOX 38-2 POSTHOSPITAL BEHAVIORS IN CHILDREN

Young Children

- They show initial aloofness toward parents; this may last from a few minutes (most common) to a few days.
- This is frequently followed by dependency behaviors:
  - Tendency to cling to parents
  - Demands for parents' attention
  - Vigorous opposition to any separation (e.g., staying at preschool or with a babysitter)
- Other negative behaviors include the following:
  - New fears (e.g., nightmares)
  - Resistance to going to bed, night waking
  - Withdrawal and shyness
  - Hyperactivity
  - Temper tantrums
  - Food peculiarities
  - Attachment to blanket or toy
  - Regression in newly learned skills (e.g., self-toileting)

Older Children

- Negative behaviors include the following:
  - Emotional coldness followed by intense, demanding dependence on parents
  - Anger toward parents
  - Jealousy toward others (e.g., siblings)

BOX 38-3 RISK FACTORS THAT INCREASE CHILDREN'S VULNERABILITY TO THE STRESSES OF HOSPITALIZATION

- "Difficult" temperament
- Lack of fit between child and parent
- Age (especially between 6 months and 5 years)
- Male gender
- Below-average intelligence
- Multiple and continuing stresses (e.g., frequent hospitalizations)

and requests; these children may need more support than "oppositional" children.

The stressors of hospitalization may cause young children to experience short- and long-term negative outcomes. Adverse outcomes may be related to the length and number of admissions, multiple invasive procedures, and the parents' anxiety. Common responses include regression, separation anxiety, apathy, fears, and sleeping disturbances, especially for children younger than 7 years of age (Melnyk, 2000). Supportive practices such as family-centered care and frequent family visiting may lessen the detrimental effects of such admissions. Nurses should attempt to identify children at risk for poor coping strategies (Small, 2002).

Changes in the Pediatric Population

The pediatric population in hospitals has changed dramatically over the past two decades. With a growing trend toward shortened hospital stays and outpatient surgery, a greater percentage of the children hospitalized today have more serious and complex problems than those hospitalized in the past. Many of these children are fragile

BOX 38-4 FACTORS AFFECTING PARENTS' REACTIONS TO THEIR CHILD'S ILLNESS

- Seriousness of the threat to the child
- Previous experience with illness or hospitalization
- Medical procedures involved in diagnosis and treatment
- Available support systems
- Personal ego strengths
- Previous coping abilities
- Additional stresses on the family system
- Cultural and religious beliefs
- Communication patterns among family members

newborns and children with severe injuries or disabilities who have survived because of major technologic advances yet have been left with chronic or disabling conditions that require frequent and lengthy hospital stays. The nature of their conditions increases the likelihood that they will experience more invasive and traumatic procedures while they are hospitalized. These factors make them more vulnerable to the emotional consequences of hospitalization and result in their needs being significantly different from those of the short-term patients of the past (see Chapter 36 for further discussion on children with special needs). Most of these children are infants and toddlers, the age-group most vulnerable to the effects of hospitalization.

Concern in recent years has focused on the increasing length of hospitalization because of complex medical and nursing care, elusive diagnoses, and complicated psychosocial issues. Without special attention devoted to meeting children's psychosocial and developmental needs in the hospital environment, the detrimental consequences of prolonged hospitalization may be severe.

Beneficial Effects of Hospitalization

Although hospitalization can be and usually is stressful for children, it can also be beneficial. The most obvious benefit is the recovery from illness, but hospitalization also can present an opportunity for children to master stress and feel competent in their coping abilities. The hospital environment can provide children with new socialization experiences that can broaden their interpersonal relationships. The psychologic benefits need to be considered and maximized during hospitalization. Appropriate nursing strategies to achieve this goal are presented on pp. 1121-1122.

STRESSORS AND REACTIONS OF THE FAMILY OF THE CHILD WHO IS HOSPITALIZED

Parental Reactions

The crisis of childhood illness and hospitalization affects every member of the family. Parents' reactions to illness in their child depend on a variety of factors. Although one cannot predict which factors are most likely to influence their response, a number of variables have been identified (Box 38-4).

Recent research has identified common themes among parents whose children were hospitalized, including feeling an overall sense of helplessness, questioning the skills of staff, accepting the reality of hospitalization, needing to have information explained in simple language, dealing with fear, coping with uncertainty, and seeking reassurance from caregivers. This reassurance involves staff being compassionate, expressing concern for the child, and attending to detail in the child's care (Stranton, 2004).

Sibling Reactions

Siblings' reactions to a sister's or brother's illness or hospitalization are discussed in Chapter 36 and differ little when a child becomes temporarily ill. Siblings experience loneliness, fear, worry, anger, resentment, jealousy, and guilt. Illness may also result in children's loss of status within their family or social group. Various factors have been identified that influence the effects of the child's hospitalization on siblings. Although these factors are similar to those seen when a child has a chronic illness, Craft (1993) reported that the following factors regarding siblings are related specifically to the hospital experience and increase the effects on the sibling:

- Being younger and experiencing many changes
- Being cared for outside the home by care providers who are not relatives
- Receiving little information about their ill brother or sister
- Perceiving that their parents treat them differently compared with before their sibling's hospitalization

Parents are often unaware of the number of effects that siblings experience during the sick child's hospitalization and the benefit of simple interventions to minimize these effects such as explicit explanations about the illness and provisions for the siblings to remain at home. Sibling visitation is usually beneficial to the patient, sibling, and parent but should be evaluated on an individual basis. Siblings should be prepared for the visit with developmentally appropriate information and be given the opportunity to ask questions.

NURSING CARE OF THE CHILD WHO IS HOSPITALIZED

Preparation for Hospitalization

Children and families require individualized care to minimize the potential negative effects of hospitalization. One method that can decrease negative feelings and fear in children is preparation for hospitalization. The rationale for preparing children for the hospital experience and related procedures is based on the principle that a fear of the unknown (fantasy) exceeds fear of the known. When children do not have paralyzing fear with which to cope, they are able to direct their energies toward dealing with the other unavoidable stresses of hospitalization.

Although preparation for hospitalization is a common practice, there is no universal standard or program for all settings. The preparation process may be elaborate with tours, puppet shows, and playtime with miniature hospital equipment; it may involve the use of books, videos, or films; or it may be limited to a brief description of the major aspects of any hospital stay. No consensus exists on the timing of preparation. Some authorities recommend preparing children 4 to 7 years of age about 1 week in advance so they can assimilate the information and ask questions. For older children the time may be longer. However, for young children who may begin to fantasize about what they observed, 1 or 2 days before admission is sufficient time for anticipatory preparation. The length of the session should be tailored to the child's attention span (i.e., the younger the child, the shorter the program). The optimal approach is one that is individualized for each child and family.

Regardless of the specific type of program, all children, even those who have been hospitalized before, benefit from an introduction to the environment and routine of the unit. Sometimes it is not possible to prepare children and families for hospitalization such as in the event of sudden, acute illness. However, care should be taken to orient them to hospital routines, establish expectations, and allow for questions.

! NURSING ALERT

In many hospitals child life specialists (i.e., health care professionals with extensive knowledge of child growth and development and the special psychosocial needs of children who are hospitalized and their families) help prepare children for hospitalization, surgery, and procedures. Although the structure of a program may vary, depending on the size of the pediatric facility, the patient population, and the availability of ancillary services, the two primary program objectives for child life are consistent: (1) to reduce the stress and anxiety related to the hospitalization or health care–related experiences, and (2) to promote normal growth and development in the health care setting and at home (Thompson, 2009).

A collaborative effort among the nurse, child life specialist, and other members of the child's health care team helps ensure the best possible hospital experience for the child and family.

Admission Assessment

The nursing admission history refers to a systematic collection of data about the child and family that allows the nurse to plan individualized care. The nursing admission history presented in Box 38-5 is organized according to the Functional Health Patterns outlined by Gordon (2002) (see Nursing Diagnosis, Chapter 26). This assessment framework is a guideline for formulating nursing diagnoses. One of the main purposes of the history is to assess the child's usual health habits at home to promote a more normal environment in the hospital. Therefore questions related to activities of daily living in the nutritional-metabolic, elimination, sleep-rest, and activity-exercise patterns are a major part of the assessment. The questions found under the health perception–health management pattern are directed toward evaluation of the child's preparation for hospitalization and are key factors in determining whether additional preparation is needed. The questions included in the self-perception–self-concept and role-relationship patterns offer insight into the child's potential reaction to hospitalization, especially in terms of separation.

The nurse should also inquire about the use of any medications at home, including complementary medicine practices (Box 38-6). In a study of children with cancer, 42% had used alternative or complementary therapies simultaneously with or after conventional treatments (Fernandez, Pyesmany, and Stutzer, 1999). It is important that the use of any herbal or complementary therapy be noted in a preoperative assessment because of possible anesthesia or surgical complications related to herbal products (Flanagan, 2001) (see Critical Thinking Case Study).

In addition to completing the nursing admission history, nurses should also perform a physical assessment (see Chapter 29) before planning care. At the very least the nurse's physical assessment of the child should include observation of the body for any bruises, rashes, signs of neglect, deformities, or physical limitations. The nurse should also listen to the heart and lungs to assess overall physical status. For example, it is impossible to evaluate improvement in respiratory function in a child admitted with pulmonary disease unless there are baseline data with which to compare subsequent findings.

Preparing the Child for Admission

The preparation that children require on the day of admission depends on the kind of prehospital counseling that they have received. If they have been prepared in a formalized program, they usually know what to expect in terms of initial medical procedures,

BOX 38-5 NURSING ADMISSION HISTORY ACCORDING TO FUNCTIONAL HEALTH PATTERNS*

Health Perception–Health Management Pattern

- Why has your child been admitted?
- How has your child's general health been?
- What does your child know about this hospitalization?
  - Ask the child why he or she came to the hospital.
  - If the answer is: "For an operation or for tests," ask the child to tell you about what will happen before, during, and after the operation or tests.
- Has your child ever been in the hospital before?
- How was that hospital experience?
- What things were important to you and your child during that hospitalization? How can we be most helpful now?
- What medications does your child take at home?
  - Why are they given?
  - When are they given?
  - How are they given (if a liquid, with a spoon; if a tablet, swallowed with water; or other)?
  - Does your child have any trouble taking medication? If so, what helps?
  - Is your child allergic to any medications?
- Which, if any, forms of complementary medicine practices are being used?

Nutrition–Metabolic Pattern

- What is the family's usual mealtime?
- Do family members eat together or at separate times?
- What are your child's favorite foods, beverages, and snacks?
  - Average amounts consumed or usual size of portions
  - Special cultural practices such as family eats only ethnic food
- Which foods and beverages does your child dislike?
- What are your child's feeding habits (bottle, cup, spoon, eats by self, needs assistance, any special devices)?
- How does your child like the food served (warmed, cold, one item at a time)?
- How would you describe your child's usual appetite (hearty eater, picky eater)?
- Has being sick affected your child's appetite? In what ways?
- Are there any known or suspected food allergies?
- Is your child on a special diet?
- Are there any feeding problems (excessive fussiness, spitting up, colic); any dental or gum problems that affect feeding?
  - What do you do for these problems?

Elimination Pattern

- What are your child's toileting habits (diaper, toilet trained—day only or day and night, use of word to communicate urination or defecation, potty chair, regular toilet, other routines)?
- What is your child's usual pattern of elimination (bowel movements)?
- Do you have any concerns about elimination (bed-wetting, constipation, diarrhea)?
  - What do you do for these problems?
- Have you ever noticed that your child sweats a lot?

Sleep-Rest Pattern

- What is your child's usual hour of sleep and awakening?
- What is your child's schedule for naps; length of naps?
- Is there a special routine before sleeping (bottle, drink of water, bedtime story, night-light, favorite blanket or toy, prayers)?
- Is there a special routine during sleep time such as waking to go to the bathroom?
- In which type of bed does your child sleep?
- Does your child have a separate room or share a room; if shares, with whom?
- Does your child sleep with someone or alone (e.g., sibling, parent, other person)?
- What is your child's favorite sleeping position?
- Are there any sleeping problems (falling asleep, waking during night, nightmares, sleep walking)?
- Are there any problems in awakening and getting ready in the morning?
  - What do you do for these problems?

Activity-Exercise Pattern

- What is your child's schedule during the day (preschool, day care center, regular school, extracurricular activities)?
- What are your child's favorite activities or toys (both active and quiet interests)?
- What is your child's usual television-viewing schedule at home?
- What are your child's favorite programs?
- Are there any television restrictions?
- Does your child have any illness or disabilities that limit activity? If so, how?
- What are your child's usual habits and schedule for bathing (bath in tub or shower, sponge bath, shampoo)?
- What are your child's dental habits (brushing, flossing, fluoride supplements or rinses, favorite toothpaste); schedule of daily dental care?
- Does your child need help with dressing or grooming such as hair combing?
- Are there any problems with these patterns (dislike of or refusal to bathe, shampoo hair, or brush teeth)?
  - What do you do for these problems?
- Are there special devices that your child requires help in managing (eyeglasses, contact lenses, hearing aid, orthodontic appliances, artificial elimination appliances, orthopedic devices)?
- NOTE: Use the following code to assess functional self-care level for feeding, bathing and hygiene, dressing and grooming, toileting:
  0—Full self-care
  I—Requires use of equipment or device
  II—Requires assistance or supervision from another person
  III—Requires assistance or supervision from another person and equipment or device
  IV—Is totally dependent and does not participate

Cognitive-Perceptual Pattern

- Does your child have any hearing difficulty?
  - Does your child use a hearing aid?
  - Have "tubes" been placed in your child's ears?
- Does your child have any vision problems?
  - Does your child wear glasses or contact lenses?
- Does your child have any learning difficulties?
- What is the child's grade in school?
- For information on pain see Chapter 30.

Self-Perception–Self-Concept Pattern

- How would you describe your child (e.g., takes time to adjust, settles in easily, shy, friendly, quiet, talkative, serious, playful, stubborn, easygoing)?
- What makes your child angry, annoyed, anxious, or sad? What helps?
- How does your child act when annoyed or upset?
- What have your child's experiences been with temporary separation from you (parent) and his or her reactions to it?

BOX 38-5 NURSING ADMISSION HISTORY ACCORDING TO FUNCTIONAL HEALTH PATTERNS*—cont'd

- Does your child have any fears (places, objects, animals, people, situations)?
  - How do you handle them?
- Do you think your child's illness has changed the way he or she thinks about himself or herself (e.g., more shy, embarrassed about appearance, less competitive with friends, stays at home more)?

Role-Relationship Pattern

- Does your child have a favorite nickname?
- What are the names of other family members or others who live in the home (relatives, friends, pets)?
- Who usually takes care of your child during the day and night (especially if other than parent such as babysitter, relative)?
- What are the parents' occupations and work schedules?
- Are there any special family considerations (adoption, foster child, stepparent, divorce, single parent)?
- Have any major changes in the family occurred lately (death, divorce, separation, birth of a sibling, loss of a job, financial strain, mother beginning a career, other)? Describe child's reaction.
- Who are your child's play companions or social groups (peers, younger or older children, adults, or prefers to be alone)?
- Do things generally go well for your child in school or with friends?
- Does your child have "security" objects at home (pacifier, bottle, blanket, stuffed animal or doll)? Did you bring any of these to the hospital?
- How do you handle discipline problems at home? Are these methods always effective?
- Does your child have any condition that interferes with communication? If so, what are your suggestions for communicating with your child?
- Will your child's hospitalization affect the family's financial support or care of other family members (e.g., other children)?
- What concerns do you have about your child's illness and hospitalization?
- Who will be staying with your child while hospitalized?
- How can we contact you or another close family member outside of the hospital?

Sexuality-Reproductive Pattern

(Answer questions that apply to your child's age-group.)

- Has your child begun puberty (developing physical sexual characteristics, menstruation)? Have you or your child had any concerns?
- Does your daughter know how to do breast self-examination?
- Does your son know how to do testicular self-examination?
- How have you approached topics of sexuality with your child?
- Do you think you might need some help with some topics?
- Has your child's illness affected the way he or she feels about being a boy or a girl? If so, how?
- Do you have any concerns with behaviors in your child such as masturbation, asking many questions or talking about sex, not respecting others' privacy, or wanting too much privacy?
- Initiate a conversation about an adolescent's sexual concerns with open-ended to more direct questions, using the terms "friends" or "partners" rather than "girlfriend" or "boyfriend":
  - Tell me about your social life.
  - Who are your closest friends? (If one friend is identified, could ask more about that relationship such as how much time they spend together, how serious they are about each other, if the relationship is going the way the teenager hoped.)
  - Might ask about dating and sexual issues such as the teenager's views on sexuality education, "going steady," "living together," or premarital sex.
  - Which friends would you like to have visit in the hospital?

Coping–Stress Tolerance Pattern

(Answer questions that apply to your child's age-group.)

- What does your child do when tired or upset?
  - If upset, does your child want a special person or object?
  - If so, explain.
- If your child has temper tantrums, what causes them, and how do you handle them?
- To whom does your child talk when worried about something?
- How does your child usually handle problems or disappointments?
- Have there been any big changes or problems in your family recently? If so, how have you handled them?
- Has your child ever had a problem with drugs or alcohol or tried to commit suicide?
- Do you think your child is "accident prone?" If so, explain.

Value-Belief Pattern

- What is your religion?
- How is religion or faith important in your child's life?
- Which religious practices would you like continued in the hospital (e.g., prayers before meals or bedtime; visit by minister, priest, or rabbi; prayer group)?

*The focus of the admission history is the child's psychosocial environment. Most of the questions are worded in terms of parental responses. Depending on the child's age, they should be addressed directly to the child when appropriate.

inpatient facilities, and nursing staff. However, prehospital counseling does not preclude the need for support during procedures such as obtaining blood specimens, x-ray film tests, or physical examination. For example, undressing young children before they feel comfortable in their new surroundings can be upsetting. Causing needless anxiety and fear during admission may adversely affect the nurse's establishment of trust with these children. Therefore nursing assistance during the admission procedure is vital regardless of how well prepared any child is for the experience of hospitalization. In addition, spending this time with the child gives the nurse an opportunity to evaluate his or her understanding of subsequent procedures (Fig. 38-4). Ideally a primary nurse is assigned whenever possible to allow for individualized care and provide a substitute support person for the child.

When a child is admitted, nurses follow several fairly universal admission procedures (Box 38-7). The minimum considerations for room assignment are age, sex, and nature of the illness. No absolute rules govern room selection, but in general placing children of the same age-group and with similar types of illness in the same room is both psychologically and medically advantageous. However, there are many exceptions. For example, a child in traction may be therapeutic for another child confined to bed because of a serious illness. A child who is independent despite physical disabilities may help another child with similar or different limitations, and the parents of the child with disabilities may achieve deeper insight and acceptance of their child's disorder.

Age-grouping is especially important for adolescents. Many hospitals make an effort to place teenagers on their own unit or in a

BOX 38-6 COMPLEMENTARY MEDICINE PRACTICES AND EXAMPLES

Nutrition, diet, and lifestyle or behavioral health changes—Macrobiotics, megavitamins, diets, lifestyle modification, health risk reduction and health education, wellness

Mind-body control therapies—Biofeedback, relaxation, prayer therapy, guided imagery, hypnotherapy, music or sound therapy, massage, aromatherapy, education therapy

Traditional and ethnomedicine therapies—Acupuncture, ayurvedic medicine, herbal medicine, homeopathic medicine, Native American medicine, natural products, traditional Asian medicine

Structural manipulation and energetic therapies—Acupressure, chiropractic medicine, massage, reflexology, rolfing, therapeutic touch, Qi Gong

Pharmacologic and biologic therapies—Antioxidants, cell treatment, chelation therapy, metabolic therapy, oxidizing agents

Bioelectromagnetic therapies—Diagnostic and therapeutic application of electromagnetic fields (e.g., transcranial electrostimulation, neuromagnetic stimulation, electroacupuncture)

CRITICAL THINKING CASE STUDY

Complementary and Alternative Medicine

Maria, a 13-year-old Hispanic girl, has had severe nosebleeds. She is admitted to the hospital for a complete workup in an attempt to determine the cause. Her parents and grandparents have gathered around her bed. When you enter her room to begin admitting procedures, you notice an unusual scent. Maria's mother is rubbing the contents from an unfamiliar bottle of liquid on Maria. Meanwhile the grandmother is rubbing Maria's head. She is startled at your entry and drops something on the floor near your feet. You bend over to pick it up and discover that it is a penny.

1. Evidence—Is there sufficient evidence to draw any conclusions?
2. Assumptions—What are some underlying assumptions that may be drawn from the data about the following:
   a. Complementary or alternative medical remedies
   b. The role of ethnic or folk remedies in modern health care practice
   c. The nurse's role in cases in which alternative medicine is practiced (versus traditional medicine)
3. What implications and priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

separate designated section of the pediatric or general unit whenever possible.

Nursing Interventions

Preventing or Minimizing Separation

A primary nursing goal is to prevent separation, particularly in children younger than 5 years of age. Many hospitals have developed a system of family-centered care. This philosophy of care recognizes the integral role of the family in a child's life and acknowledges the family as an essential part of the child's care and illness experience. The family is considered to be partners in the care of the child (Smith and Conant Rees, 2000) (see Chapter 26). Family-centered care also supports the family by establishing priorities based on the needs and values of the family unit (Lewandowski and Tesler, 2003).

BOX 38-7 GUIDELINES FOR ADMISSION

Preadmission

- Assign a room based on developmental age, seriousness of diagnosis, communicability of illness, and projected length of stay.
- Prepare roommate(s) for the arrival of a new patient; when children are too young to benefit from this consideration, prepare parents.
- Prepare room for child and family with admission forms and equipment nearby to eliminate need to leave child.

Admission

- Introduce primary nurse to child and family.
- Orient child and family to inpatient facilities, especially to assigned room and unit; emphasize positive areas of pediatric unit.
  - *Room*—Explain call light, bed controls, television, bathroom, telephone, and so on.
  - *Unit*—Direct to playroom, desk, dining area, or other areas.
- Introduce family to roommate and his or her parents.
- Apply identification band to child's wrist, ankle, or both (if not already done).
- Explain hospital regulations and schedules (e.g., visiting hours, mealtimes, bedtime, limitations [give written information if available]).
- Perform nursing admission history (see Box 38-5).
- Take vital signs, blood pressure, height, and weight.
- Obtain specimens as needed and order needed laboratory work.
- Support child and assist practitioner with physical examination (for purposes of nursing assessment).

FIG 38-4 The initial admission procedures give the nurse an opportunity to get to know the child and assess his or her understanding of the hospital experience.

At the very least most hospitals welcome parents at any time. Many provide facilities such as a chair or bed for at least one person per child, unit kitchen privileges, and other amenities that create a welcoming atmosphere for parents. However, not all hospitals provide such amenities, and parents' own schedules may prevent

rooming-in. In such instances strategies to minimize the effects of separation must be implemented.

Nurses must have an appreciation of the child's separation behaviors. As discussed earlier, the phases of protest and despair are normal. The child is allowed to cry. Even if the child rejects strangers, the nurse provides support through physical presence. Presence is defined as spending time being physically close to the child while using a quiet tone of voice, appropriate choice of words, eye contact, and touch in ways that establish rapport and communicate empathy. If detachment behaviors are evident, the nurse maintains the child's contact with the parents by talking about them frequently; encouraging the child to remember them; and stressing the significance of their visits, telephone calls, or letters. The use of cellular phones can increase the contact between the hospitalized child and parents or other significant family members and friends. However, wireless technology devices may not be compatible with medical equipment, and use may be restricted in certain areas within the hospital.

Parental Absence During Infant Hospitalization

Familiar surroundings also increase the child's adjustment to separation. If the parents cannot stay with the child, they should leave favorite articles from home such as a blanket, toy, bottle, feeding utensil, or article of clothing with him or her. Because young children associate such inanimate objects with significant people, they gain comfort and reassurance from these possessions. They make the association that, if the parents left this, they will surely return. Placing an identification band on the toy lessens the chances of it being misplaced and provides a symbol that the toy is experiencing the same needs as the child. Other reminders of home include photographs and recordings of family members reading a story, singing a song, saying prayers before bedtime, relating events at home, or taking a "talking walk" through the home. These reminders can be played at lonely times such as on awakening or before sleeping. Some units allow pets to visit, which can have therapeutic benefits for a child. Older children also appreciate familiar articles from home, particularly photographs, a radio, a favorite toy or game, and their own pajamas. Often the importance of treasured objects to school-age children is overlooked or criticized. However, many school-age children have a special object to which they formed an attachment in early childhood. Therefore such treasured or transitional objects can help even older children feel more comfortable in a strange environment.

The strange sights, smells, and sounds in the hospital that are commonplace for the nurse can be frightening and confusing for children. It is important for the nurse to try to evaluate stimuli in the environment from the child's point of view (considering also what the child may see or hear happening to other patients) and make every effort to protect the child from frightening and unfamiliar sights, sounds, and equipment. The nurse should offer explanations or prepare the child for experiences that are unavoidable. Combining familiar or comforting sights with the unfamiliar can relieve much of the harshness of medical equipment.

Helping children maintain their usual contacts also minimizes the effects of separation imposed by hospitalization. This includes continuing school lessons during the illness and confinement, visiting with friends either directly or through letter writing or telephone calls, age-appropriate social media, and participating in stimulating projects whenever possible (Fig. 38-5). For extended hospitalizations youngsters enjoy personalizing the hospital room to make it "home" by decorating the walls with posters and cards, rearranging the furniture, and displaying a collection or hobby.

FIG 38-5 For extended hospitalizations, children enjoy doing projects to occupy time.

Minimizing Loss of Control

Feelings of loss of control result from separation, physical restriction, changed routines, enforced dependency, and magical thinking. Although some of these cannot be prevented, most can be minimized through individualized planning of nursing care.

Promoting Freedom of Movement. Younger children react most strenuously to any type of physical restriction or immobilization. Although temporary immobilization may be necessary for some interventions such as maintaining an intravenous line, most physical restriction can be prevented if the nurse gains the child's cooperation.

For young children, particularly infants and toddlers, preserving parent-child contact is the best means of decreasing the need for or stress of restraint. For example, almost the entire physical examination can be done in a parent's lap with the parent hugging the child for procedures such as an otoscopic examination. For painful procedures the nurse should assess the parents' preferences for helping, observing, or waiting outside the room.

Environmental factors may also restrict movement. Keeping children in cribs or play yards may not represent immobilization in a concrete sense, but it certainly limits sensory stimulation. Increasing mobility by transporting children in carriages, wheelchairs, carts, or wagons provides them with a sense of freedom.

In some cases physical restraint or isolation is necessary because of the child's medical diagnosis. In these cases the environment can be altered to increase sensory freedom (e.g., moving the bed toward the window; opening window shades; providing musical, visual, or tactile activities).

Maintaining the Child's Routine. Altered daily schedules and loss of rituals are particularly stressful for toddlers and early preschoolers and may increase the stress of separation. The nursing admission history provides a baseline for planning care around the child's usual home activities. A frequently neglected aspect of altered routines is the change in the child's daily activities. A typical child's day, especially during the school years, is structured with specific times for eating, dressing, going to school, playing, and sleeping. However, this time structure vanishes when the child is hospitalized. Although nurses have a set schedule, the child is frequently unaware of it, and the new schedules that are imposed may be rigid. For example, some units have uniform nap times and bedtimes for all children, but others allow children to stay up late at night. Many children obtain significantly less sleep in the hospital than at home;

Eric's Daily Schedule

7:30 AM	– Breakfast, morning bath	3:00 PM	– Tutor (M, W, F)
			– Study time (T, Th)
9:00	– Medications, dressing change	4:00	– Physical therapy
		5:30	– Dinner
11:00	– Physical therapy	9:00	– Medications, dressing change
12:00 PM	– Lunch		
		9:15	– Bedtime

FIG 38-6 Time structuring is an effective strategy for normalizing the hospital environment and increasing the child's sense of control.

the primary causes are a delay in sleep onset and early termination of sleep because of hospital routines. Not only are hours of sleep disrupted, but waking hours are spent in passive activities. For example, few institutions impose any limits on the amount of time the child spends watching television. This may lead to children's being less "tired" at bedtime and delay the onset of sleep.

One technique that can minimize the disruption in the child's routine is establishing a daily schedule. This approach is most suitable for noncritically ill school-age and adolescent children who have mastered the concept of time. It involves scheduling the child's day to include all the activities that are important to the child and nurse such as treatment procedures, schoolwork, exercise, television, playroom, and hobbies. Together the nurse, parent, and child then plan a daily schedule with times and activities written down (Fig. 38-6). This is left in the child's room, and a clock or watch is available for his or her use. Whenever possible a calendar is also constructed with special events such as favorite television programs, visits by friends or relatives, events in the playroom, and holidays or birthdays marked. If specific changes in treatment are expected (e.g., "beginning physical therapy in 2 days"), these are added.

! NURSING ALERT

Ask the young child to select or draw pictures or symbols to represent daily or weekly fun activities (e.g., favorite television programs, family visits, and playroom times). Draw a clock face with the hands of the clock depicting the time that each event will occur next to the child's representation. Have the child compare the clock on the schedule with a clock or watch in the room. When the two match, the child knows that it is time for a favorite activity.

Encouraging Independence. The dependent role of the hospitalized patient imposes tremendous feelings of loss on older children. Principal interventions should focus on respect for individuality and the opportunity for decision making. Although these sound simple, their efficacy lies with nurses who are flexible and tolerant. It is also important for the nurse to empower the patient while not feeling threatened by a sense of lessened control.

Enabling children's control involves helping them maintain independence and promoting the concept of self-care. Self-care refers to the practice of activities that individuals personally initiate and perform on their own behalf in maintaining life, health, and well-being (Orem, 2001). Although self-care is limited by the child's age and physical condition, most children beyond infancy can perform some activities with little or no help. Whenever possible, these activities are encouraged in the hospital. Other approaches include jointly planning care, time structuring, wearing street clothes, making choices in food selections and bedtime, continuing school activities, and rooming with an appropriate age mate.

BOX 38-8 BILL OF RIGHTS FOR CHILDREN AND TEENS

In this hospital you and your family have the right to:

- Respect and personal dignity.
- Care that supports you and your family.
- Information you can understand.
- Quality health care.
- Emotional support.
- Care that respects your need to grow, play, and learn.
- Make choices and decisions.

From Association for the Care of Children's Health: *A pediatric bill of rights*, Bethesda, MD, 1991, Author.

Promoting Understanding. Loss of control can occur from feelings of having too little influence on one's destiny or sensing overwhelming control or power over fate. Although preschoolers' cognitive abilities predispose them most to magical thinking and delusions of power, all children are vulnerable to misinterpreting causes for stresses such as illness and hospitalization.

Most children feel more in control when they know what to expect because the element of fear is reduced. Anticipatory preparation and provision of information help to lessen stress and increase understanding (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 39).

Informing children of their rights while hospitalized fosters greater understanding and may relieve some of the feelings of powerlessness that they typically experience. An increasing number of hospitals and organizations have developed a patient "bill of rights" that is prominently displayed throughout the hospital or presented to children and their families on admission (Box 38-8).

Preventing or Minimizing Fear of Bodily Injury

Beyond early infancy all children fear bodily injury from mutilation, bodily intrusion, body image change, disability, or death. In general preparation of children for painful procedures decreases their fears and increases cooperation. Modifying procedural techniques for children in each age-group also minimizes fear of bodily injury. For example, because toddlers and young preschoolers are traumatized by insertion of a rectal thermometer, axillary temperatures or temperatures taken with electronic or tympanic membrane devices can be substituted effectively. Whenever procedures are performed on young children, the most supportive intervention is to do the procedure as quickly as possible while maintaining parent-child contact.

Because of toddlers' and preschool children's poorly defined body boundaries, the use of bandages may be particularly helpful. For example, telling children that the bleeding will stop after the needle is removed does little to relieve their fears, but applying a small Band-Aid usually reassures them. The size of bandages is also significant to children in this age-group; the larger the bandage, the more importance is attached to the wound. Watching their surgical dressings become successively smaller is one way that young children can measure healing and improvement. Prematurely removing a dressing may cause these children considerable concern for their well-being. Specific pain management strategies are discussed in Chapter 30.

For children who fear mutilation of body parts, it is essential that the nurse repeatedly stress the reason for a procedure and evaluate

the child's understanding. For example, explaining cast removal to preschoolers may seem simple enough, but children's comprehension of the details may vary considerably from the explanation. Asking the child to draw a picture of what they foresee happening presents substantial evidence of how they perceive events.

Children may fear bodily injury from a great variety of sources. Imaging machines, strange equipment used for examination, unfamiliar rooms, and awkward positions can be perceived as potentially hazardous. In addition, thoughts and actions can be imagined sources of bodily damage. Therefore it is important to investigate imagined reasons, particularly of a sexual nature, for illness. Because children may fear revealing such thoughts, using techniques such as drawing or doll play may elicit previously undisclosed misconceptions.

Older children fear bodily injury of both internal and external origins. For example, school-age children are aware of the significance of the heart and may fear the actual operation as much as the pain, the stitches, and the possible scar. Adolescents may express concern about the actual procedure but be much more anxious over the resulting scar.

Children can grasp information only if it is presented on or close to their level of cognitive development. This necessitates an awareness of the words used to describe events or processes. For example, young children told that they are going to have a CAT (i.e., computed tomography [CT]) scan may wonder, "Will there be cats? Or something that scratches?" It is clearer to describe the procedure in simple terms and explain what the letters of the common name stand for. Therefore to prevent or alleviate fears nurses must be keenly aware of the medical terminology and vocabulary that they use every day.

When children are upset about their illness, their perception can be changed by (1) providing a somewhat different and less negative account of the disease, or (2) offering an explanation that is characteristic of the next stage of cognitive development. An example of the first strategy is reassuring a preschooler who fears that after a tonsillectomy another sore throat means a second operation. Explaining that after tonsils are "fixed" they do not need fixing again can help relieve the fear. An example of the latter strategy is to explain that germs made the tonsils sick but, even though germs can cause another sore throat, they cannot cause the tonsils to ever be sick again. This higher-level explanation is based on the school-age child's concept of germs as a cause of disease.

Providing Developmentally Appropriate Activities

A primary goal of nursing care for the child who is hospitalized is to minimize threats to the child's development. Many strategies (e.g., minimizing separation) have been discussed and may be all that the short-term patient requires. However, children who experience prolonged or repeated hospitalization are at greater risk for developmental delays or regression. The nurse who provides opportunities for the child to participate in developmentally appropriate activities further normalizes his or her environment and helps reduce interference with the child's ongoing development.

Interference with normal development may have long-term implications for developing infants and toddlers. The nurse plays a primary role in identifying children at risk and helping to plan, implement, and evaluate developmental intervention.

School is an integral part of the school-age child's and adolescent's development. Accreditation standards for hospitals serving children consider access to appropriate educational services to be a key factor in the accreditation decision process when a child's treatment requires a significant absence from school (The Joint Commission, 2011). The nurse can encourage children to resume schoolwork as quickly as their condition permits, help them schedule and protect a selected time for studies, and help the family coordinate hospital educational services with their children's schools. Children should have the opportunity to continue art and music classes and their academic subjects.

To meet the unique developmental needs of adolescents, special units may be developed that provide privacy, increased socialization, and appropriate activities for these young people. Typically these units can be set apart from the general pediatric facility so the teenagers do not share space with younger children, who are often perceived as a threat to their maturity.

In caring for adolescent patients it is essential to provide flexible routines and activities such as more group activity, wearing of street clothes, and access to the items so critical to adolescents (i.e., wireless technology devices, MP3 players, DVD players, computers, e-mail, electronic video game systems, and high-definition televisions). Because adolescents' food habits are rarely limited to the three traditional meals a day, a ready supply of snacks should be available. However, the most important benefit of these units is increased socialization with peers. In addition, staff members usually enjoy working with this age-group and are able to establish the trust that is so essential for communication.

! NURSING ALERT

When adolescents must share a common activity room with younger patients, referring to the area as the "activity" room rather than the "playroom" may entice them to visit the room and participate in activities.

Although regression is expected and normal for all age-groups, nurses are responsible for fostering the child's growth and development. Hospitalization can become a significant opportunity for learning and advancing. Extended hospitalizations for long-term chronic illness or situations of failure to thrive, abuse, or neglect represent instances in which regression must be seen as an adjustment period to be followed by plans for promoting appropriate developmental skills.

Providing Opportunities for Play and Expressive Activities

Play is one of the most important aspects of a child's life and one of the most effective tools for managing stress. Because illness and hospitalization constitute crises in a child's life and often involve overwhelming stresses, children need to act out their fears and anxieties as a means of coping with these stresses. Play is essential to children's mental, emotional, and social well-being; it doesn't stop when children are ill or in the hospital. On the contrary, play in the hospital serves many functions (Box 38-9). Of all hospital facilities, no room probably alleviates the stressors of hospitalization more than the playroom (or activity room). In the playroom children temporarily distance themselves from their illness, hospitalization, and the associated stressors. This room should be a safe haven for children, free from medical or nursing procedures (including medication administration), strange faces, and probing questions. The playroom becomes a sanctuary in an otherwise frightening environment.

Engaging in play activities gives children a sense of control. In the hospital environment most decisions are made for the child; play and other expressive activities offer the child much-needed opportunities to make choices for themselves. Even if a child chooses not to participate in a particular activity, the nurse has offered him or

BOX 38-9 FUNCTIONS OF PLAY IN THE HOSPITAL

- Provides diversion and brings about relaxation
- Helps the child feel more secure in a strange environment
- Lessens the stress of separation and the feeling of homesickness
- Provides a means for release of tension and expression of feelings
- Encourages interaction and development of positive attitudes toward others
- Provides an expressive outlet for creative ideas and interests
- Provides a means for accomplishing therapeutic goals (see Use of Play in Procedures, Chapter 39)
- Places child in active role and provides opportunity to make choices and be in control

FIG 38-7 Play materials for children in the hospital need to be appropriate for their age, interests, and limitations.

her a choice, perhaps one of only a few real choices the child has had that day.

Hospitalized children typically have lower energy levels than healthy children of the same age. Therefore children may not appear engaged and enthusiastic about an activity even though they are enjoying the experience. Activities may need to be adjusted or limited based on the child's age, endurance, and any special needs.

Diversional Activities. Almost any form of play can be used for diversion and recreation, but the activity should be selected on the basis of the child's age, interests, and limitations (Fig. 38-7). Children do not necessarily need special direction for using play materials. All they require are the raw materials with which to work and adult approval and supervision to help keep their natural enthusiasm or expression of feelings from getting out of control. Small children enjoy a variety of small, colorful toys with which they can play in bed or in their room or more elaborate play equipment such as playhouses, sandboxes, rhythm instruments, or large boxes and blocks that may be a part of the hospital playroom.

Games that can be played alone or with another child or an adult are popular with older children, as are puzzles; reading material; quiet, individual activities such as sewing, stringing beads, and weaving; and Lego blocks and other building materials. Assembling models is an excellent pastime, but one should make certain that all pieces and necessary materials are included in the package so the child is not disappointed and frustrated.

Well-selected books are of infinite value to children. Children never tire of stories; having someone read aloud gives them endless hours of pleasure and is of special value to children who have limited energy to expend in play. A radio, DVD player, electronic games, and television, included among most hospital room equipment, are useful tools for entertaining children. Computers with access to the Internet can provide diversion, educational opportunities, and online support groups.

When supervising play for ill or convalescent children, it is best to select activities that are simpler than would normally be chosen for the child's specific developmental level. These children usually do not have the energy to cope with more challenging activities. Other limitations also influence the type of activities. Special consideration must be given to children who are confined in terms of movement, have a restricted extremity, or are isolated. Toys for isolated children must be disposable or need to be disinfected after every use.

Toys. Parents of hospitalized children often ask nurses about the types of toys that would be best to bring for their child. Although they want to buy new toys for the hospitalized child to offer cheer and comfort, it is often better to wait to bring new things, especially in the case of younger children. Small children need the comfort and reassurance of familiar things such as the stuffed animal the child hugs for comfort and takes to bed at night. These familiar items are a link with home and the world outside the hospital. All toys brought into the hospital should be assessed for safety.

Large numbers of toys often confuse and frustrate small children. A few small, well-chosen toys are usually preferred to one large, expensive one. Children who are hospitalized for an extended time benefit from changes. Rather than a confusing accumulation of toys, older toys should be replaced periodically as interest wanes.

A highly successful diversion for a child who is hospitalized for a length of time and whose parents are unable to visit frequently is having the parents bring a box with several small, inexpensive, brightly wrapped items with a different day of the week printed on the outside of each package. The child will eagerly anticipate the time for opening each one. If the parents know when their next visit will be, they can provide the number of packages that corresponds to the time between visits. In this way the child knows that the diminishing packages also represent the anticipated visit from the parent.

Expressive Activities. Play and other expressive activities provide one of the best opportunities for encouraging emotional expression, including the safe release of anger and hostility. Nondirective play that allows children freedom for expression can be tremendously therapeutic. However, therapeutic play should not be confused with play therapy, a psychologic technique reserved for use by trained and qualified therapists as an interpretative method with emotionally disturbed children. On the other hand, therapeutic play is an effective, nondirective modality for helping children deal with their concerns and fears; at the same time it often helps the nurse gain insights into children's needs and feelings.

Tension release can be facilitated through almost any activity; with younger ambulatory children, large-muscle activity such as use of tricycles and wagons is especially beneficial. Much aggression can be safely directed into pounding and throwing games or activities. Beanbags are often thrown at a target or open receptacle with surprising vigor and hostility. A pounding board is used with enthusiasm by young children; clay and play dough are beneficial for use at any age.

Creative Expression. Although all children derive physical, social, emotional, and cognitive benefits from engaging in art and other creative activities, children's need for such activities is intensified when they are hospitalized. Drawing and painting are excellent media for expression. Children are more at ease expressing their

FIG 38-8 Drawing and painting are excellent media for expression.

thoughts and feelings through art because humans think first in images and later learn to translate these images into words. Children need only to be supplied with the raw materials such as crayons and paper, large brushes, an ample supply of newsprint supported on easels, or materials for finger painting (Fig. 38-8). They can work individually or together on a group project such as a mural painted on a long piece of paper.

Although interpretation of children's drawings requires special training, observing changes in a series of the child's drawings over time can be helpful in assessing psychosocial adjustment and coping. The nurse can use children's drawings, stories, poetry, and other products of creative expression as a springboard for discussion of thoughts, fears, and understanding of concepts or events (see Communication Techniques, Chapter 29). For example, a child's drawing before surgery may reveal unvoiced concerns about mutilation, body changes, and loss of self-control.

Nurses can incorporate opportunities for musical expression into routine nursing care. For example, simple musical instruments such as bracelets with bells can be placed on infants' legs for them to shake to accompany mealtime music or dressing changes. Dance and movement suggestions may encourage a child to ambulate.

Dramatic Play. Dramatic play is a well-recognized technique for emotional release, allowing children to reenact frightening or puzzling hospital experiences. Through use of puppets, replicas of hospital equipment, or actual hospital equipment, children can act out the situations that are a part of their hospital experience. Dramatic play enables children to learn about procedures and events that concern them and assume the roles of the adults in the hospital environment.

Puppets are universally effective for communicating with children. Most children see them as peers and readily communicate with them. Children will tell the puppet feelings that they hesitate to express to adults. Puppets can share children's own experiences and help them find solutions to their problems. Puppets dressed to represent figures in the child's environment (e.g., a health care provider, nurse, child patient, therapist, and members of the child's own family) are especially useful. Small, appropriately attired dolls are equally effective in encouraging the child to play out situations, although puppets are usually best for direct conversation.

CRITICAL THINKING CASE STUDY

Playroom and Hospital Procedures

Joel, an 8-year-old with cystic fibrosis, has been hospitalized numerous times with complications from the condition. He is playing a board game with his brother, sister, and several other children in the playroom on the pediatric unit. A pediatric phlebotomist enters the playroom and says, "Joel, I need to take some blood. I can see that you are playing a game, so I'll just do it while you play. It will just take a minute." The playroom is usually off limits for invasive procedures. As Joel's nurse you are aware that Dr. Lung wants the results of the laboratory studies as soon as possible to make a decision about the course of therapy.

1. Evidence—Is there sufficient evidence to draw any conclusions about this situation at this time?
2. Assumptions—What are some underlying assumptions about the following:
   a. Children and painful procedures such as venipunctures
   b. The function of play in a hospitalized child
   c. The priority in performing the procedure
   d. Implications of performing the procedure in the playroom
3. What implications and priorities for nursing care can be drawn at this time (i.e., what will you do)?
4. Does the evidence objectively support your argument (conclusion)?

Play must consider medical needs, but at times a procedure can be postponed briefly to allow the child to complete a special activity (see Critical Thinking Case Study). Play must consider any limitations imposed by the child's condition. For example, small children may eat paste and other creative media; therefore a child who is allergic to wheat should not be given finger paint made from wallpaper paste or modeling dough made with flour. A child on a restricted salt intake should not play with modeling dough because salt is one of its major constituents. At home the play program can be planned around the therapy regimen. However, play can be satisfactorily incorporated into the child's care if the nurse and others involved allow some flexibility and use creativity in planning for it.

Maximizing Potential Benefits of Hospitalization

Although hospitalization generally represents a stressful time for children and families, it also represents an opportunity for facilitating positive change within the child and among family members. For some families the stress of a child's illness, hospitalization, or both can lead to strengthening of family coping behaviors and the emergence of new coping strategies.

Fostering Parent-Child Relationships. The crisis of illness or hospitalization can mobilize parents into more acute awareness of their child's needs. For example, hospitalization provides opportunities for parents to learn more about their children's growth and development. When parents are helped to understand children's usual reactions to stress such as regression or aggression, not only are they better able to support the child through the hospital experience, but they also may extend their insights into childrearing practices after discharge.

Difficulties in parent-child relationships that existed before hospitalization (i.e., characterized by feeding problems, negative behavior, and sleep disturbances) may decrease during hospitalization. The temporary cessation of such problems sometimes alerts parents to the role that they may be playing in propagating the negative behavior. With help from health professionals, parents can

restructure ways of relating to their children to foster more positive behavior.

Hospitalization may also represent a temporary reprieve or refuge from a disturbed home. Typically abused or neglected children's dramatic physical and social improvement during hospitalization is proof of the benefits and potential growth that can occur during hospitalization. These children temporarily are able to seek support, reassurance, and security from new relationships, particularly with nurses and hospitalized peers.

Providing Educational Opportunities. Illness and hospitalization represent excellent opportunities for children and other family members to learn more about their bodies, one another, and the health professions. For example, during a hospital admission for a diabetic crisis the child may learn about the disease; the parents may learn about the child's needs for independence, normalcy, and appropriate limits; and each of them may find a new support system in the hospital staff.

Illness or hospitalization can also help older children choose a career. Frequently children have impressions of physicians or nurses that are disproportionately positive or negative. Actual experience with different health professionals can influence their attitude about them and even a decision regarding a career in health care.

Promoting Self-Mastery. The experience of facing a crisis such as illness or hospitalization, coping successfully with it, and maturing as a result of it constitutes an opportunity for self-mastery. Younger children have the chance to test fantasy-versus-reality fears. They realize that they were not abandoned, mutilated, or punished. In fact, they were loved, cared for, and treated with respect for their individual concerns. It is not unusual for children who have undergone hospitalization or surgery to tell others that "it was nothing" or to display proudly their scars or bandages. For older children hospitalization may represent an opportunity for decision making, independence, and self-reliance. They are proud of having survived the experience and may feel a genuine self-respect for their achievements. Nurses can facilitate such feelings of self-mastery by emphasizing aspects of personal competence in the child and not focusing on uncooperative or negative behavior.

Providing Socialization. Hospitalization may offer children a special opportunity for social acceptance. Lonely, asocial, and even delinquent children find a sympathetic environment in the hospital. Children who have a physical disability or are in some other way "different" from their age mates may find an accepting social peer group (Fig. 38-9). Although this does not always occur spontaneously, nurses can structure the environment to foster a supportive child group. For example, selection of a compatible roommate can help children gain a new friend and learn more about themselves. Forming relationships with significant members of the care team such as the health care provider, nurse, child life specialist, or social worker can greatly enhance children's adjustment in many areas of life.

Parents may also encounter a new social group in other parents who have similar problems. The waiting room or hallway "self-help" groups are inherent to every institution. Parents meet while in the hospital or clinic and discuss their children's illnesses and treatments. Nurses can capitalize on this informal gathering by encouraging parents to discuss collectively their concerns and feelings. They can also refer parents to organized parent groups or use the help and support of parents of recovered hospitalized patients. It is important that nurses emphasize to families that each child responds differently to disease, treatments, and care. Any questions raised during group discussions should be clarified with a nurse or health care provider.

FIG 38-9 Placing children of the same age-group with similar illnesses near one another on the unit is both psychologically and medically supportive. (Courtesy E. Jacob, Texas Children's Hospital, Houston, TX.)

NURSING CARE OF THE FAMILY

Although it is not possible to predict exactly which factors are most likely to have an effect on a family's reactions, important variables are (1) the seriousness of the child's illness, (2) the family's previous experience with hospitalization, and (3) the medical procedures involved in the diagnosis and treatment. Important information is also obtained in the nursing admission history (see Box 38-5).

Supporting Family Members

Support involves the willingness to stay and listen to parents' verbal and nonverbal messages. Sometimes the nurse does not give this support directly. For example, he or she may offer to stay with the child to allow the parents time alone or may discuss with other family members the parents' need for extra relief. Often relatives and friends want to help but do not know how. Suggesting ways such as babysitting, preparing meals, doing laundry, or transporting the siblings to school can prompt others to help reduce the responsibilities that burden parents.

Support may also be provided through the clergy. Parents with deep religious beliefs may appreciate the counsel of a clergy member; but, because of their stress, they may not have sufficient energy to initiate the contact. Nurses can be supportive by arranging for clergy to visit, upholding parents' religious beliefs, and respecting the individual meaning and significance of those beliefs (Feudtner, Haney, and Dimmers, 2003).

Support involves accepting cultural, socioeconomic, and ethnic values. For example, health and illness are defined differently by various ethnic groups. For some a disorder that has few outward manifestations of illness such as diabetes, hypertension, or cardiac problems is not a sickness. Consequently following a prescribed

FAMILY-CENTERED CARE

Supporting Siblings During Hospitalization

- Trade off staying at the hospital with spouse or have a surrogate who knows the siblings well stay in the home.
- Offer information about the child's condition to both young and older siblings; respect the sibling who avoids information as a means of coping with the situation.
- Arrange for children to visit their brother or sister in the hospital if possible.
- Encourage phone visits and mail between brothers and sisters; provide children with phone numbers, writing supplies, and stamps.
- Help each sibling identify an extended family member or friend to be his or her support person and provide extra attention during parental absence.
- Make or buy inexpensive toys or trinkets for siblings, one gift for each day the child will be hospitalized.
  - Wrap each gift separately and place them in a basket, box, or other container at the child's bedside.
  - Instruct siblings to open one gift at bedtime and to remember that he or she is in their parent's thoughts.
- If the child's condition is stable and distance is not prohibitive, plan a special time at home with the siblings or have spouse or another relative or friend bring the children to meet parent(s) at a restaurant or other location near the hospital.
  - Have extended family members or friends schedule a visit to the child in the hospital during parental absence.
  - Arrange a pass for the child to leave the hospital to join the family if his or her condition permits.

Modified from Craft M, Craft J: Perceived changes in siblings of hospitalized children: a comparison of sibling and parent reports, *Child Health Care* 18(1):42-48, 1989; Rollins J: *Brothers and sisters: a discussion guide for families*, Landover, MD, 1992, Epilepsy Foundation of America.

treatment may be seen as unnecessary. Nurses who appreciate the influences of culture are more likely to intervene therapeutically. (See also Cultural Influences, Chapter 27.)

Parents need help in accepting their own feelings toward the ill child. If given the opportunity, they often disclose their feelings of loss of control, anger, and guilt. They often resist admitting to such feelings because they expect others to disapprove of behavior that is less than perfect. Unfortunately health personnel, including nurses, sometimes do exercise little tolerance for deviation from the norm. This only increases the psychologic impact of a child's illness on family members. Helping parents identify the specific reason for such feelings and emphasizing that each is a normal, expected, and healthy response to stress may reduce the parents' emotional burden.

Family-centered care also addresses the needs of siblings. Support may involve preparing siblings for hospital visits, assessing their adjustment, and providing appropriate interventions or referrals when needed. The Family-Centered Care box suggests ways that parents can support siblings during hospitalization.

Providing Information

One of the most important nursing interventions is providing information about (1) the disease, its treatment, prognosis, and home care; (2) the child's emotional and physical reactions to illness and hospitalization; and (3) the probable emotional reactions of family members to the crisis.

For many families the child's illness is the first contact they have with the hospital experience. Often parents are not prepared for the child's behavioral reactions to hospitalization such as separation behaviors, regression, aggression, and hostility. Providing the parents with information about these normal and expected behavioral responses can lessen the parents' anxiety during the hospital admission. The family is equally unfamiliar with hospital rules, which often compounds their confusion and anxiety. Therefore they need clear explanations about what to expect and what is expected of them.

Parents also need to be aware of the effects of illness on the family and strategies that prevent negative changes. Specifically parents should keep the family well informed and communicate with everyone as much as possible. They should treat all the children equally and as normally as before the illness occurred. Discipline, which initially may be lessened for the ill child, should be continued to provide a measure of security and predictability. When ill children know that their parents expect certain standards of conduct from them, they feel certain that they will recover. Conversely, when all limits are removed, they fear that something catastrophic will happen.

Helping parents understand the meaning of posthospitalization behaviors in the sick child is necessary for them to tolerate and support such behaviors. In addition, parents should be forewarned of the common reactions after discharge (see Box 38-2). Parents who do not expect such reactions may misinterpret them as evidence of the child's "being spoiled" and demand perfect behavior at a time when the child is still reacting to the stress of illness and hospitalization. If the behaviors, especially the demand for attention, are dealt with in a supportive manner, most children are able to relinquish them and assume prior levels of functioning.

Nurses should also prepare parents for the reactions of siblings, particularly anger, jealousy, and resentment. Older siblings may deny such reactions because they provoke feelings of guilt. However, everyone needs outlets for emotions, and the repressed feelings may surface as problems in school or with age mates, as psychosomatic illnesses, or in delinquent behavior.

Probably one of the most neglected areas of communication involves giving information to siblings. Frequently age becomes the only factor that leads to an awareness of this problem because older children may begin to ask questions or request explanations. However, even in this situation the information may be seriously inadequate. Children in every age-group deserve some explanation of the sibling's illness or hospitalization. In addition, nurses can minimize a sibling's fear of also getting sick or having caused the illness.

Encouraging Parent Participation

Preventing or minimizing separation is a key nursing goal with the child who is hospitalized, but maintaining parent-child contact is also beneficial for the family. One of the best approaches is encouraging parents to stay with their child and participate in the care whenever possible. Although some health facilities provide special accommodations for parents, the concept of rooming-in can be instituted anywhere. The first requirement is the staff's positive attitude toward parents. A negative attitude toward parent participation can create barriers to collaborative working relationships.

When hospital staff genuinely appreciate the importance of continued parent-child attachment, they foster an environment that encourages parents to stay. When parents are included in the care planning and understand that they are a contributing factor to the child's recovery, they are more inclined to remain with their child

and have more emotional reserves to support themselves and the child through the crisis. An empowerment model of helping allows the nurse to focus on parents' strengths and seek ways to promote growth and family functioning so the parents become empowered in caring for their child. Strategies such as bedside reporting that allow parents to be involved in the discussion of the child's current status are moving health care settings closer to family-centered care (Anderson and Mangino, 2006). Liaison nursing roles in tertiary care settings are also focused on improving communication between parents and health care providers (Caffin, Linton, and Pellegrini, 2007).

Because the mother tends to be the usual family caregiver, she usually spends more time in the hospital than the father. However, not all parents feel equally comfortable assuming responsibility for their child's care. Some may be under such great emotional stress that they need a temporary reprieve from total participation in caregiving activities. Others may feel insecure in participating in specialized areas of care such as bathing the child after surgery. On the other hand, some mothers may feel a great need to control their child's care. This seems particularly true of young mothers who have recently established their role as a parent, mothers of children too young to verbalize their needs, and ethnic minority mothers when the hospital setting is predominantly staffed by nonminority personnel. Individual assessment of each parent's preferred involvement is necessary to prevent the effects of separation while supporting parents in their needs as well.

With lifestyles and gender roles changing, fathers may assume all or some of the usual "mothering" roles in the household. In these cases it may be the father-child relationship that needs to be preserved. Fathers need to be included in the care plan and respected for their parental role. For some fathers the child's hospitalization may represent an opportunity to alter their usual caregiving role and increase their involvement. In single-parent families the caregiver may not be a parent but an extended family member such as a grandparent or aunt.

One of the potential problems with continuous parent involvement is neglect of the parent's need for sleep, nutrition, and relaxation. Often the sleeping accommodations are limited to a chair, and sleep is disrupted by nursing procedures. Encouraging the parents to leave for brief periods, arranging for sleeping quarters on the unit but outside the child's room, and planning a schedule of alternating visits with another family member can minimize the stresses for the parent.

All too often nurses respond to parent participation by abandoning their patient responsibilities. They need to restructure their roles to complement and augment the caregiving functions of parents (Hopia, Tomlinson, Paavilainen, et al., 2005). Even in units structured to provide care by parents, parents frequently feel anxiety in their caregiving responsibilities; those more involved in direct care may feel more anxiety than those less involved. Therefore 24-hour responsibility may be too much for some parents. Assistance and relief by nursing personnel should always be available to these families, and nurses may need to work diligently to establish the strong bond of trust that some parents need to take advantage of these opportunities.

Preparing for Discharge and Home Care

Most hospitalizations necessitate some type of discharge preparation. Often this involves education of the family for continued care and follow-up in the home. Depending on the diagnosis, this may be relatively simple or highly complex. Preparing the family for home care demands a high degree of competence in planning and implementing discharge instructions.

Nurses are often key individuals in initiating and carrying out the discharge process. They collaborate with others in the planning and implementation phases to ensure appropriate care after hospitalization. Throughout the hospitalization the nurse should be aware of the need for discharge planning and the assessment factors that affect the family's ability to provide home care. A thorough assessment of the family and home environment should be performed to ensure that the family's emotional and physical resources are sufficient to manage the tasks of home care. (For a discussion of family and home assessment strategies, see Chapter 29.) In addition to adequate family resources, an investigation of community services, including respite care, is needed to ensure that appropriate support agencies such as emergency facilities, home health agencies, and equipment vendors are available. Financial resources are also a consideration. To coordinate the immense task of assessment and plan implementation, a care coordinator or manager should be appointed early in the discharge process.

The preparation for hospital discharge and home care begins during the admission assessment. Short- and long-term goals are established to meet the child's physical and psychosocial needs. For children with complex care needs, discharge planning focuses on obtaining appropriate equipment and health care personnel for the home. It is also concerned with treatments that parents or children are expected to continue at home. In planning appropriate teaching, nurses need to assess (1) the actual and perceived complexity of the skill, (2) the parents' or child's ability to learn the skill, and (3) the parents' or child's previous or present experience with such procedures.

The teaching plan incorporates levels of learning such as observing, participating with assistance, and finally acting without help or guidance. The skill is divided into discrete steps, and each step is taught to the family member until it is learned. Return demonstration of the skill is requested before new skills are introduced. A record of teaching and performance provides an efficient checklist for evaluation. All families need to receive detailed *written* instructions about home care with telephone numbers for assistance before they leave the hospital. Communication between the nurse performing discharge planning and home health care is essential for ensuring a smooth transition for the child and family.

After the family is competent in performing the skill, they are given responsibility for the care. When possible the family should have a transition or trial period to assume care with minimal health care supervision. This may be arranged on the unit, during a home pass, or in a facility such as a motel near the hospital. Such transitions provide a safe practice period for the family with assistance readily available when needed and are especially valuable when the family lives far from the hospital.

In many instances parents need only simple instructions and understanding of follow-up care. However, the often overwhelming care assumed by some families coupled with other stressors they may be experiencing necessitates continued professional support after discharge. A follow-up home visit or telephone call gives the nurse an opportunity to individualize care and provide information in perhaps a less stressful learning environment than the hospital. Appropriate referrals and resources may include visiting nurse or home health agencies, private nurse services, the school system, a physical therapist, a mental health counselor, a social worker, and any number of community agencies. Sharing the important issues surrounding the child's and family's needs is essential. Referral summaries should be concise, specific, and factual. When numerous support services are required, periodic collaboration among the professionals involved and the family is

an excellent strategy to ensure efficient use and comprehensive delivery of services.

CARE OF THE CHILD AND FAMILY IN SPECIAL HOSPITAL SITUATIONS

In addition to a general pediatric unit, children may be admitted to special facilities such as an ambulatory or outpatient setting, an isolation room, or intensive care.

Ambulatory or Outpatient Setting

The ambulatory or outpatient setting provides needed medical services for the child while eliminating the necessity of overnight admission. The benefits of ambulatory care are (1) minimized stressors of hospitalization, especially separation from the family; (2) reduced chances of infection; and (3) increased cost savings. Admission to the ambulatory or outpatient hospital setting usually is for surgical or diagnostic procedures such as insertion of tympanostomy tubes, hernia repair, adenoidectomy, tonsillectomy, cystoscopy, or bronchoscopy.

In the ambulatory or outpatient setting adequate preparation is particularly challenging. Ideally the child and parents should receive preadmission preparation, including a tour of the facility and a review of the day's events. Parents need information in advance to help prepare the child and themselves for surgery and enable them to care for the child at home after the procedure. They also appreciate suggestions for items to bring to the hospital such as blankets or stuffed animals. When preadmission preparation is not possible, time should be allowed on the day of the procedure for children to become acquainted with their surroundings and for nurses to assess, plan, and implement appropriate teaching.

Explicit discharge instructions are important after outpatient surgery (see Family-Centered Care box). Parents need guidelines on when to call their practitioner regarding a change in the child's condition. A follow-up telephone call system allows for nurses to check on the child's progress within 48 to 72 hours after discharge. It also provides an opportunity for the nurse to review discharge information and answer questions.

! NURSING ALERT

Help the family prepare for the transportation home by offering these suggestions:

- Have a blanket and pillow in the car. (Always use the car safety restraint system.)
- Take a basin or plastic bag in case of vomiting.
- Use a cup with a cap and straw for the child to drink fluids (except in cases of oral facial surgery in which a straw may be contraindicated).
- Give any prescribed pain medication before leaving facility.

Provide parents verbal and written information regarding potential side effects of pain medication for which they should be vigilant after discharge.

Isolation

Admission to an isolation room increases all of the stressors typically associated with hospitalization. There is further separation from familiar persons; additional loss of control; and added environmental changes such as sensory deprivation and the strange appearance of visitors. Orientation to time and place is affected. These stressors

FAMILY-CENTERED CARE

Discharge from Ambulatory Settings

1. Before beginning, explain that all instructions will also be presented in writing for the family to reference later.
2. Provide an overview of the typical trajectory (expected pattern) of recovery.
3. Discuss expected progression of the child's activity level during the postdischarge period (e.g., "Mary will probably sleep for the rest of the day and feel kind of tired most of tomorrow but will be back to her usual activities the next day.").
4. Explain which activities the child is allowed and what is not permitted (e.g., bed rest, bathing).
5. Discuss dietary restrictions, being very specific and giving examples of "clear fluids" or what is meant by a "full liquid diet."
6. Discuss nausea and vomiting, if applicable, explaining how much is "normal" and what to do if more occurs (e.g., "Juan may be sick to his stomach and vomit. This is normal. However, if he vomits more than 3 times, please call us at this number right away.").
7. Discuss fever and appropriate comfort measures, explaining how much fever is considered "normal" and specifically what to do if the child goes beyond the range.
8. Explain the amount, location, and kind of pain or discomfort the child may experience.
   - Give any prescribed medication before leaving the facility.
   - Send a pain scale home with the family.
   - Explain how much pain and discomfort is "normal" and what to do if the child surpasses that level or if pain-management interventions are unsuccessful.
   - Discuss pain management, including dosage for pain medications and details on how to administer them.
   - Describe appropriate nonpharmacologic comfort measures such as holding, rocking, or swaddling.
9. Provide information about each medication that the child will be taking at home.
   - Review the details, including dose and route.
   - Demonstrate how to administer medications if necessary (e.g., how to take outer packaging off suppositories, how to insert).
   - Discuss guidelines for requesting other medications.
   - Request that all prescriptions be filled and given to the family before discharge.
10. Make certain that the family has all of the equipment and supplies (e.g., gauze and tape for dressing changes) that they will need at home.
11. Discuss complications that may occur and the steps to take if they do.
12. Ensure that appropriate measures are in place for safe transport home.
    - Remind family to use a seat belt or car seat for the child.
    - Determine if there will be one person whose sole responsibility is helping ensure the child's safety and comfort during transport.
    - Discuss measures the driver may need to take if this is impossible (e.g., be certain a basin is within the child's reach in case vomiting occurs; take a route that permits slower traffic and has places along the roadside to stop if necessary).
    - Determine the availability of a blanket, pillow, and cup with a lid and straw for the child's use in the car.
13. Provide emergency phone numbers for the family to call with any concerns.
14. Explain that the family will be contacted (give an approximate time) to follow up on the child but that they should not hesitate to call if concerns arise before then.
15. Ask the family and child, if appropriate, if they have any questions and problem solve with family members to meet their unique needs.

are compounded by children's limited understanding of isolation. Preschool children have difficulty understanding the rationale for isolation because they cannot comprehend the cause-and-effect relationship between germs and illness. They are likely to view isolation as punishment. Older children understand the causality better but still require information to decrease fantasizing or misinterpretation.

When a child is placed in isolation, preparation is essential for him or her to feel in control. With young children the best approach is a simple explanation such as, "You need to be in this room to help you get better. This is a special place to make all the germs go away. The germs made you sick, and you could not help that."

All children, but especially younger ones, need preparation in terms of what they will see, hear, and feel in isolation. Therefore they are shown the mask, gloves, and gown and encouraged to "dress up" in them. Playing with the strange apparel lessens the fear of seeing "ghostlike" people walk into the room. Before entering the room, nurses and other health personnel should introduce themselves and let the child see their faces before donning masks. In this way the child associates them with significant experiences and gains a sense of familiarity in an otherwise strange and lonely environment.

When the child's condition improves, appropriate play activities are provided to minimize boredom, stimulate the senses, provide a real or perceived sense of movement, orient the child to time and place, provide social interaction, and reduce depersonalization. For example, the environment can be manipulated to increase sensory freedom by moving the bed toward the door or window. Opening window shades; providing musical, visual, or tactile toys; and increasing interpersonal contact can substitute mental mobility for the limitations of physical movement. Rather than dwelling on the negative aspects of isolation, the child can be encouraged to view this experience as challenging and positive. For example, the nurse can help the child look at isolation as a method of keeping others out and letting only special people in. Children often think of intriguing signs for their doors such as, "Enter at your own risk." These signs also encourage people "on the outside" to talk with the child about the ominous greeting.

Emergency Admission

One of the most traumatic hospital experiences for the child and parents is an emergency admission. The sudden onset of an illness or the occurrence of an injury leaves little time for preparation and explanation. Sometimes the emergency admission is compounded by admission to an intensive care unit (ICU) or the need for immediate surgery. However, even in instances requiring only outpatient treatment, the child is exposed to a strange, frightening environment and experiences that may elicit fear or cause pain.

There is a wide discrepancy between what constitutes a medically defined emergency and a patient-defined emergency. A growing concern is the use of major emergency departments for routine primary care health visits. To offset overcrowding in emergency departments, many facilities have minor emergency units or pediatric minor emergency units for after-hours' health care. Telephone triage for minor illnesses for patients is also emerging as a health care delivery mode to differentiate illnesses such as a common cold from true life-threatening conditions that require immediate practitioner attention and intervention. Other factors contributing to the overuse of emergency departments (as opposed to the primary practitioner's office) include the increasing number of uninsured persons and households in which both parents work full time and cannot afford to take off during the daytime to take the sick child to a practitioner.

In pediatric populations most visits to an emergency department are for respiratory infections, with skin conditions, gastrointestinal disorders, and trauma such as poisoning accounting for the remainder of cases. The most common reason parents give for bringing the child to the emergency department is concern about the illness worsening. However, practitioners may not think that the progressive symptoms necessitate immediate or emergency care. One of the nurse's primary goals is to assess the parents' perception of the event and their reasons for considering it serious or life threatening.

Lengthy preparatory admission procedures are often inappropriate for emergency situations. In such instances nurses must focus their nursing interventions on the essential components of admission counseling (Box 38-10) and complete the process as soon as the child's condition has stabilized.

Unless an emergency is life threatening, children need to participate in their care to maintain a sense of control. Because emergency departments are frequently hectic, there is a tendency to rush through procedures to save time. However, the extra few minutes needed to allow children to participate may save many more minutes of useless resistance and lack of cooperation during subsequent procedures. Other supportive measures include ensuring privacy, accepting various emotional responses to fear or pain, preserving parent-child contact, explaining all events before or as they occur, and personally remaining calm. Pain management strategies are discussed in Chapter 30.

At times, because of the child's physical condition, little or no preparatory counseling for emergency hospitalization can be done. In such situations counseling subsequent to the event has therapeutic value. Counseling should focus on evaluating children's thoughts regarding admission and related procedures. It is similar to precounseling techniques; however, instead of supplying information, the nurse listens to the explanations offered by the child. Projective techniques such as drawing, doll play, or storytelling are especially effective. The nurse then bases additional information on what has already been understood.

Intensive Care Unit

Admission to an ICU can be traumatic for both the child and parents (Fig. 38-10). The nature and severity of the illness and the

FIG 38-10 Parental presence during hospitalization provides emotional support for the child and increases the parent's sense of empowerment in the caregiver role. (Courtesy E. Jacob, Texas Children's Hospital, Houston, TX.)

circumstances surrounding the admission are major factors, especially for parents. Parents experience significantly more stress when the admission is unexpected rather than expected. Although several studies have described what parents perceive to be most stressful, the most effective strategy may simply be to ask parents what is stressful and implement interventions that will enhance their ability to cope (Board and Ryan-Wenger, 2003). Assessment should be repeated periodically to account for changes in perceptions over time. The use of daily patient goal sheets has been successful in improving communication among health care providers caring for children in the ICU (Agarwal, Frankel, Tourner, et al., 2008; Phipps and Thomas, 2007). By clearly defining daily patient care goals, health care providers believed that care was improved.

The family's emotional needs are paramount when a child is admitted to an ICU. A major stressor for parents of a child in the ICU is the child's appearance (Latour, van Goudoever, and Hazelzet, 2008). Although the same interventions discussed earlier for the stressors of separation and loss of control apply here, additional interventions may also benefit the family and child. In a qualitative study of 19 parents of 10 children in an ICU, parents reported that they simply wanted nurses to nurture the child in the same way the family would (Harbaugh, Tomlinson, and Kirschbaum, 2004). Nurse behaviors that exemplified caring and affection were perceived as helpful in decreasing stress. Behaviors perceived as not helpful included separating the child from the parents and communicating poorly with parents. Therefore even critical care must be centered on the family. It is important that visiting hours be liberal and flexible enough to accommodate parental needs and involvement.

Critically ill children become the focus of the parents' lives, and parents' most pressing need is for information. They want to know if their child will live and, if so, whether the child will be the same as before. They need to know why various interventions are being done for the child, that the child is being treated for pain or is

BOX 38-10 GUIDELINES FOR SPECIAL HOSPITAL ADMISSION*

Emergency Admission

- Lengthy preparatory admission procedures are often impossible and inappropriate for emergency situations.
- Focus assessment on airway, breathing, and circulation; weigh child whenever possible for calculation of drug dosages.
- Unless an emergency is life threatening, children need to participate in their care to maintain a sense of control.
- Focus on essential components of admission counseling, including the following:
  - Appropriate introduction to the family
  - Use of child's name, not terms such as "honey" or "dear"
  - Determination of child's age and some judgment about developmental age (If the child is of school age, asking about the grade level offers some evidence of intellectual ability.)
  - Information about child's general state of health, any problems that may interfere with medical treatment (e.g., allergies), and previous experience with hospital facilities
  - Information about the chief complaint from both the parents and the child

Admission to Intensive Care Unit

- Prepare child and parents for elective intensive care unit (ICU) admission such as for postoperative care after cardiac surgery.
- Prepare child and parents for unanticipated ICU admission by focusing primarily on the sensory aspects of the experience and usual family concerns (e.g., people in charge of child's care, schedule for visiting, area where family can stay).
- Prepare parents regarding child's appearance and behavior when they first visit child in ICU.
- Accompany family to bedside to provide emotional support and answer questions.
- Prepare siblings for their visit; plan length of time for sibling visitation; monitor siblings' reactions during visit to prevent them from becoming overwhelmed.
- Encourage parents to stay with their child:
  - If visiting hours are limited, allow flexibility in schedule to accommodate parental needs.
  - Give family members a written schedule of visiting times.
  - If visiting hours are liberal, be aware of family members' needs and suggest periodic respites.
  - Assure family they can call the unit at any time.
- Prepare parents for expected role changes and identify ways for them to participate in child's care without overwhelming them with responsibilities:
  - Help with bath or feeding.
  - Touch and talk to child.
  - Help with procedures.
- Provide information about child's condition in understandable language:
  - Repeat information often.
  - Seek clarification of understanding.
  - During bedside conferences interpret information for family members and child or, if appropriate, conduct report outside room.
- Prepare child for procedures even if it involves explanation while procedure is performed.
- Assess and manage pain; recognize that a child who cannot talk such as an infant or child in a coma or on mechanical ventilation can be in pain.
- Establish a routine that maintains some similarity to daily events in child's life whenever possible:
  - Organize care during normal waking hours.
  - Keep regular bedtime schedules, including quiet times when television or radio is lowered or turned off.
  - Provide uninterrupted sleep cycles (60 minutes for infants; 90 minutes for older children).
  - Close and open drapes and dim lights to allow for day and night.
  - Place curtain around bed for privacy.
  - Orient child to day and time; have clocks or calendars in easy view for older children.
- Schedule a time when child is left undisturbed (e.g., during naps, visit with family, playtime, or favorite program).
- Provide opportunities for play.
- Reduce stimulation in environment:
  - Refrain from loud talking or laughing.
  - Keep equipment noise to a minimum:
    - Turn alarms as low as safely possible.
    - Perform treatments requiring equipment at one time.
    - Turn off bedside equipment that is not in use such as suction and oxygen.
  - Avoid loud, abrupt noises.

*See also Box 38-7.

comfortable, and that the child may be able to hear them even though not awake. When parents first visit the child in the ICU, they need preparation regarding his or her appearance. Ideally the nurse should accompany the parents to the bedside to provide emotional support and answer any questions.

Despite the stresses normally associated with ICU admission, a special security develops from being monitored carefully and receiving individualized care. Therefore planning for transition to the regular unit is essential and should include the following:

- Assignment of a primary nurse on the regular unit
- Continued visits by the ICU staff to assess the child's and parents' adjustment and act as a temporary liaison with the nursing staff
- Explanation of the differences between the two units and the rationale for the change to less intense monitoring of the child's physical condition
- Selection of an appropriate room such as one that is close to the nursing station and a compatible roommate

KEY POINTS

- Children are particularly vulnerable to the stressors of illness and hospitalization because stress represents a change from the usual state of health and routine and because they possess limited coping mechanisms.
- The three stages of separation anxiety are protest, despair, and detachment.
- Feelings of loss of control are caused by unfamiliar environmental stimuli, physical restriction, altered routine, and dependency.
- Fear of bodily pain may be manifested in the following ways: infants—facial expressions and body movements; toddlers—intense emotional upset and physical resistance; preschoolers—aggression, verbal expression, and dependency; school-age children—precise verbalization of pain, passive requests for support or help, and procrastination technique; and adolescents—self-control and limited movement.
- Because of their separation from significant people, children who are hospitalized may lack the opportunity to form new attachments in the strange environment of the hospital and exhibit negative behaviors after discharge.
- Nursing care of children in the hospital is aimed at preventing or minimizing separation, decreasing loss of control, minimizing fear of bodily injury, using play or expressive activities to lessen stress, and maximizing the potential benefits of hospitalization.
- The nurse can maximize potential benefits of hospitalization by fostering parent-child relations, providing educational opportunities, promoting self-mastery, and encouraging socialization.
- Family reactions are influenced by the seriousness of the illness, experience with illness or hospitalization and diagnostic or therapeutic procedures, available support systems, personal ego strengths, coping abilities, presence of additional stressors, cultural and religious beliefs, and family communication patterns.
- Fear of contracting illness, their younger age, a close relationship with the ill sibling, substitute child care, minimal explanation of the illness, and perceived changes in parenting all increase the deleterious effects of a brother's or sister's illness and hospitalization on siblings.
- Nursing care of the family involves listening to parents' verbal and nonverbal messages; providing clergy support; accepting cultural, socioeconomic, and ethnic values; giving information to families and siblings; and preparing for discharge and home care.
- Admission to an outpatient setting, emergency department, isolation room, or ICU requires additional intervention strategies to meet the child's and family's needs.

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify instances in which informed consent is required and in which minors may be considered emancipated.
- Formulate general guidelines for preparing children for procedures, including surgery.
- Implement play in therapeutic procedures.
- List general strategies for enhancing compliance in children and families.
- Outline general hygiene and care procedures for hospitalized children.
- Implement feeding techniques that encourage food and fluid intake.
- Describe methods of reducing the temperature in a child with fever or hyperthermia.
- Describe systems that can be used for infection control.
- Describe safe methods of administering oral, parenteral, rectal, optic, otic, and nasal medications to children.
- Identify nursing responsibilities in maintaining fluid balance.
- Demonstrate correct procedures for postural drainage and tracheostomy care.
- Describe the procedures involved in providing nutrition via gavage, gastrostomy, and parenteral routes.
- Describe the procedures involved in administering an enema and ostomy care to children.

GENERAL CONCEPTS RELATED TO PEDIATRIC PROCEDURES

Informed Consent

Before undergoing any invasive procedure, the patient or the patient's legal surrogate must receive sufficient information on which to make an informed health care decision. Informed consent should include the expected care or treatment; potential risks, benefits, and alternatives; and what might happen if the patient chooses not to consent. To obtain valid informed consent, health care providers must meet the following three conditions:

1. The person must be capable of giving consent; he or she must be over the age of majority (usually age 18 years) and considered competent (i.e., possessing the mental capacity to make choices and understand their consequences).
2. The person must receive the information needed to make an intelligent decision.
3. The person must act voluntarily when exercising freedom of choice without force, fraud, deceit, duress, or other forms of constraint or coercion.

The patient has the right to accept or refuse any health care. If a patient is treated without consent, the hospital or health care provider may be charged with assault and held liable for damages.

Requirements for Obtaining Informed Consent

Written informed consent of the parent or legal guardian is usually required for medical or surgical treatment of a minor, including many diagnostic procedures. One universal consent is not sufficient. Separate informed permissions must be obtained for each surgical or diagnostic procedure, including the following:

- Major surgery
- Minor surgery (e.g., cutdown, biopsy, dental extraction, suturing a laceration [especially one that may have a cosmetic effect], removal of a cyst, closed reduction of a fracture)
- Diagnostic tests with an element of risk (e.g., bronchoscopy, angiography, lumbar puncture [LP], cardiac catheterization, bone marrow aspiration)
- Medical treatments with an element of risk (e.g., blood transfusion, thoracentesis or paracentesis, radiotherapy)

Other situations that require patient or parental consent include the following:

- Photographs for medical, educational, or public use
- Removal of the child from the health care institution against medical advice
- Postmortem examination, except in unexplained deaths such as sudden infant death, violent death, or suspected suicide
- Release of medical information

Decision making involving the care of older children and adolescents should include the patient's assent (if feasible) and the parent's consent. Assent means that the child or adolescent has been informed about the proposed treatment, procedure, or research and is willing to allow a health care provider to perform it. Assent should include the following:

- Helping the patient achieve a developmentally appropriate awareness of the nature of his or her condition
- Telling the patient what he or she can expect
- Making a clinical assessment of the patient's understanding
- Soliciting an expression of the patient's willingness to accept the proposed procedure

Health care providers should use multiple methods to provide information, including age-appropriate methods (e.g., videos, peer discussion, diagrams, and written materials). The nurse should provide an assent form for the child to sign, and the child should keep a copy. By including the child in the decision-making process and gaining his or her acceptance, staff members demonstrate respect for the child. Assent is not a legal requirement but an ethical one to protect the rights of children.

Eligibility for Giving Informed Consent

Informed Consent of Parents or Legal Guardians. Parents have full responsibility for the care and rearing of their minor children, including legal control over them. As long as children are minors, their parents or legal guardians are required to give informed consent before medical treatment is rendered or any procedure is performed. If the parents are married to one another, consent from only one parent is required for nonurgent pediatric care. If the parents are divorced, consent usually rests with the parent who has legal custody (Berger and AAP Committee on Medical Liability, 2003). Parents also have a right to withdraw consent later.

Evidence of Consent. Regulations on obtaining informed consent vary from state to state, and policies differ at each health care facility. It is the health care provider's legal responsibility to explain the procedure, risks, benefits, and alternatives. The nurse witnesses the patient's, parent's, or legal guardian's signature on the consent form and may reinforce what the patient has been told. A signed consent form is the legal document that signifies that the process of informed consent has occurred. If parents are unavailable to sign consent forms, verbal consent may be obtained via the telephone in the presence of two witnesses. Both witnesses record that informed consent was given and by whom. Their signatures indicate that they witnessed the verbal consent.

Informed Consent of Mature and Emancipated Minors. State laws differ with regard to the age of majority (i.e., the age at which a person is considered to have all the legal rights and responsibilities of an adult). In most states 18 years is the age of majority. Competent adults can give informed consent on their own behalf. An emancipated minor is one who is legally under the age of majority but is recognized as having the legal capacity of an adult under circumstances prescribed by state law such as pregnancy, marriage, high school graduation, independent living, or military service.

Treatment Without Parental Consent. Exceptions to requiring parental consent before treating minor children occur in situations in which children need urgent medical or surgical treatment and a parent is not readily available or refuses to give consent. For example, a child may be brought to an emergency department accompanied by a grandparent, child care provider, teacher, or others. In the absence of parents or legal guardians, people in charge of the child may be given permission by the parents to give informed consent by proxy. In emergencies, including danger to life or the possibility of permanent injury, appropriate care should not be withheld or delayed because of problems obtaining consent (AAP, 2003; Berger and AAP Committee on Medical Liability, 2003). The nurse should document any efforts made to obtain consent.

Refusal to give consent can occur when the treatment such as blood transfusions conflicts with the parents' religious beliefs. All states recognize such exceptions and have statutory procedures to permit treatment if the life or health of such a minor is in jeopardy or if delayed treatment would create a risk to the minor's health. Evaluation for child abuse or neglect can occur without parental consent and without notification to the state before evaluation in most states.

Adolescents, Consent, and Confidentiality. The Health Insurance Portability and Accountability Act of 1996 (HIPAA) was passed to help protect and safeguard the security and confidentiality of health information. Because adolescents are not yet adults, parents have the right to make most decisions on their behalf and receive information. However, adolescents are more likely to seek care in a setting in which they believe their privacy will be maintained. All 50 states have enacted legislation that entitles them to consent to treatment for one or more "medically emancipated" conditions such as sexually transmitted infections, mental health services, alcohol and drug dependency, pregnancy, and contraceptive advice without the parents' knowledge (AAP, 2003; Anderson, Schaechter, and Brosco, 2005; Tillett, 2005). Consent to abortion is controversial, and statues vary widely by state. State law preempts HIPAA, regardless of whether that law prohibits, mandates, or allows discretion about a disclosure.

Preparation for Diagnostic and Therapeutic Procedures

Technologic advances and changes in health care have resulted in more pediatric procedures being performed in a variety of settings. Many procedures are both stressful and painful experiences. For most procedures the focus of care is psychologic preparation of the child and family. However, some procedures require the administration of sedatives and analgesics.

Psychologic Preparation

Preparing children for procedures decreases their anxiety, promotes their cooperation, supports their coping skills and may teach them new ones, and facilitates a feeling of mastery in experiencing a potentially stressful event. Many institutions have developed preadmission teaching programs designed to educate the pediatric patient and family by offering hands-on experience with hospital equipment, the procedure performed, and departments they will visit. Preparatory methods may be formal such as group preparation for hospitalization. Most preparation strategies are informal, focus on providing information about the experience, and are directed at stressful or painful procedures. The most effective preparation includes providing sensory-procedural information and helping the child develop coping skills such as imagery, distraction, or relaxation.

The Guidelines boxes describe general guidelines for preparing children for procedures along with age-specific guidelines that consider their developmental needs and cognitive abilities. In addition

to these suggestions, nurses should consider the child's temperament, existing coping strategies, and previous experiences in individualizing the preparatory process. Children who are distractible and highly active or those who are "slow to warm up" may need individualized sessions (i.e., shorter for active children and more slowly paced for shy children). Youngsters who tend to cope well may need more emphasis on using their present skills, whereas those who appear to cope less adequately can benefit from more time devoted to simple coping strategies such as relaxing, breathing, counting, squeezing a hand, or singing. Children with previous health-related experiences still need preparation for repeat or new procedures; however, the nurse must assess what they know, correct their misconceptions, supply new information, and introduce new coping skills as indicated by their previous reactions. Especially for painful procedures, the most effective preparation includes providing sensory-procedural information and helping the child develop coping skills such as imagery or relaxation (see Guidelines boxes).

Children differ in their "information-seeking dimension." Some actively ask for information about the intended procedure, but others characteristically avoid it. Parents can often guide nurses in deciding how much information is enough for the child because they know whether he or she is typically inquisitive or satisfied with short answers. Asking older children their preferences about the amount of explanation is also important.

The exact timing of the preparation for a procedure varies with the child's age and the type of procedure. No exact guidelines govern timing; but in general the younger the child, the closer the explanation should be to the actual procedure to prevent undue fantasizing and worrying. With complex procedures more time may be needed for assimilation of information, especially with older children. For example, the explanation for an injection can immediately precede the procedure for all ages; but preparation for surgery may begin the day before for young children and a few days before for older children, although the nurse should elicit older children's preferences.

Establish Trust and Provide Support. The nurse who has spent time with and established a positive relationship with a child usually finds it easier to gain cooperation. If the relationship is based on trust, the child associates the nurse with caregiving activities that give comfort and pleasure most of the time rather than discomfort and stress. If the nurse does not know the child, it is best for he or she to be introduced by another staff person whom the child trusts. The first visit with the child should not include any painful procedure and ideally should focus on the child first and then on an explanation of the procedure.

Parental Presence and Support. Children need support during procedures, and for young children the greatest source of support is the parents. They represent security, protection, safety, and comfort. Several studies have reported a positive impact on parental distress and satisfaction and no difference in technical complications when parents remain with children (Piira, Sugiura, Champion, et al., 2005). Controversy exists regarding the role parents should assume during the procedure, especially if discomfort is involved. Several professional associations support the option of family presence during invasive procedures (American Association of Critical Care Nurses, 2006; Emergency Nurses Association, 2005). The nurse should assess the parents' preferences for assisting, observing, or waiting outside the room and the child's preference for parental presence. Respect the child's and parents' choices. Give parents who wish to stay appropriate explanation about the procedure and coach them about where to sit or stand and what to say or do to help the child through it. Support parents who do not want to be present in their decision and encourage them to remain close by so they can be available to support the child immediately after the procedure. Parents should also know that someone will be with their child to provide support. Ideally this person should inform the parents after the procedure about how the child did.

Provide an Explanation. Age-appropriate explanations are one of the most widely used interventions for reducing anxiety in children undergoing procedures. Before performing a procedure, explain what is to be done and what is expected of the child. The explanation should be short, simple, and appropriate to the child's

GUIDELINES

Preparing Children for Procedures

- Determine details of exact procedure to be performed.
- Review parents' and child's present understanding.
- Base teaching on developmental age and existing knowledge.
- Incorporate parents in teaching if they desire, especially if they plan to participate in care.
- Inform parents of their supportive role during procedure such as standing near child's head or in child's line of vision and talking softly to child and the typical responses to be expected from children undergoing the procedure.
- Allow for ample discussion to prevent information overload and ensure adequate feedback.
- Use concrete, not abstract, terms and visual aids to describe procedure. For example, use a simple line drawing of a boy or girl and mark the body part that will be involved in the procedure. Use nonthreatening but realistic models.*
- Emphasize that no other body part will be involved.
- If the body part is associated with a specific function, stress the change or noninvolvement of that ability (e.g., after tonsillectomy, child can still speak).
- Use words and sentence length appropriate to child's level of understanding (a rule of thumb for the number of words in a child's sentence is equal to his or her age in years plus 1).
- Avoid words and phrases with dual meanings (see Table 39-1, p. 1135) unless child understands such words.
- Clarify all unfamiliar words (e.g., "Anesthesia is a *special* sleep").
- Emphasize sensory aspects of procedure—what child will feel, see, hear, smell, and touch and what he or she can do during procedure (e.g., lie still, count out loud, squeeze a hand, hug a doll).
- Allow child to practice procedures that require cooperation (e.g., turning, deep breathing, using an incentive spirometry).
- Introduce anxiety-inducing information last (e.g., starting an intravenous line).
- Be honest with child about unpleasant aspects of a procedure but avoid creating undue concern. When discussing that a procedure may be uncomfortable, state that it feels differently to different people.
- Emphasize end of procedure and any pleasurable events afterward (e.g., going home, seeing parents).
- Stress positive benefits of procedure (e.g., "After your tonsils are fixed, you won't have as many sore throats").
- Provide a positive ending, praising efforts at cooperation and coping.

*Soft-sculptured dolls and customized adapters and overlays for preparing children and families about procedures and as teaching models for technical care are available from Legacy Products, Inc., 120 West Main Street, PO Box 267, Cambridge City, IN 47327, 800-238-7951, e-mail: info@legacyproductsinc.com, www.legacyproductsinc.com.

GUIDELINES

Age-Specific Preparation of Children for Procedures Based on Developmental Characteristics

Infant—Developing Trust and Sensorimotor Thought

Attachment to Parent

- Involve parent in procedure if desired.*
- Keep parent in infant's line of vision.
- If parent is unable to be with infant, place familiar object with him or her (e.g., stuffed toy).

Stranger Anxiety

- Have usual caregivers perform or assist with procedure.*
- Make advances slowly and in nonthreatening manner.
- Limit number of strangers entering room during procedure.*

Sensorimotor Phase of Learning

- During procedure use sensory soothing measures (e.g., stroking skin, talking softly, giving pacifier).
- Use analgesics (e.g., topical anesthetic, intravenous opioid) to control discomfort.*
- Cuddle and hug infant after stressful procedure; encourage parent to comfort infant.

Increased Muscle Control

- Expect older infants to resist.
- Restrain adequately.
- Keep harmful objects out of reach.

Memory for Past Experiences

- Realize that older infants may associate objects, places, or people with prior painful experiences and will cry and resist at the sight of them.
- Keep frightening objects out of view.*
- Perform painful procedures in a separate room, not in crib (or bed).*
- Use nonintrusive procedures whenever possible (e.g., axillary or tympanic temperatures, oral medications).*

Imitation of Gestures

- Model desired behavior (e.g., opening mouth).

Toddler—Developing Autonomy and Sensorimotor to Preoperational Thought

Use same approaches as for infant plus the following.

Egocentric Thought

- Explain procedure in relation to what child will see, hear, taste, smell, and feel.
- Emphasize aspects of procedure that require cooperation (e.g., lying still).
- Tell child that it is okay to cry, yell, or use other means to express discomfort verbally.
- Designate one health care provider to speak during procedure. Hearing more than one can be confusing to child.*

Negative Behavior

- Expect treatments to be resisted; child may try to run away.
- Use firm, direct approach.
- Ignore temper tantrums.
- Use distraction techniques (e.g., singing a song *with* child).
- Restrain adequately.

Animism

- Keep frightening objects out of view (young children believe that objects have lifelike qualities and can harm them).

Limited Language Skills

- Communicate using gestures or demonstrations.
- Use a few simple terms familiar to child.
- Give child one direction at a time (e.g., "Lie down" and then "Hold my hand").
- Use small replicas of equipment; allow child to handle equipment.
- Use play; demonstrate on doll but avoid child's favorite doll because child may think doll is really "feeling" procedure.
- Prepare parents separately to avoid child's misinterpreting words.

Limited Concept of Time

- Prepare child shortly or immediately before procedure.
- Keep teaching sessions short (≈5-10 minutes).
- Have preparations completed before involving child in procedure.
- Have extra equipment nearby (e.g., alcohol swabs, new needle, adhesive bandages) to avoid delays.
- Tell child when procedure is completed.

Striving for Independence

- Allow choices whenever possible but realize that child may still be resistant and negative.
- Allow child to participate in care and help whenever possible (e.g., drink medicine from a cup, hold a dressing).

Preschooler—Developing Initiative and Preoperational Thought

Egocentric

- Explain procedure in simple terms and in relation to how it affects child (as with toddler, stress sensory aspects).
- Demonstrate use of equipment.
- Allow child to play with miniature or actual equipment.
- Encourage "playing out" experience on a doll both before and after procedure to clarify misconceptions.
- Use neutral words to describe the procedure (see Table 39-1, p. 1135).

Increased Language Skills

- Use verbal explanation but avoid overestimating child's comprehension of words.
- Encourage child to verbalize ideas and feelings.

Limited Concept of Time and Frustration Tolerance

- Implement same approaches as for toddler but may plan longer teaching session (10-15 minutes); may divide information into more than one session.

Illness and Hospitalization Viewed As Punishment

- Clarify why each procedure is performed; child will find it difficult to understand how medicine can make him or her feel better and can taste bad at the same time.
- Ask child thoughts regarding why a procedure is performed.
- State directly that procedures are never a form of punishment.

*Applies to any age.

Continued

GUIDELINES

Age-Specific Preparation of Children for Procedures Based on Developmental Characteristics—cont'd

Animism
- Keep equipment out of sight except when shown to or used on child.

Fears of Bodily Harm, Intrusion, and Castration
- Point out on drawing, doll, or child where procedure is performed.
- Emphasize that no other body part will be involved.
- Use nonintrusive procedures whenever possible (e.g., axillary temperatures, oral medication).
- Apply adhesive bandage over puncture site.
- Encourage parental presence.
- Realize that procedures involving genitalia provoke anxiety.
- Allow child to wear underpants with gown.
- Explain unfamiliar situations, especially noises or lights.

Striving for Initiative
- Involve child in care whenever possible (e.g., hold equipment, remove dressing).
- Give choices whenever possible but avoid excessive delays.
- Praise child for helping and attempting to cooperate; never shame child for lack of cooperation.

School-Age Child—Developing Industry and Concrete Thought

Increased Language Skills; Interest in Acquiring Knowledge
- Explain procedures using correct scientific and medical terminology.
- Explain procedure using simple diagrams and photographs.
- Discuss why procedure is necessary; concepts of illness and bodily functions are often vague.
- Explain function and operation of equipment in concrete terms.
- Allow child to manipulate equipment; use doll or another person as model to practice using equipment whenever possible (doll play may be considered childish by older school-age child).
- Allow time before and after procedure for questions and discussion.

Improved Concept of Time
- Plan for longer teaching sessions (≈20 minutes).
- Prepare up to 1 day in advance of procedure to allow for processing information.

Increased Self-Control
- Gain child's cooperation.
- Tell child what is expected.
- Suggest several ways of maintaining control from which the child may select (e.g., deep breathing, relaxation, counting).

Striving for Industry
- Allow responsibility for simple tasks (e.g., collecting specimens).
- Include child in decision making (e.g., time of day to perform procedure, preferred site).
- Encourage active participation (e.g., removing dressings, handling equipment, opening packages).

Developing Relationships with Peers
- Prepare two or more children for same procedure or encourage one to help prepare another.
- Provide privacy from peers during procedure to maintain self-esteem.

Adolescent—Developing Identity and Abstract Thought

Increasing Abstract Thought and Reasoning
- Discuss why procedure is necessary or beneficial.
- Explain long-term consequences of procedures; include information about body systems working together.
- Realize that adolescent may fear death, disability, or other potential risks.
- Encourage questioning regarding fears, options, and alternatives.

Consciousness of Appearance
- Provide privacy; describe how body will be covered and what will be exposed.
- Discuss how procedure may affect appearance (e.g., scar) and what can be done to minimize it.
- Emphasize any physical benefits of procedure.

Concern More with Present Than with Future
- Realize that immediate effects of procedure are more significant than future benefits.

Striving for Independence
- Involve adolescent in decision making and planning (e.g., time, place, clothing, individuals present during procedure, whether they will watch procedure).
- Impose as few restrictions as possible.
- Explore which coping strategies have worked in the past; children may need descriptions to identify various techniques.
- Accept regression to more childish methods of coping.
- Realize that adolescent may have difficulty accepting new authority figures and resist complying with procedures.

Developing Peer Relationships and Group Identity
- Same as for school-age child but assumes even greater significance.
- Allow adolescents to talk with other adolescents who have had same procedure.

level of comprehension. Long explanations may increase anxiety in a young child. When explaining the procedure to parents with the child present, the nurse uses language appropriate to the child because unfamiliar words can be misunderstood (Table 39-1). If the parents need additional preparation, it is done in an area away from the child. Teaching sessions are planned at times most conducive to the child's learning (e.g., after a rest period) and for the usual span of attention.

Special equipment is not necessary for preparing a child; but for young children who cannot yet think conceptually, using objects to supplement verbal explanation is important. Allowing children to handle actual items that will be used in their care such as a stethoscope, sphygmomanometer, or oxygen mask helps them develop familiarity with these items and reduces the fear often associated with their use. Miniature versions of hospital items such as gurneys and x-ray and intravenous (IV) equipment can be used to explain what the children can expect and permit them to safely experience situations that are unfamiliar and potentially frightening. Use photographs of children in different areas of the hospital (e.g., radiology department, operating room) to give children a more realistic idea

TABLE 39-1 SELECTING NONTHREATENING WORDS OR PHRASES

WORDS AND PHRASES TO AVOID	SUGGESTED SUBSTITUTIONS
Shot, bee sting, stick	Medicine under the skin
Organ	Special place in body
Test	To see how (specify body part) is working
Incision, cut	Special opening
Edema	Puffiness
Stretcher, gurney	Rolling bed, bed on wheels
Stool	Child's usual term
Dye	Special medicine
Pain	Hurt, discomfort, "owie," "boo-boo," sore, achy, scratchy
Deaden	Numb, make sleepy
Fix	Make better
Take (as in "take your temperature")	See how warm you are
Take (as in "take your blood pressure")	Check your pressure; hug your arm
Put to sleep, anesthesia	Special sleep so you won't feel anything
Catheter	Tube
Monitor	Television screen
Electrodes	Stickers, ticklers
Specimen	Sample

of equipment they may encounter. Written and illustrated materials are also valuable aids to preparation.*

Physical Preparation

One area of special concern is the administration of appropriate sedation and analgesia before stressful procedures. Chapter 30 describes sedative medications used for procedures.

Performance of the Procedure

Supportive care continues during the procedure and can be a major factor in a child's ability to cooperate. Ideally the same nurse who explains the procedure should perform or assist with the procedure. Before beginning, all equipment is assembled, and the room is readied to prevent unnecessary delays and interruptions that increase the child's anxiety. To avoid a delay during a procedure, have extra supplies handy. For example, have tape, bandages, alcohol swabs, and an extra needle when performing an injection or venipuncture. Minimizing the number of people present during the procedure also can decrease the child's anxiety.

To promote long-term coping and adjustment, give special consideration to the patient's age, coping skills, and procedure to be performed in determining where a procedure will occur. Treatment rooms should be used for procedures requiring sedation such as bone marrow aspirates and LPs in younger children. Traumatic procedures should never be performed in "safe" areas such as the playroom. If the procedure is lengthy, avoid conversation that could be misinterpreted by the child. As the procedure is nearing completion, the nurse should inform the child that it is almost over in language the child understands.

Expect Success. Nurses who approach children with confidence and convey the impression that they expect to be successful are less likely to encounter difficulty. It is best to approach a child as though cooperation is expected. Children sense anxiety and uncertainty in an adult and respond by striking out or actively resisting. Although it is not possible to eliminate such behavior in every child, a firm approach with a positive attitude tends to convey a feeling of security to most children.

Involve the Child. Involving children helps to gain their cooperation. Permitting choices gives them some measure of control. However, a choice is given only in situations in which one is available. Asking children, "Do you want to take your medicine now?" leads them to believe that they have an option and provides them the opportunity to legitimately refuse or delay the medication. This places the nurse in an awkward, if not impossible, position. It is much better to state firmly, "It's time to drink your medicine now." Children usually like to make choices, but the choice must be one that they do indeed have (e.g., "It's time for your medicine. Do you want to drink it plain or with a little water?").

Many children respond to tactics that appeal to their maturity or courage. This also gives them a sense of participation and achievement. For example, preschool children are proud that they can hold the dressing during the procedure or remove the tape. The same is true for school-age children, who often cooperate with minimal resistance.

Provide Distraction. Distraction is a powerful coping strategy during painful procedures (Uman, Chambers, McGrath, et al., 2006). It is accomplished by focusing the child's attention on something other than the procedure. Singing favorite songs, listening to music with a headset, counting aloud, or blowing bubbles to "blow the hurt away" are effective techniques. (For other nonpharmacologic interventions, see Chapter 30.)

Allow Expression of Feelings. The child should be allowed to express feelings of anger, anxiety, fear, frustration, or any other emotion. It is natural for children to strike out in frustration or try to avoid stress-provoking situations. The child needs to know that it is all right to cry. Behavior is children's primary means of communication, and coping and should be permitted unless it inflicts harm on them or those caring for them.

Postprocedural Support

After the procedure the child continues to need reassurance that he or she performed well and is accepted and loved. If the parents did not participate, the child is united with them as soon as possible so they can provide comfort.

Encourage Expression of Feelings. Planned activity after the procedure is helpful in encouraging constructive expression of feelings. For verbal children reviewing the details of the procedure can clarify misconceptions and garner feedback for improving the

*Preparatory materials, such as *Going to the Doctor*, are available from The Fred Rogers Company, 4802 Fifth Ave., Pittsburgh, PA 15213; 412-687-2990, www.fci.org. *Hospital Friends* is available from Centering Corporation, 7230 Maple St., Omaha, NE 68134, 866-218-0101, www.centering.org. Other resources include *Berenstein Bears Go to the Doctor* and *Berenstein Bears Visit the Dentist* (New York, Random House).

FIG 39-1 Playing with medical objects provides children with the opportunity to play out fears and concerns with supervision by a nurse or child life specialist.

nurse's preparatory strategies. Play is an excellent activity for all children. Infants and young children should have the opportunity for gross motor movement. Older children are able to vent their anger and frustration in acceptable pounding or throwing activities. Play-Doh is a remarkably versatile medium for pounding and shaping. Dramatic play provides an outlet for anger and places the child in a position of control in contrast to the position of helplessness in the real situation. Puppets also allow the child to communicate feelings in a nonthreatening way. One of the most effective interventions is **therapeutic play,** which includes well-supervised activities such as permitting the child to give an injection to a doll or stuffed toy to reduce the stress of injections (Fig. 39-1).

Positive Reinforcement. Children need to hear from adults that they did the best they could in the situation, no matter how they behaved. It is important for them to know that their worth is not being judged on the basis of their behavior in a stressful situation. Reward systems such as earning stars, stickers, or a badge of courage are appealing to children.

Returning to the child a short while after the procedure helps the nurse strengthen a supportive relationship. Relating with the child in a relaxed and nonstressful period allows him or her to see the nurse not only as someone associated with stressful situations but also as someone with whom to share pleasurable experiences.

Use of Play in Procedures

The use of play is an integral part of relationships with children. As such its value in specific situations is discussed throughout this book such as in Chapter 26 in relation to hospitalization. Many institutions have elaborate and well-organized play areas and programs under the direction of child life specialists. Other institutions have limited facilities. No matter what the institution provides for children, nurses can include play activities as part of nursing care. Play can be used to teach, express feelings, or achieve a therapeutic goal. Consequently it should be included in preparing children for and encouraging their cooperation during procedures. Play sessions after procedures can be structured such as directed toward needle play or general, with a wide variety of equipment available with which children can play.

Routine procedures such as measuring blood pressure and oral administration of medication may be of concern to children.

GUIDELINES

Family Preparation for Procedures

Family education for specific procedures is included throughout this unit. General concepts applicable to most family education sessions include the following:

- Name of procedure
- Purpose of procedure
- Length of time anticipated to complete procedure
- Anticipated effects
- Signs of adverse effects
- Assessment of family's level of understanding
- Demonstration and having family return it (if appropriate)

Box 39-1 describes suggestions for incorporating play into nursing procedures and activities for the hospitalized child that facilitate learning and adjustment to a new situation.

Preparing the Family

The process of patient education involves giving the family information about the child's condition, the regimen that must be followed and why, and other health teaching as indicated. The goal of this education is to enable the family to modify behaviors and adhere to the regimen that has been mutually established.

If equipment will be needed at home (e.g., suction machines, syringes), begin making the necessary arrangements in advance so discharge can proceed smoothly. Whenever possible, make arrangements for the family to use the same equipment in the home that they are using in the hospital. This allows them to become familiar with the items. In addition, the staff can help troubleshoot the equipment in a controlled environment. Plan the teaching sessions well in advance of the time the family will be responsible for performing the care. The more complex the procedure, the more time is needed for training.

Review the instructions with family members (see Guidelines box). Encourage note taking if they desire. Allow ample practice time under supervision. At least one family member, but preferably two members, should demonstrate the procedure before they are expected to care for the child at home. Provide the family with the telephone numbers of resource individuals who are available to help them in the event of a problem.

Surgical Procedures

Preoperative Care

Children experiencing surgical procedures require both psychologic and physical preparation. An important concern is restriction of food and fluids before surgery to avoid aspiration during anesthesia. Infants require special attention to fluid needs. They should not be without oral fluids for an extended period before surgery to avoid glycogen depletion and dehydration. Table 39-2 contains current preoperative fasting guidelines.

In general, psychologic preparation is similar to that discussed earlier for any procedure and incorporates many of the same techniques used in preparing a child for hospitalization such as films, books, brochures, play, and tours (see Chapter 38). Stress points before and after surgery include the admission process, blood tests, injection of preoperative medication (if prescribed), transport to the operating room, the mask on the face during induction, and the stay in the postanesthesia care unit (PACU). Wearing a hospital gown without the security of underpants or pajama bottoms can also be

BOX 39-1 PLAY ACTIVITIES FOR SPECIFIC PROCEDURES

Fluid Intake
- Make ice pops using child's favorite juice.
- Cut gelatin into fun shapes.
- Make a game out of taking a sip when turning page of a book or in games such as Simon Says.
- Use small medicine cups; decorate the cups.
- Color water with food coloring or powdered drink mix.
- Have a tea party; pour at a small table.
- Let child fill a syringe and squirt it into mouth or use it to fill small decorated cups.
- Cut straws in half and place in a small container (much easier for child to suck liquid).
- Use a "crazy" straw.
- Make a "progress poster"; give rewards for drinking a predetermined quantity.

Deep Breathing
- Blow bubbles with a bubble blower.
- Blow bubbles with a straw (no soap).
- Blow on a pinwheel, feather, whistle, harmonica, balloon, or party blower.
- Practice band instruments.
- Have a blowing contest using balloons,* boats, cotton balls, feathers, marbles, Ping-Pong balls, pieces of paper; blow such objects on a table top over a goal line, over water, through an obstacle course, up in the air, against an opponent, or up and down a string.
- Suck paper or cloth from one container to another using a straw.
- Dramatize stories such as, "I'll huff and puff and blow your house down" from the "Three Little Pigs."
- Do straw-blowing painting.
- Take a deep breath and "blow out the candles" on a birthday cake.
- Use a little paint brush to "paint" nails with water and blow nails dry.

Range of Motion and Use of Extremities
- Throw beanbags at a fixed or movable target or wadded-up paper into a wastebasket.
- Touch or kick Mylar balloons held or hung in different positions (if child is in traction, hang balloon from a trapeze).
- Play "tickle toes"; have the child wiggle them on request.
- Play Twister game or Simon Says.
- Play pretend and guessing games (e.g., imitate a bird, butterfly, or horse).
- Have tricycle or wheelchair races in safe area.
- Play kickball or throw ball with a soft foam ball in a safe area.
- Position bed so child must turn to view television or doorway.
- Climb wall with fingers like a "spider."
- Pretend to teach aerobic dancing or exercises; encourage parents to participate.
- Encourage swimming if feasible.
- Play video games or pinball (fine-motor movement).
- Play hide and seek: hide toy somewhere in bed (or room if ambulatory) and have child find it using specified hand or foot.
- Provide clay to mold with fingers.
- Paint or draw on large sheets of paper placed on floor or wall.
- Encourage combing own hair; play "beauty shop" with "customer" in different positions.

Soaks
- Play with small toys or objects (cups, syringes, soap dishes) in water.
- Wash dolls or toys.
- Pick up marbles or pennies* from bottom of bath container.
- Make designs with coins on bottom of container.
- Pretend a boat is a submarine by keeping it immersed.
- Read to child during soaks; sing with child; or play game such as cards, checkers, or other board game (if both hands are immersed, move board pieces for child).
- Sitz bath: give child something to listen to (music, stories) or look at (View-Master, book).
- Punch holes in bottom of plastic cup, fill with water, and let it "rain" on child.

Injections
- Let child handle syringe, vial, and alcohol swab and give an injection to doll or stuffed animal.
- Use syringes to decorate cookies with frosting, squirt paint, or target shoot into a container.
- Draw a "magic circle" on area before injection; draw smiling face in circle after injection but avoid drawing on puncture site.
- Allow child to have a "collection" of syringes (without needles); make "wild" creative objects with syringes.
- If multiple injections or venipunctures are planned, make a "progress poster"; give rewards for predetermined number of injections.
- Have child count to 10 or 15 during injection.

Ambulation
- Give child something to push:
  - Toddler: push-pull toy
  - School-age child: wagon or a doll in a stroller or wheelchair
  - Adolescent: decorated intravenous stand
- Have a parade; make objects such as hats and drums.

Extending Environment (e.g., for Patients in Traction)
- Make bed into a pirate ship or airplane with decorations.
- Put up mirrors so patient can see around room.
- Move bed frequently to playroom, hallway, or outside.

*Small objects such as marbles, coins, gloves, and balloons are unsafe for young children because of possible aspiration. Latex products also carry the risk of an allergic reaction.

traumatic. Therefore these articles of clothing should be allowed to be worn into the operating room and removed after induction of anesthesia. Children are at higher risk of ineffective response to anesthesia because of higher anxiety associated with stranger anxiety (infants), separation anxiety (toddlers and preschoolers), and fear of injury or death (adolescents) (Romino, Keatley, Secrest, et al., 2005).

Psychologic intervention consisting of systematic preparation, rehearsal of the forthcoming events, and supportive care at each of these points has shown to be more effective than a single-session preparation or consistent supportive care without systematic preparation and rehearsal (Kain, Caldwell-Andrews, Mayes, et al., 2007). A family-centered preoperative preparation program may consist of a tour of the perioperative areas with short explanations of the events 5 to 7 days before surgery, a video to take home and review a couple of times with additional explanations and demonstrations of perioperative processes, a mask to take home with which to practice, pamphlets to guide parents on supporting children during

TABLE 39-2 FASTING RECOMMENDATIONS TO REDUCE THE RISK OF PULMONARY ASPIRATION*

INGESTED MATERIAL	MINIMUM FASTING PERIOD (hr)†
Clear liquids‡	>2
Breast milk	4
Infant formula	6
Nonhuman milk§	6
Light meal¶	6

From American Society of Anesthesiologists: Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures, *Anesthesiology* 90(3):896-905, 1999.

*These recommendations apply to healthy patients who are undergoing elective procedures. They are not intended for women in labor. Following the guidelines does not guarantee that complete gastric emptying has occurred.

†Fasting periods noted in chart apply to all ages.

‡Examples of clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee.

§Because nonhuman milk is similar to solids in gastric emptying time, the amount ingested must be considered when determining appropriate fasting period.

¶A light meal typically consists of toast and clear liquids. Meals that include fried or fatty foods or meat may prolong gastric emptying time. Both the amount and type of foods ingested must be considered when determining an appropriate fasting period.

induction, phone calls to coach parents on preparing children 1 or 2 days before surgery, and toys and supplies in the holding area. Therapeutic play is an effective strategy in preparing children, and increased familiarity with medical procedures decreases anxiety (Li, Lopez, and Lee, 2007).

Parental Presence. Some institutions support parental presence during induction of anesthesia (Fig. 39-2). Appropriate education is essential to help parents understand the stages of anesthesia, what to expect, and how to support their child. When parents choose not to or are not allowed to attend the induction, leaving a favorite possession with the child and uniting the child and parents as soon as possible after surgery (preferably in the PACU) are important interventions. During surgery the family should have a designated place to wait and be kept informed of the child's progress. They also should know where and when they can visit the child after surgery.

According to research conducted by Kain, Caldwell-Andrews, Mayes, et al. (2007), benefits of well-prepared children and parents along with parental presence during induction of anesthesia include reduced anxiety for children and parents, lower doses of postoperative analgesia, lower incidence of severe emergence delirium symptoms, and shorter discharge time for short procedures. Other studies have not universally supported these benefits. Concern exists regarding the appropriateness of this practice for all parents. Some parents may become upset by the rapid succession of induction events, by observing their child becoming limp, and by leaving the child in the care of strangers. Even though some parents may become anxious, most control their anxiety, do not disrupt the induction, and support

FIG 39-2 Parental presence during induction of anesthesia can minimize the child's and parents' anxiety during the preoperative period.

the child (Munro and D'Errico, 2000). Parents who are anxious before surgery tend to become even more anxious after the induction; the reverse is true of parents with little anxiety.

Preoperative Sedation. Historically the most upsetting event for children has been the preoperative injection. An increasing number of anesthesiologists use preoperative sedative premedication, usually midazolam (Versed), and parental presence for children undergoing surgery (Kain, Caldwell-Andrews, Krivutza, et al., 2004).

The goals for using preoperative medications include (1) anxiety reduction, (2) amnesia, (3) sedation, (4) antiemetic effect, and (5) reduction of secretions (Manworren and Fledderman, 2000). Chapter 30 includes a discussion of pain management strategies for children undergoing surgery. When drugs are administered, they should be delivered atraumatically via oral or IV routes. Numerous preanesthetic drug regimens are used with children, and no consensus exists on the optimal method. However, if children have no preoperative pain, are well prepared psychologically for surgery, and have their parents nearby, preoperative medication may be unnecessary.

Postoperative Care

Various psychologic and physical interventions and observations help prevent or minimize possible unpleasant effects from anesthesia and the surgical procedure. Although the incidence of serious postoperative complications in healthy children undergoing surgery is less than 1% (Maxwell and Yaster, 2000), continuous monitoring of the child's cardiopulmonary status is essential during the immediate postoperative period. Postanesthesia complications such as airway obstruction, postextubation croup, laryngospasm, and bronchospasm make maintaining a patent airway and maximum ventilation critical.

Monitoring the patient's oxygen saturation and providing supplemental oxygen as needed, maintaining body temperature, and promoting fluid and electrolyte balance are important aspects of immediate postoperative care. Vital signs are monitored continuously, and each vital sign is evaluated in terms of side effects from anesthesia, shock, or respiratory compromise (Table 39-3).

TABLE 39-3 POTENTIAL CAUSES OF POSTOPERATIVE VITAL SIGN ALTERATIONS IN CHILDREN

ALTERATION	POTENTIAL CAUSE	COMMENTS
Heart Rate		
Increase	Decreased perfusion (shock) Elevated temperature Pain Respiratory distress (early) Medications (atropine, morphine, epinephrine) Hypoxia	Heart rate may increase to maintain cardiac output.
Decrease	Vagal stimulation Increased intracranial pressure Respiratory distress (late) Medications (neostigmine [Prostigmin])	Bradycardia is of more concern in young child than tachycardia.
Respiratory Rate		
Increase	Respiratory distress Fluid volume excess Hypothermia Elevated temperature Pain	Body responds to respiratory distress primarily by increasing rate.
Decrease	Anesthetics, opioids Pain	Decreased respiratory rate from opioids may be compensated for by increased depth of respiration.
Blood Pressure		
Increase	Excess intravascular volume Increased intracranial pressure Carbon dioxide retention Pain Medication (ketamine, epinephrine)	This is serious in premature infants because it increases risk of intraventricular hemorrhage.
Decrease	Vasodilating anesthetic agents (halothane, isoflurane, enflurane) Opioids (e.g., morphine)	Decreased blood pressure is late sign of shock because of elasticity and constriction of vessels to maintain cardiac output.
Temperature		
Increase	Shock (late sign) Infection Environmental causes (warm room, excess coverings) Malignant hyperthermia	Fever associated with infection usually occurs later than fever of noninfectious origin. Absence of fever does not rule out infection, especially in infants. Malignant hyperthermia requires immediate treatment.
Decrease	Vasodilating anesthetic agents (halothane, isoflurane, enflurane) Muscle relaxants Environmental causes (cool room) Infusion of cool fluids or blood	Neonates are especially susceptible to hypothermia, with serious or fatal consequences.

From Smith DP: *Comprehensive child and family nursing skills,* St Louis, 1991, Mosby.

A change in vital signs that demands immediate attention in the perioperative period is caused by malignant hyperthermia (MH), a potentially fatal pharmacogenetic disorder involving a defective calcium channel in the sarcoplasmic reticulum membrane. In susceptible children inhaled anesthetics and the muscle relaxant succinylcholine trigger the disorder, producing hypermetabolism. Symptoms of MH include hypercarbia (increasing end-tidal carbon dioxide), elevated temperature, tachycardia, tachypnea, acidosis, muscle rigidity, and rhabdomyolysis (Rosenberg, Davis, and James, 2007). A family or previous history of sudden high fever associated with a surgical procedure and myotonia increase the risk for MH. Children who have successfully undergone prior surgery without adverse effects may still be considered susceptible.

Treatment of MH includes immediate discontinuation of the triggering agent, hyperventilation with 100% oxygen, and IV dantrolene sodium. If the child is hyperthermic, initiate cooling measures such as ice packs to the groin, axillae, and neck and iced nasogastric (NG) lavage. The surgery may be discontinued; or, if it is emergent, it may be continued with a different anesthetic agent. The patient should be transferred to an intensive care unit for at least 36 hours and is closely monitored for stabilization of vital signs, metabolic state, and possible recurrence of symptoms.

Managing pain is a major nursing responsibility after surgery. The nurse should assess pain frequently and administer analgesics to provide comfort and facilitate cooperation with postoperative care such as ambulation and deep breathing. Opioids are the most

commonly used analgesics. Routinely scheduled IV analgesics, patient-controlled analgesia, and epidural infusions, rather than as-needed orders, provide excellent analgesia in postoperative pediatric patients.

Because respiratory tract infections are a potential complication of anesthesia, make every effort to aerate the lungs and remove secretions. Auscultate the lungs regularly to identify abnormal sounds or any areas of diminished or absent breath sounds. To prevent pneumonia encourage respiratory movement with incentive spirometers or other motivating activities (see Box 39-1). If these measures are presented as games, the child is more likely to comply. The child's position is changed every 2 hours, and deep breathing is encouraged.

During the recovery period spend some time with the child to assess his or her perceptions of surgery. Play, drawing, and storytelling are excellent methods of discovering the child's thoughts. With such information the nurse can support or correct the child's perceptions and boost his or her self-esteem for having endured a stressful procedure.

Many pediatric patients are discharged shortly after surgery. Preparation for discharge begins with the preadmission preparation visit. The nurse should discuss instructions for postoperative care and review them throughout the perioperative visit. After discharge the nursing staff often makes phone calls to check the patient's status. Patient education and compliance with discharge instructions can also be assessed during these phone calls (Barnes, 2000) (see Guidelines box).

GENERAL HYGIENE AND CARE

Maintaining Healthy Skin

Maintaining an IV line, removing a dressing, positioning a child in bed, changing a diaper, using electrodes, or using restraints have the potential to contribute to skin injury. General guidelines for skin care are listed in the Guidelines box on p. 1141.

Assessment of the skin is easiest to accomplish during the bath. Examine for early signs of injury. Risk factors include impaired mobility, protein malnutrition, edema, incontinence, sensory loss, anemia, infection, failure to turn the patient, and intubation. Critically ill children are at a higher risk of pressure ulcers and skin breakdown because they often have several risk factors combined. The incidence in these children has been reported as high as 27% (Curley, Quigley, and Lin, 2003). Identification of risk factors helps to determine children who need a more thorough skin assessment. Several risk assessment scales are available for use in pediatrics such as the Braden Q Scale (Curley, Razmus, Roberts, et al., 2003) and the Glamorgan Scale (Willock, Baharestani, and Anthony, 2009). Assessment should occur within 24 hours of admission to identify pressure ulcers and wounds that occurred before admission. Pressure ulcers in children typically occur on the occiput, ears, sacrum, and scapula (Amlung, Miller, and Bosley, 2001); the heels and sacrum are common sites in adults.

When capillary blood flow is interrupted by pressure, the blood flows back into the tissue when the pressure is relieved. As the body attempts to reoxygenate the area, a bright red flush appears. This reactive hyperemia, or flush, is the earliest sign of tissue compromise and pressure-related ischemia. If pressure is prolonged, reactive hyperemia is not sufficient to revitalize ischemic tissue. Pressure ulcers in hospitalized children are uncommon, with reported rates of 1% to 13% (Noonan, Quigley, and Curley, 2006). Risk factors associated with pressure ulcers in pediatric intensive care unit patients include edema, length of stay, increasing positive end-expiratory pressure, lack of turning, use of a specialty bed in the turning mode, and weight loss (McCord, McElvain, Sachdeva, et al., 2004). Medical devices such as pulse oximeter probes, bilevel and continuous positive airway pressure masks, oxygen cannulas, orthotics, and casts can also cause pressure ulcers.

Pressure ulcers are staged to classify the amount of tissue damage that has occurred.* Necrotic tissue must be removed so the tissue depth can be assessed accurately. Accurate documentation of redness or obvious skin breakdown is essential. Color, size (diameter and depth), location, presence of sinus tracts, odor, exudate, and response to treatment are observed and recorded at least daily.

Pressure ulcers can develop when the pressure on the skin and underlying tissues is greater than the capillary closing pressure, causing capillary occlusion. If the pressure remains unrelieved, vessels can collapse, resulting in tissue anoxia and cellular death. Pressure ulcers most often occur over bony prominences. These lesions are usually very deep (stage IV), extending into subcutaneous tissue or even more deeply into muscle, tendon, or bone.

GUIDELINES

Postoperative Care

- Ensure that preparations are made to receive child:
  - Bed or crib is ready.
  - Intravenous pumps and poles, suction apparatus, and oxygen flow meter are at bedside.
- Obtain baseline information:
  - Take vital signs, including blood pressure; keep blood pressure cuff in place and deflated to lessen disturbance to child.
  - Take and record vital signs more frequently if any value fluctuates.
  - Inspect operative area.
  - Check dressing if present.
    - Outline any bleeding area on dressing or cast with pen.
    - Reinforce, but do not remove, loose dressing.
    - Observe areas below surgical site for blood that may have drained toward bed.
    - Assess for bleeding and other symptoms in areas not covered with a dressing such as throat after tonsillectomy.
  - Assess skin color and characteristics.
  - Assess level of consciousness and activity.
- Notify health care provider of any irregularities in child's condition.
- Assess for evidence of pain. (See Pain Assessment, Chapter 30.)
- Review surgeon's orders after completing initial assessment and check that any preoperative orders such as seizure or cardiac medications have been reordered and can be given by available routes (oral preparations may be contraindicated).
- Monitor vital signs as ordered and more often if indicated.
- Check dressings for bleeding or other abnormalities.
- Check bowel sounds.
- Observe for signs of shock, abdominal distention, and bleeding.
- Assess for bladder distention.
- Observe for signs of dehydration.
- Detect presence of infection:
  - Take vital signs every 2 to 4 hours as ordered.
  - Collect or request needed specimens.
  - Inspect wound for signs of infection—redness, swelling, heat, pain, and purulent drainage.

*Staging of pressure ulcers and guidelines for prevention and management of pressure ulcers are available from the National Pressure Ulcer Advisory Panel, npuap.org.

GUIDELINES

Skin Care

- Keep skin free of excess moisture (e.g., urine or fecal incontinence, wound drainage, excessive perspiration).
- Cleanse skin with mild nonalkaline soap or soap-free cleaning agents for routine bathing.
- Provide daily cleansing of eyes, oral and diaper or perineal areas, and any areas of skin breakdown.
- Apply non–alcohol-based moisturizing agents after cleansing to retain moisture and rehydrate skin.
- Use minimum amount of tape and adhesives. On very sensitive skin use a protective, pectin-based or hydrocolloid skin barrier between skin and tape or adhesives.
- Place pectin-based or hydrocolloid skin barriers directly over excoriated skin. Leave barrier undisturbed until it begins to peel off or for 5 to 7 days. With wet, oozing excoriations, place a small amount of stoma powder on site, remove excess powder, and apply skin barrier. Hold barrier in place for several minutes to allow it to soften and mold to skin surface.
- Alternate electrode and probe placement sites and thoroughly assess underlying skin typically every 8 to 24 hours.
- Eliminate pressure secondary to medical devices such as tracheostomy tubes, wheelchairs, braces, and gastrostomy tubes.
- Be certain that fingers or toes are visible whenever extremity is used for intravenous (IV) or arterial line.
- Use a drawsheet to move child in bed or onto a stretcher; do not drag child from under arms.
- Position in neutral alignment; pillows, cushions, or wedges may be needed to prevent hip abduction and pressure to bony prominences such as heels, elbows, and sacral and occipital areas. When child is positioned laterally, pillows or cushions between knees, under head, and under upper arm helps promote neutral body alignment. Avoid donut cushions because they can cause tissue ischemia. Elevate head of bed 30 degrees or less to reduce pressure unless contraindicated.
- Do not massage reddened bony prominences because this can cause deep tissue damage; provide pressure relief to those areas instead.
- Routinely assess the child's nutritional status. A child who is NPO (nothing by mouth) for several days and is receiving only IV fluids is nutritionally at risk, which can also affect the ability of the skin to maintain its integrity. Consider parenteral nutrition.

A pressure-reduction device reduces pressure but does not prevent it from causing capillary closure; therefore turning and repositioning are always included when using these devices. Most of these items are overlays that are placed on top of the regular mattress. A pressure-relief device maintains pressure below that which would cause capillary closure. These devices are usually high-technology beds that are used for patients who have multiple problems and cannot be turned effectively.

Friction and shear contribute to pressure ulcers. Friction occurs when the surface of the skin rubs against another surface such as bedsheets. The skin may have the appearance of an abrasion. Skin damage is usually limited to the epidermal and upper layers. It most often occurs over the elbows, heels, or occiput. Prevention of friction injury includes the use of customized splinting over infants' heels; gel pillows under the heads of infants and toddlers; moisturizing agents; transparent dressings over susceptible areas; and soft, smooth bed linens and clothing (Baharestani and Ratliff, 2007). By itself friction does not cause tissue necrosis; however, when it acts with gravity, it results in shear injury.

Shear is the result of the force of gravity pushing down on the body and friction of the body against a surface such as the bed or chair. For example, when a patient is in the semi-Fowler position and begins to slide to the foot of the bed, the skin over the sacral area remains in the same place because of the resistance of the bed surface. The blood vessels in the area are stretched and may cause small-vessel thrombosis and tissue death (Bryant and Doughty, 2000). Prevention of shear injury includes using lift sheets when repositioning a patient, elevating the bed no more than 30 degrees for short periods, and using the knee gatch to interrupt the pull of gravity on the body toward the foot of the bed.

Epidermal stripping results when the epidermis is removed unintentionally when tape is removed. These lesions are usually shallow and irregularly shaped. Babies are at increased risk for epidermal injury. Prevention includes using no tape when possible, securing dressings with laced binders (Montgomery straps) or stretchy netting (Spandage or stockinette). Using porous or low-tack tapes (e.g., Medipore, paper, hydrogel), using alcohol-free skin sealants (No Sting Barrier Film), or picture framing wounds with hydrocolloid or wafer barriers (e.g., DuoDERM, Coloplast, Stomahesive) and then taping on top of the barrier also reduces epidermal stripping.

Tape is placed so there is no tension, traction, or wrinkles on the skin. To remove tape, slowly peel it away while stabilizing the underlying skin. Adhesive remover may be used to break the adhesive bond but may be drying to the skin. Avoid adhesive removers in preterm neonates because absorption rates vary and toxicity may occur. Remove the adhesive with water to prevent absorption and irritation. Wetting the tape with water or alcohol-based foam hand cleansers may facilitate removal.

Chemical factors can also lead to skin damage. Fecal incontinence, especially when mixed with urine; wound drainage; or gastric drainage around gastrostomy tubes can erode the epidermis. The skin can quickly progress from redness to denudement if exposure continues. Moisture barriers, gentle cleansing as soon after exposure as possible, and skin barriers can be used to prevent damage caused by chemical factors. In addition, foam dressings that wick moisture away from the skin are helpful around gastrostomy tubes and tracheostomy sites.

Bathing

Most infants and children can be bathed in a basin at the bedside or on the bed in a standard bathtub or shower. For infants and young children confined to bed, use the towel method. Immerse two towels in a dilute soap solution and wring them damp. With the child lying supine on a dry towel, place one damp towel on top of the child and use it to gently clean the body. Discard the towel, dry the child, and turn him or her prone. Repeat the procedure using the second damp towel.

School-age children and adolescents may shower or bathe. Nurses need to use judgment regarding the amount of supervision the child requires. Some can assume this responsibility unaided, but others need someone in constant attendance. Children with cognitive impairments, physical limitations such as severe anemia or leg deformities, or suicidal or psychotic problems (who may commit bodily harm) require close supervision.

Areas that require special attention are the ears, between skinfolds, the neck, the back, and the genital area. The genital area should be cleansed carefully and dried, with particular care given to skinfolds. In uncircumcised boys, usually those older than 3 years of age, the foreskin should be retracted gently, the exposed surfaces cleansed, and the foreskin then replaced. If the condition of the glans indicates inadequate cleaning such as accumulated smegma, inflammation,

phimosis, or foreskin adhesions, teaching proper hygiene is indicated. In the Vietnamese and Cambodian cultures the foreskin traditionally is not retracted until adulthood. Older children have a tendency to avoid cleaning the genitalia; therefore they may need a gentle reminder.

Oral Hygiene

Mouth care is an integral part of daily hygiene and should be continued in the hospital. For some young children this is their first introduction to the use of a toothbrush. Infants and debilitated children require the nurse or a family member to perform mouth care. Although young children can manage a toothbrush and are encouraged to use it, most need assistance to perform satisfactorily. Although older children are capable of brushing and flossing without assistance, they sometimes need to be reminded.

Hair Care

Children should have their hair brushed and combed at least once daily. The hair is styled for comfort and in a manner pleasing to the child and parents. It should not be cut without parental permission, although clipping hair to provide access to a scalp vein for IV insertion may be necessary.

If children are hospitalized for more than a few days, the hair may need to be shampooed. Infants' hair may be washed during the daily bath or less frequently. For most children washing the hair and scalp once or twice weekly is sufficient unless there is an indication for more frequent washing such as after a high fever and profuse sweating. Adolescents normally have increased oily sebaceous secretions that require frequent hair care and more frequent shampoos.

Almost any child can be transported to an accessible sink for shampooing. Those who are unable to be transported can receive a shampoo in their beds with adequate protection, specially adapted equipment or positioning, or dry shampoo caps. When necessary a shampoo basin may be used or the child may be positioned near the edge of the bed, towels placed under the shoulders, a large plastic garbage bag draped at the edge of the bed with one open end under the shoulders, and the hair placed inside the opening. The other end is opened and placed in a collection container. Water can be transported in a basin.

Feeding the Sick Child

Loss of appetite is a symptom common to most childhood illnesses. Because an acute illness is usually short, the nutritional state is seldom compromised. Urging food on the sick child may precipitate nausea and vomiting. In most cases children can usually determine their own need for food.

Refusing to eat may also be one way children can exert power and control in an otherwise helpless situation. For young children loss of appetite may be related to depression caused by separation from their parents. Parents' concern with eating can intensify the problem. Forcing a child to eat meets with rebellion and reinforces the behavior as a control mechanism. Encourage parents to relax any pressure during an acute illness. Although it is best to provide high-quality, nutritious foods, the child may desire foods and liquids that contain mostly empty or nonnutritional calories. Some well-tolerated foods include gelatin, diluted clear soups, carbonated drinks, flavored ice pops, dry toast, and crackers. Even though these substances are not nutritious, they can provide necessary fluid and calories.

Dehydration is always a hazard when children have a fever or anorexia, especially when accompanied by vomiting or diarrhea. Fluids should not be forced, and the child is not awakened to take fluids. Forcing fluids may create the same difficulties as urging the child to eat unwanted food. Gentle persuasion with preferred beverages will usually meet with success. Using play techniques can also be effective (see Guidelines box).

When the child is feeling better, appetite usually begins to improve. It is best to take advantage of any hungry period by serving

GUIDELINES

Feeding a Sick Child

- Take a dietary history (see Chapter 29) and use information to make eating time as similar to eating at home as possible.
- Encourage parents or other family members to feed child or be present at mealtimes.
- Make mealtimes pleasant; avoid any procedures immediately before or after eating; make certain that child is rested and pain free.
- Serve small, frequent meals rather than three large meals or serve three meals and nutritious between-meal snacks.
- Provide finger foods for young children.
- Involve children in food selection and preparation whenever possible.
- Serve small portions and serve each course separately such as soup first followed by meat, potatoes, and vegetables and ending with dessert. With young children camouflage size of food by cutting meat thicker so less appears on plate or folding a cheese slice in half. Offer second helpings.
- Ensure a variety of foods, textures, and colors.
- Provide food selections that are favorites of most children such as peanut butter and jelly sandwiches, hot dogs, hamburgers, macaroni and cheese, pizza, spaghetti, tacos, fried chicken, corn, and fruit yogurt.
- Avoid foods that are highly seasoned, have strong odors, or are all mixed together unless typical of cultural practices.
- Provide fluid selections that are favorites of most children such as fruit punch, cola, ginger ale, sweetened tea, flavored ice pops, sherbet, ice cream, milk, milkshakes, pudding, gelatin, clear broth, or creamed soups.
- Offer nutritious snacks such as frozen yogurt or pudding, ice cream, oatmeal or peanut butter cookies, hot cocoa, cheese slices, pieces of raw vegetable or fruit, and dried fruit or cereal.
- Make food attractive and different; for example:
  - Serve a "picnic lunch" in a paper bag.
  - Pack food in a Chinese take-out container; decorate container.
  - Put a "face" or a "flower" on a hamburger or sandwich with pieces of vegetable.
  - Use a cookie cutter to shape a sandwich.
  - Serve pudding, yogurt, or juice frozen as an ice pop.
  - Make Slurpies or snow cones by pouring flavored syrup on crushed ice.
  - Add food coloring to water or milk.
  - Serve fluids through brightly colored or unusually shaped straws.
  - Make "bowtie" sandwiches by cutting them in triangles and placing two points together.
  - Slice sandwiches into "fingers."
  - Grate mounds of cheese.
  - Cut apples horizontally to make circles.
  - Put a banana on a hot dog bun and spread with peanut butter.
  - Break uncooked spaghetti into toothpick lengths and skewer cheese, cold meat, vegetables, or fruit chunks.
- Praise children for what they do eat.
- Do not punish children for not eating by removing their dessert or putting them to bed.

high-quality foods and snacks. If the child still refuses to eat, offer nutritious fluids such as prepared breakfast drinks. Parents can help by bringing in food items from home, especially if the family's cultural eating habits differ from the hospital food. A clinical dietitian may be consulted for alternative food choices.

When children are placed on special diets such as clear liquids after surgery or during episodes of diarrhea, it is essential to assess their intake and readiness to advance to more complex foods.

Regardless of the type of diet, charting the amount consumed is an important nursing responsibility. Descriptions need to be detailed and accurate such as "4 oz of orange juice, one pancake, and 8 oz of milk." Comments such as "ate well" or "ate poorly" are inadequate. Charting the percentage of the meal eaten is also inadequate unless food is measured before serving.

If the parents are involved in the child's care, encourage them to keep a list of everything he or she eats. Using a premeasured cup for fluids ensures a more accurate estimate of intake. A comparison of the intake at each meal can isolate food deficiencies such as insufficient intake of meat or vegetables. Behaviors associated with mealtime also identify possible factors influencing appetite. For example, the observation, "Child eats well when with other children but plays with food if left alone in room," helps the nurse plan mealtime activities that stimulate the child's appetite.

Although sick children's appetites may be poor and not characteristic of their home eating habits, the hospital stay provides numerous opportunities for nurses to assess the family's knowledge of good nutrition and to implement teaching as needed to improve nutritional intake.

Controlling Elevated Temperatures

An elevated temperature, most frequently from fever but occasionally caused by hyperthermia, is one of the most common symptoms of illness in children. This manifestation is a great concern to parents. To facilitate an understanding of fever, the following terms are defined:

- *Set point*—The temperature around which body temperature is regulated by a thermostat-like mechanism in the hypothalamus
- *Fever (hyperpyrexia)*—An elevation in set point such that body temperature is regulated at a higher level; may be arbitrarily defined as temperature above 38° C (100.4° F)
- *Hyperthermia*—Body temperature exceeding the set point, which usually results from the body or external conditions creating more heat than the body can eliminate such as in heat stroke, aspirin toxicity, seizures, or hyperthyroidism

Body temperature is regulated by a thermostat-like mechanism in the hypothalamus. This mechanism receives input from centrally and peripherally located receptors. When temperature changes occur, these receptors relay the information to the thermostat, which either increases or decreases heat production to maintain a constant set point temperature. However, during an infection pyrogenic substances cause an increase in the normal set point of the body, a process that is mediated by prostaglandins. Consequently the hypothalamus increases heat production until the core temperature reaches the new set point.

During the fever (febrile) state shivering and vasoconstriction generate and conserve heat during the chill phase of fever, raising central temperatures to the level of the new set point. The temperature reaches a plateau when it stabilizes in the higher range. When the temperature is greater than the set point or when the pyrogen is no longer present, a crisis, or defervescence, of the temperature occurs.

Most fevers in children are of brief duration with limited consequences and are viral in origin. When fever is caused by bacteria, endotoxins are produced that activate the inflammatory process and produce fever (Rote, Huether, and McCance, 2000). Fever has physiologic benefits, including increased white blood cell activity, interferon production and effectiveness, and antibody production and enhancement of some antibiotic effects (Considine and Brennan, 2007). Contrary to popular belief, neither the rise in temperature nor its response to antipyretics indicates the severity or etiology of the infection, which casts doubt on the value of using fever as a diagnostic or prognostic indicator.

Therapeutic Management

Treatment of elevated temperature depends on whether it is attributable to a fever or hyperthermia. Because the set point is normal in hyperthermia but increased in fever, different approaches must be used to lower body temperature successfully.

Fever. The principal reason for treating fever is the relief of discomfort. Relief measures include pharmacologic and environmental intervention. The most effective intervention is the use of antipyretics to lower the set point.

Antipyretics include acetaminophen, aspirin, and nonsteroidal antiinflammatory drugs (NSAIDs). Acetaminophen is the preferred drug. Aspirin should not be given to children because of its association in children with influenza virus or chickenpox and Reye syndrome. One nonprescription NSAID, ibuprofen, is approved for fever reduction in children as young as 6 months of age. The dosage is based on the initial temperature level: 5 mg/kg of body weight for temperatures less than 39.2° C (102.6° F) or 10 mg/kg for temperatures greater than 39.2° C. The recommended dosage for pain is 10 mg/kg every 6 to 8 hours, and the recommended maximum daily dose for pain and fever is 40 mg/kg. The duration of fever reduction is generally 6 to 8 hours and is longer with the higher dose.

The recommended doses of acetaminophen should never be exceeded. Acetaminophen should be given every 4 hours but no more than 5 times in 24 hours. Because body temperature normally decreases at night, three or four doses in 24 hours will control most fevers. The temperature is usually retaken 30 minutes after the antipyretic is given to assess its effect but should not be measured repeatedly. The child's level of discomfort is the best indication for continued treatment.

The nurse can use environmental measures to reduce fever if they are tolerated by the child and if they do not induce shivering. Shivering is the way that the body has of maintaining the elevated set point by producing heat. Compensatory shivering greatly increases metabolic requirements above those already caused by the fever.

Traditional cooling measures such as wearing minimum clothing; exposing the skin to air; reducing room temperature; increasing air circulation; and applying cool, moist compresses to the skin (e.g., the forehead) are effective if used approximately 1 hour after an antipyretic is given so the set point is lowered. Cooling procedures such as sponging or tepid baths are ineffective in treating febrile children (these measures are effective for hyperthermia) either when used alone or in combination with antipyretics, and they cause considerable discomfort (Axelrod, 2000).

Seizures associated with a fever occur in 3% to 4% of all children, usually in those between 6 months and 6 years of age. Approximately 30% of children have subsequent febrile seizures; a younger age at onset and a family history of febrile seizures are associated with increased incidence of recurring episodes. There is little evidence to support the use of antipyretic drugs or anticonvulsants to prevent a second febrile seizure; nursing intervention should focus on ways to

provide care and comfort during a febrile illness. Simple febrile seizures lasting less than 10 minutes do not cause brain damage or other debilitating effects (Jones and Jacobsen, 2007; Sadleir and Scheffer, 2007). (See Febrile Seizures, Chapter 45.)

Hyperthermia. Unlike in fever, antipyretics are of no value in hyperthermia because the set point is already normal. Consequently cooling measures are used. Cool applications to the skin help reduce the core temperature. Cooled blood from the skin surface is conducted to inner organs and tissues; and warm blood is circulated to the surface, where it is cooled and recirculated. The surface blood vessels dilate as the body attempts to dissipate heat to the environment and facilitate this cooling process.

Commercial cooling devices such as cooling blankets or mattresses are available to reduce body temperature. Place the patient on the bed and cover with a sheet or lightweight blanket. Frequent temperature monitoring is essential to prevent excessive cooling of the body.

Traditionally cool compresses decrease high temperature. For tepid tub baths it is usually best to start with warm water and gradually add cool water until the desired water temperature of 37° C (98.6° F) is reached to acclimate the child to the lower water temperature. Generally the temperature of the water only has to be 1° C (or 2° F) less than the child's temperature to be effective. The child is placed directly in the tub of tepid water for 15 to 20 minutes while water is gently squeezed from a washcloth over the back and chest or gently sprayed over the body from a sprayer. In the bed or crib cool washcloths or towels are used, exposing only one area of the body at a time. Continue sponging for approximately 20 minutes.

After the tub or sponge bath the child is dried and dressed in lightweight pajamas, a nightgown, or a diaper and placed in a dry bed. He or she is dried by gently rubbing the skin surface with a towel to stimulate circulation. The temperature is retaken 30 minutes after the tub or sponge bath. The tub or sponge bath should not be continued or restarted until the skin surface is warm or if the child feels chilled. Chilling causes vasoconstriction, which defeats the purpose of the cool applications. In this condition little blood is carried to the skin surface; the blood remains primarily in the viscera to become heated.

Whether a temperature elevation in the critically ill child is caused by fever or hyperthermia, it should be treated aggressively. The metabolic rate increases 10% for every 1° C increase in temperature and 3 to 5 times during shivering, thus increasing oxygen, fluid, and caloric requirements. If the child's cardiovascular or neurologic system is already compromised, these increased needs are especially hazardous. In all children with an elevated temperature, attention to adequate hydration is essential. Most children's needs can be met through additional oral fluids.

Family Teaching and Home Care

Fever is one of the most common problems for which parents seek health care. High levels of parental anxiety (fever phobia) surrounding potential complications of fever such as seizures and dehydration are prevalent and can result in overusing antipyretics (Purssell, 2008). Parents need to know that sponging is indicated for elevated temperatures from hyperthermia rather than fever and that ice water and alcohol are inappropriate, potentially dangerous solutions (Axelrod, 2000). They should know how to take the child's temperature, how to read the thermometer accurately, and when to seek professional care (see Family-Centered Care box). Some of the newer temperature-measuring devices such as plastic strip or digital thermometers may be better suited for home use. (See Temperature, Chapter 29.) If the use of acetaminophen or ibuprofen is indicated, the parents need instructions in administering the drug. Emphasize accuracy in both the amount of drug given and the time intervals at which the drug is administered. Along with reduced activity, encourage small, frequent sips of clear liquids. Dress the child in light clothing; use a light blanket for children who are cold or shivering (Walsh and Edwards, 2006).

FAMILY-CENTERED CARE

The Child with Fever

Call Office Immediately If:

- Your child is younger than 2 months old.
- The fever is over 40.6° C (105° F).
- Your child looks or acts very sick, including a stiff neck, persistent vomiting, purplish spots on the skin, confusion, trouble breathing after you have cleaned his or her nose, or inability to be comforted.

Call Within 24 Hours If:

- The fever is between 40° and 40.6° C (104° and 105° F), especially if your child is younger than 2 years old.
- Your child has had a fever for more than 24 hours without an obvious cause or location of infection.
- Your child has had a fever for more than 3 days.
- Your child has burning or pain with urination.
- Your child has a history of febrile seizures.
- The fever went away for more than 24 hours and then returned.
- You have other concerns or questions.

Modified from Schmitt BD: *Instructions for pediatric patients,* ed 2, Philadelphia, 1999, Saunders.

SAFETY

Safety is an essential component of any patient's care, but children have special characteristics that require an even greater concern for safety. Because small children in the hospital are separated from their usual environment and do not possess the capacity for abstract thinking and reasoning, it is the responsibility of everyone who comes in contact with them to maintain protective measures throughout their hospital stay. Nurses need to understand the age level at which each child is operating and plan for safety accordingly.

Identification (ID) bands are particularly important for children. Infants and unconscious patients are unable to tell or respond to their names. Toddlers may answer to any name or to a nickname only. Older children may exchange places, give an erroneous name, or choose not to respond to their own names as a joke, unaware of the hazards of such practices.

Environmental Factors

All of the environmental safety measures for the protection of adults apply to children, including good illumination, floors that are clear of fluid and objects that might contribute to falls, and nonskid surfaces in showers and tubs. All staff members should be familiar with the area-specific fire plan. Elevators and stairways should be made safe.

All windows should be secured. Window blind and curtain cords should be out of reach with split cords to prevent strangulation. Pacifiers should not be tied around the neck or attached to an infant by string.

Electrical equipment should be in proper working order and used only by personnel familiar with its use. It should not be in

contact with moisture or situated near tubs. Electrical outlets should have covers to prevent burns in small children, whose exploratory activities may extend to inserting objects into the small openings.

Staff members should practice proper care and disposal of small objects such as syringe caps, needle covers, and temperature probes. Staff also must check bathwater carefully before placing the child in it and never leave children alone in a bathtub. Infants are helpless in water, and small children (and some older ones) may turn on the hot water faucet and be burned severely.

Furniture is safest when it is scaled to the child's proportions, sturdy, and well balanced to prevent it being tipped over easily. A special hazard for children is the danger of entrapment under an electronically controlled bed when it is activated to descend. Infants and small children must be securely strapped into infant seats, feeding chairs, and strollers. Baby walkers should not be used because they provide access to hazards, resulting in burns, falls, and poisonings. Infants; young children; and children who are weak, paralyzed, agitated, confused, sedated, or cognitively impaired are never left unattended on treatment tables, on scales, or in treatment areas. Even premature infants are capable of surprising mobility; therefore portholes in incubators must be securely fastened when not in use.

Crib sides up should always be raised and fastened securely. Use cribs that meet federal safety standards (www.cpsc.gov/info/cribs/index.html). Anyone attending an infant or small child on a stretcher or table should never turn away without maintaining hand contact with the child (i.e., keeping one hand on the child's back or abdomen to prevent rolling, crawling, or jumping from the open crib (Fig. 39-3).

The safest sleeping position to prevent sudden infant death syndrome is wholly supine (AAP, Task Force on Sudden Infant Death Syndrome, 2005). No pillows should be placed in a young infant's crib while the infant is sleeping.

Toys

Toys play a vital role in the everyday lives of children, and they are no less important in the hospital setting. Nurses are responsible for assessing the safety of toys brought to the hospital by well-meaning parents and friends. They should be appropriate to the child's age, condition, and treatment. For example, if the child is receiving oxygen, electrical or friction toys or equipment are not safe because sparks can cause oxygen to ignite. Inspect toys to ensure that they are nonallergenic, washable, and unbreakable and that they have no small, removable parts that can be aspirated or swallowed or otherwise inflict injury on a child. All objects within reach of children younger than 3 years of age should pass the choke tube test. A toilet paper roll is a handy guide. If a toy or object fits into the cylinder (items <1¼ inches [3.175 cm] across or balls <1¾ inches [4.45 cm] in diameter), it is a potential choking danger to the child. Latex balloons pose a serious threat to children of all ages. If the balloon breaks, a child may put a piece of the latex in his or her mouth. If it is aspirated or swallowed, the latex piece is difficult to remove, resulting in choking. Latex balloons should never be permitted in the hospital setting.

FIG 39-3 The nurse maintains hand contact when her back is turned.

Preventing Falls

Falls prevention begins with identification of children most at risk for falls. Pediatric hospitals use various methods to identify a child's risk for falls (Child Health Corporation of America, 2009). After a risk assessment is performed, multiple interventions are needed to minimize pediatric patients' risk of falling, including education of patient, family, and staff.

To identify children at risk of falling, perform a fall risk assessment on patients on admission and throughout hospitalization. Risk factors for hospitalized children include the following:

- Medication effects—Postanesthesia or sedation; analgesics or narcotics, especially in those who have never had narcotics in the past and in whom effects are unknown
- Altered mental status—Secondary to seizures, brain tumors, or medications
- Altered or limited mobility—Reduced skill at ambulation secondary to developmental age, disease process, tubes, drains, casts, splints, or other appliances; new to ambulation with assistive devices such as walkers or crutches
- Postoperative children—Risk of hypotension or syncope secondary to large blood loss, a heart condition, or extended bed rest
- History of falls
- Infants or toddlers in cribs with side rails down or on the daybed with family members
- Once children at risk for falls have been identified, alert other staff members by posting signs on the door and at the bedside, applying a special colored armband labeled "Fall Precautions," labeling the chart with a sticker, or documenting information on the chart.

Prevention of falls requires alterations in the environment, including the following:

- Keep the bed in the lowest position with the breaks locked and the side rails up.
- Place the call bell within reach.
- Ensure that all necessary and desired items are within reach (e.g., water, glasses, tissues, snacks).
- Offer toileting on a regular basis, especially if the patient is taking diuretics or laxatives.
- Keep lights on at all times, including dim lights while sleeping.
- Lock wheelchairs before transferring patients.
- Ensure that the patient has an appropriate-size gown and nonskid footwear. Do not allow gowns or ties to drag on the floor during ambulation.
- Keep the floor clean and free of clutter. Post a "wet floor" sign if the floor is wet.
- Ensure that the patient has glasses on if he or she normally wears them.

Preventing falls also relies on age-appropriate education of patients. Help the child ambulate even though he or she may have ambulated well before hospitalization. Patients who have been lying in bed need to get up slowly, sitting on the side of the bed before standing.

The nurse also needs to educate family members:

- Call the nursing staff for assistance and do not allow patients to get up independently.
- Keep the side rails of the crib or bed up whenever patient is in it.
- Do not leave infants on the daybed; put them in the crib with the side rails up.
- When all family members need to leave the bedside, notify the staff and ensure that the patient is in the bed or crib with the side rails up and call bell within reach (if appropriate).

Infection Control

According to the Centers for Disease Control and Prevention (CDC), approximately 2 million patients each year develop nosocomial (hospital-acquired) infections. These infections occur when there is interaction among patients, health care personnel, equipment, and bacteria (Quality, Equipment Hold Keys to Infection Control, 2006). Nosocomial infections are preventable if caregivers practice meticulous cleaning and disposal techniques.

Standard Precautions synthesize the major features of universal (blood and body fluid) precautions (designed to reduce the risk of transmission of bloodborne pathogens) and body substance isolation (designed to reduce the risk of transmission of pathogens from moist body substances). Standard Precautions involve the use of barrier protection such as gloves, goggles, gown, or mask to prevent contamination from (1) blood; (2) all body fluids, secretions, and excretions except sweat, regardless of whether they contain visible blood; (3) nonintact skin; and (4) mucous membranes. They are designed for the care of all patients to reduce the risk of transmission of microorganisms from both recognized and unrecognized sources of infection.

Transmission-based precautions are designed for patients with documented or suspected infection or colonization (presence of microorganisms in or on patient but without clinical signs and symptoms of infection) with highly transmissible or epidemiologically important pathogens for which additional precautions beyond Standard Precautions are needed to interrupt transmission in hospitals. There are three types of transmission-based precautions: Airborne Precautions, Droplet Precautions, and Contact Precautions. They may be combined for diseases that have multiple routes of transmission (Box 39-2). They are to be used in addition to Standard Precautions.

Airborne Precautions reduce the risk of airborne transmission of infectious agents. Airborne transmission occurs by dissemination of either airborne droplet nuclei (small-particle residue [<5 mm] of evaporated droplets that may remain suspended in the air for long periods) or dust particles containing the infectious agent. Microorganisms carried in this manner can be dispersed widely by air currents and may become inhaled by or deposited on a susceptible host within the same room or over a longer distance from the source patient, depending on environmental factors. Special air handling and ventilation are required to prevent airborne transmission. Airborne Precautions apply to patients with known or suspected infection with pathogens transmitted by the airborne route such as measles, varicella, and tuberculosis.

Droplet Precautions reduce the risk of droplet transmission of infectious agents. Droplet transmission involves contact of the conjunctivae or the mucous membranes of the nose or mouth of a susceptible person with large-particle droplets (>5 mm) containing microorganisms generated from a person who has a clinical disease or who is a carrier of the microorganism. Droplets are generated from the source person primarily during coughing, sneezing, or talking and during procedures such as suctioning and bronchoscopy. Transmission requires close contact between source and recipient persons because droplets do not remain suspended in the air and generally travel only short distances, usually 3 feet or less, through the air. Because droplets do not remain suspended in the air, special air handling and ventilation are not required to prevent droplet

BOX 39-2 TYPES OF PRECAUTIONS AND PATIENTS REQUIRING THEM

Standard Precautions for Preventing Transmission of Pathogens

Use Standard Precautions for the care of all patients.

Airborne Precautions

In addition to Standard Precautions, use Airborne Precautions for patients known or suspected to have serious illnesses transmitted by airborne droplet nuclei. Examples of such illnesses include measles, varicella (including disseminated zoster), and tuberculosis.

Droplet Precautions

In addition to Standard Precautions, use Droplet Precautions for patients known or suspected to have serious illnesses transmitted by large-particle droplets. Examples of such illnesses include the following:

- Invasive *Haemophilus influenzae* type b disease, including meningitis, pneumonia, epiglottitis, and sepsis
- Invasive *Neisseria meningitidis* disease, including meningitis, pneumonia, and sepsis
- Other serious bacterial respiratory tract infections spread by droplet transmission, including diphtheria (pharyngeal), mycoplasmal pneumonia, pertussis, pneumonic plague, streptococcal pharyngitis, pneumonia, and scarlet fever in infants and young children
- Serious viral infections spread by droplet transmission, including adenovirus, influenza, mumps, parvovirus B19, and rubella

Contact Precautions

In addition to Standard Precautions, use Contact Precautions for patients known or suspected to have serious illnesses easily transmitted by direct patient contact or contact with items in the patient's environment. Examples of such illnesses include the following:

- Gastrointestinal, respiratory, skin, or wound infections or colonization with multidrug-resistant bacteria judged by the infection control program based on current state, regional, or national recommendations to be of special clinical and epidemiologic significance
- Enteric infections with a low infectious dose or prolonged environmental survival, including *Clostridium difficile;* for diapered or incontinent patients: enterohemorrhagic *Escherichia coli* O157:H7, *Shigella* organisms, hepatitis A, or rotavirus
- Respiratory syncytial virus, parainfluenza virus, or enteroviral infections in infants and young children.
- Skin infections that are highly contagious or that may occur on dry skin, including diphtheria (cutaneous), herpes simplex virus (neonatal or mucocutaneous), impetigo, major (noncontained) abscesses, cellulitis or decubitus, pediculosis, scabies, staphylococcal furunculosis in infants and young children, zoster (disseminated or in the immunocompromised host)
- Viral or hemorrhagic conjunctivitis
- Viral hemorrhagic infections (Ebola, Lassa, or Marburg)

Modified from Garner JS: Guidelines for isolation precautions in hospitals, *Infect Control Hosp Epidemiol* 17(1):66, 1996.

transmission. Droplet Precautions apply to any patient with known or suspected infection with pathogens that can be transmitted by infectious droplets (see Box 39-2).

Contact Precautions reduce the risk of transmission of microorganisms by direct or indirect contact. Direct-contact transmission involves skin-to-skin contact and physical transfer of microorganisms to a susceptible host from an infected or colonized person such as occurs when turning or bathing patients. Direct-contact transmission also can occur between two patients (e.g., by hand contact). Indirect contact transmission involves contact of a susceptible host with a contaminated intermediate object, usually inanimate, in the patient's environment. Contact Precautions apply to specified patients known or suspected to be infected or colonized with microorganisms that can be transmitted by direct or indirect contact.

! NURSING ALERT

The most common piece of medical equipment, the stethoscope, can be a potent source of harmful microorganisms and nosocomial infections.

Nurses caring for young children are frequently in contact with body substances, especially urine, feces, and vomitus. They need to exercise judgment concerning situations when gloves, gowns, or masks are necessary. For example, nurses should wear gloves and possibly gowns for changing diapers when there are loose or explosive stools. Otherwise the plastic lining of disposable diapers provides a sufficient barrier between the hands and body substances.

Antimicrobial-resistant organisms are causing increasing numbers of nosocomial infections. In hospitals patients are the most significant sources of methicillin-resistant *Staphylococcus aureus,* and the main mode of transmission is patient to patient via the hands of a health care provider (Eaton, 2005; Quality, Equipment Hold Keys to Infection Control, 2006). Hand washing is the most critical infection control practice.

During feedings wear a gown if the child is likely to vomit or spit up, which often occurs during burping. When wearing gloves, wash the hands thoroughly after removing them because gloves fail to provide complete protection. The absence of visible leaks does not indicate that the gloves are intact.

Another essential practice of infection control is that all needles (uncapped and unbroken) are disposed of in a rigid, puncture-resistant container located near the site of use. Consequently these containers are installed in patients' rooms. Because children are naturally curious, extra attention is needed in selecting a suitable type of container and a location that prevents access to the discarded needles (Fig. 39-4). The use of needleless systems allows secure syringe or IV tubing attachment to vascular access devices without the risk of needlestick injury to the child or nurse.

Transporting Infants and Children

Infants and children need to be transported within the unit and to areas outside the pediatric unit. Infants and small children can be carried for short distances within the unit, but for more extended trips the child should be securely transported in a suitable conveyance.

Small infants can be held or carried in the horizontal position with the back supported and the thigh grasped firmly by the carrying arm (Fig. 39-5, *A*). In the football hold the infant is carried on the nurse's arm with the head supported by the hand and the body held securely between the nurse's body and elbow (Fig. 39-5, *B*). Both of these holds leave the nurse's other arm free for activity. The

FIG 39-4 To prevent needlestick injuries, used needles (and other sharp instruments) are not capped or broken and are disposed of in rigid, puncture-resistant container located near site of use. Note placement of container to prevent children's access to contents.

infant also can be held in the upright position with the buttocks on the nurse's forearm and the front of the body resting against the nurse's chest. The infant's head and shoulders are supported by the nurse's other arm in case the infant moves suddenly (Fig. 39-5, *C*). Older infants are able to hold their heads erect but are still subject to sudden movements.

Special care is needed in transporting critically ill patients in the hospital. Critically ill children should always be transported on a stretcher or bed (rather than carried) by at least two staff members with monitoring continued during transport. A blood pressure monitor (or standard blood pressure cuff), pulse oximeter, and cardiac monitor/defibrillator should accompany every patient (Warren, Fromm, Orr, et al., 2004). Airway equipment and emergency medications should accompany the patient.

Restraining Methods and Therapeutic Holding

The Joint Commission (Joint Commission on Accreditation of Healthcare Organizations, 2001) defines restraint as "any method, physical or mechanical, which restricts a person's movement, physical activity, or normal access to his or her body." Before initiating restraints the nurse completes a comprehensive assessment of the patient to determine whether the need for a restraint outweighs the risk of not using one. Restraints can result in loss of dignity, violation of patient rights, psychologic harm, physical harm, and even death.

Consider alternative methods first and document them in the patient's record. Some examples of alternative measures include bringing a child to the nurses' station for continuous observation, providing diversional activities such as music, encouraging the participation of the parents, or therapeutic holding. Therapeutic holding is the use of a secure, comfortable, temporary holding position that provides close physical contact with the parent or caregiver for 30 minutes or less. The use of restraints can often be avoided with adequate preparation of the child, parental or staff supervision of the child, or adequate protection of a vulnerable site such as an infusion device.

The nurse needs to assess the child's development, mental status, potential to hurt others or self, and safety. He or she is responsible

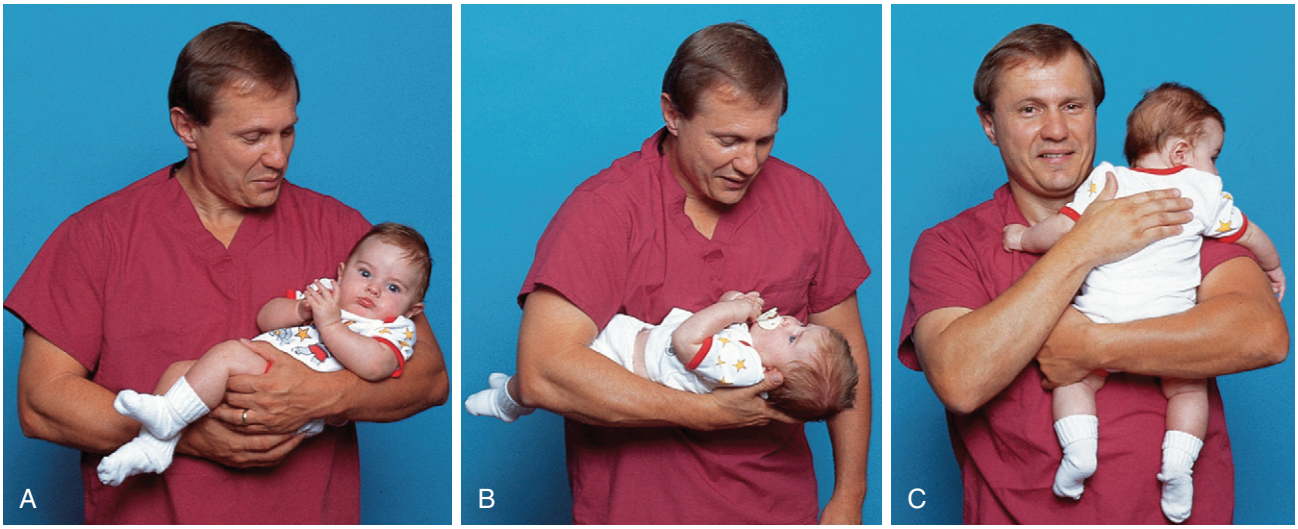

FIG 39-5 Transporting infants. **A,** Infant's thigh firmly grasped in nurse's hand. **B,** Football hold. **C,** Back supported.

for selecting the least restrictive type of restraint. Using less restrictive restraints is often possible by gaining the cooperation of the child and parents. Examples of less restrictive restraints are provided in Table 39-4.

The two types of restraints used with children are classified as medical-surgical and behavioral restraints. When a standard or protocol states that immobilization is required 100% of the time as part of the procedure or postprocedural care process, the restraint device is considered a part of routine care. For example, the postoperative use of elbow restraints after a cleft lip repair, if written in the protocol or standard of care and used for 100% of patients, would not fall under The Joint Commission or Centers for Medicare and Medicaid Services mandates concerning restraints.

Medical-surgical restraints are used for children with an artificial airway or airway adjunct for delivery of oxygen, indwelling catheters, tubes, drains, lines, pacemaker wires, or suture sites. The medical-surgical restraint is used to ensure that safe care is given to the patient. The potential risks of the restraint are offset by the potential benefit of providing safer care. Medical-surgical restraints may be instituted for any of the following reasons:

- Risk for interruption of therapy used to maintain oxygenation or airway patency
- Risk of harm if indwelling catheter, tube, drain, line, pacemaker wire, or suturing is removed, dislodged, or ruptured
- Patient confusion, agitation, unconsciousness, or developmental inability to understand direct requests or instructions

Medical-surgical restraints can be initiated by an individual order or protocol; the use of protocol must be authorized by an individual order. The order for continued use of restraints must be renewed each day. Patients are monitored at least every 2 hours.

Behavioral restraints are limited to situations in which there is a significant risk of patients physically harming themselves or others because of behavior and when nonphysical interventions are not effective. Before initiating a behavioral restraint, the nurse should assess the patient's mental, behavioral, and physical status to determine the cause for the child's potentially harmful behavior. If behavioral restraints are indicated, a collaborative approach involving the patient (if appropriate), the family, and the health care team should be used. An order must be obtained as soon as possible but no longer than 1 hour after the initiation of behavioral restraints. Behavioral

restraints for children must be reordered every 1 to 2 hours based on age. A licensed independent practitioner must conduct an in-person evaluation within 1 hour and again every 4 hours until restraints are discontinued. Children in behavioral restraints must be observed continuously and assessed every 15 minutes. Assessment components include signs of injury associated with applying restraint, nutrition and hydration, circulation and range-of-motion of extremities, vital signs, hygiene and elimination, physical and psychologic status and comfort, and readiness for discontinuation of restraint. The nurse must use clinical judgment in setting a schedule for when each of these parameters needs to be evaluated because every parameter must be assessed during each 15-minute physical assessment.

Restraints with ties must be secured to the bed or crib frame, not the side rails. Suggestions for increasing safety and comfort while the child is in a restraint include leaving one finger breadth between skin and the device and tying knots that allow for quick release. The nurse can also increase safety by ensuring that the restraint does not tighten as the child moves and decreasing wrinkles or bulges in it. Placing jacket restraints over an article of clothing; placing limb restraints below waist level, below knee level, or distal to the IV; and tucking in dangling straps also increase safety and comfort.

Mummy Restraint or Swaddle

When an infant or small child requires short-term restraint for examination or treatment that involves the head and neck (e.g., venipuncture, throat examination, gavage feeding), a papoose board with straps or a mummy wrap effectively controls the child's movements. A blanket or sheet is opened on the bed or crib with one corner folded to the center. The infant is placed on the blanket with the shoulders at the fold and feet toward the opposite corner. With the infant's right arm straight down against the body, the right side of the blanket is pulled firmly across the infant's right shoulder and chest and secured beneath the left side of the body. The left arm is placed straight against the infant's side, and the left side of the blanket is brought across the shoulder and chest and locked beneath the body on the right side. The lower corner is folded and brought over the body and tucked or fastened securely with safety pins. Safety pins can be used to fasten the blanket in place at any step in the process. To modify the mummy restraint for chest examination, bring the folded edge of the blanket over each arm and under the back and then fold the loose edge over and secure it at a point below the chest to allow visualization and access to the chest (Fig. 39-6, *A*).

Jacket Restraint

A jacket restraint is sometimes used to keep the child safe in various chairs. The jacket is put on the child with the ties in back so he or she is unable to manipulate them. The jacket restraint is also useful as a means of maintaining the child in a desired horizontal position. The long tapes secured to the understructure of the crib keep the child inside the crib.

Arm and Leg Restraints

Occasionally the nurse needs to restrain one or more extremities or limit their motion. Several commercial restraining devices are available, including disposable wrist and ankle restraints (Fig. 39-6, *B*). Restraints must be appropriate to the child's size and padded to prevent undue pressure, constriction, or tissue injury; and the extremity must be observed frequently for signs of irritation or impaired circulation. The ends of the restraints are never tied to the side rails because lowering the rail disturbs the extremity, frequently with a jerk that may hurt or injure the child.

FIG 39-6 Restraint examples from most restrictive to least restrictive. **A,** Mummy restraint. **B,** Wrist restraints. **C,** Elbow restraints.

Elbow Restraint

Sometimes it is important to prevent the child from reaching the head or face (e.g., after lip surgery, when a scalp vein infusion is in place, or to prevent scratching in skin disorders). Elbow restraints fashioned from a variety of materials function well (Fig. 39-6, *C*). Commercial elbow restraints are available. An improvised form of elbow restraint consists of a piece of muslin long enough to reach

comfortably from just below the axilla to the wrist with a number of vertical pockets into which tongue depressors are inserted. The restraint is wrapped around the arm and secured with tapes or pins. It may be necessary to pin the top of the restraint to the undershirt sleeve to prevent the restraint from slipping.

POSITIONING FOR PROCEDURES

Infants and small children are unable to cooperate for many procedures. Therefore the nurse is responsible for minimizing their movement and discomfort with proper positioning. Older children usually need only minimal, if any, restraint. Careful explanation and preparation beforehand and support and simple guidance during the procedure are usually sufficient. For painful procedures the child should receive adequate analgesia and sedation to minimize pain and the need for excessive restraint. For local anesthesia use buffered lidocaine to reduce the stinging sensation or a topical anesthetic. (See Pain Management, Chapter 30.)

Femoral Venipuncture

The nurse places the child supine with the legs in a frog position to provide extensive exposure of the groin area. The infant's legs can be controlled effectively by the nurse's forearms and hands (Fig. 39-7). Only the side used for the venipuncture is uncovered so the practitioner is protected if the child urinates during the procedure. Pressure is applied to the site to prevent oozing from it.

Extremity Venipuncture or Injection

The most common sites of venipuncture are the veins of the extremities, especially the arm and hand. A convenient position is to place the child in the parent's (or assistant's) lap with the child facing the parent and in the straddle position. Next place the child's arm for venipuncture on a firm surface such as a treatment table. The nurse can partially stabilize the child's outstretched arm and have the parent hug the child's upper body, preventing movement; the nurse can then use the parent's arm to immobilize the venipuncture site. This type of restraint also comforts the child because of the close body contact and allows each person to maintain eye contact (Fig. 39-8).

Lumbar Puncture

Pediatric LP sets contain smaller spinal needles, but sometimes the practitioner will specify a different size or type of needle. The technique for LP in infants and children is similar to that in adults, although modifications are suggested in neonates, who have less distress in a side-lying position with modified neck extension than in flexion or a sitting position.

Children are usually easiest to control in the side-lying position, with the head flexed and the knees drawn up toward the chest. Even cooperative children need to be held gently to prevent possible trauma from unexpected, involuntary movement. They can be reassured that, although they are trusted, holding will serve as a reminder to maintain the desired position. It also provides a measure of support and reassurance to them.

A flexed sitting or side-lying position may be used, depending on the child's ability to cooperate and whether sedation will be used. In the sitting position with the hips flexed the interspinous space is maximized (Abo, Chen, Johnston, et al., 2010). The child is placed with the buttocks at the edge of the table. The nurse's hands immobilize the infant's arms and legs. Neck flexion is not necessary (Fig. 39-9).

! NURSING ALERT

The sitting position may interfere with chest expansion and diaphragm excursion; and in infants the soft, pliable trachea may collapse. Therefore observe the child for difficulty breathing.

FIG 39-8 Therapeutic holding of child for extremity venipuncture with parental assistance.

FIG 39-7 Positioning infant for femoral venipuncture.

FIG 39-9 Side-lying position for lumbar puncture.

Specimens and spinal fluid pressure are obtained, measured, and sent for analysis in the same manner as for adult patients. Take vital signs as ordered and observe the child for any changes in level of consciousness, motor activity, and other neurologic signs. Post-LP headache may occur and is related to postural changes; this is less severe when the child lies flat. Headache is seen much less frequently in young children than in adolescents.

Bone Marrow Aspiration or Biopsy

The position for a bone marrow aspiration or biopsy depends on the chosen site. In children the posterior or anterior iliac crest is used most frequently, but in infants the tibia may be selected because it is easy to access the site and hold the child.

If the posterior iliac crest is used, the child is positioned prone. Sometimes a small pillow or folded blanket is placed under the hips to facilitate obtaining the bone marrow specimen. Children should receive adequate analgesia or anesthesia to relieve pain. If the child might awaken, he or she may need to be held, preferably by two people (i.e., one person to immobilize the upper body and a second person to immobilize the lower extremities).

COLLECTION OF SPECIMENS

Many of the specimens needed for diagnostic examination of children are collected in much the same way as they are for adults. Older children are able to cooperate if given proper instruction regarding what is expected of them. However, infants and small children are unable to follow directions or control body functions sufficiently to help in collecting some specimens.

Fundamental Procedure Steps Common to All Procedures

The following steps are very important for every procedure and should be considered fundamental aspects of care. Although these steps are important, they are not listed in each of the specimen collection procedures.

1. Assemble the necessary equipment.
2. Identify the child using two patient identifiers (e.g., patient name and medical record or birth date; neither can be a room number). Compare the same two identifiers with the specimen container and order.
3. Perform hand hygiene, maintain aseptic technique, and follow Standard Precautions.
4. Explain the procedure to parents and child according to the developmental level of the child; reassure the child that the procedure is not a punishment.
5. Provide atraumatic care and position the child securely.
6. Prepare area with antiseptic agent.
7. Place specimens in appropriate containers and apply a patient identification label to the specimen container in the presence of the child and family.
8. Discard puncture device in puncture-resistant container near the site of use.
9. Wash the procedural preparation agent off if povidone-iodine is used, if skin is sensitive, and for infants.
10. Remove gloves and perform hand hygiene after the procedure. Have children wash their hands if they have helped.
11. Praise the child for helping.
12. Document pertinent aspects of the procedure such as number of attempts, site and amount of blood or urine withdrawn, and type of test performed.

Urine Specimens

Older children and adolescents can use a bedpan or urinal or be trusted to follow directions for collection in the bathroom. However, they may have special needs. School-age children are cooperative but curious. They are concerned about the reasons behind things and are likely to ask questions regarding the disposition of their specimen and what one expects to discover from it. Self-conscious adolescents may be reluctant to carry a specimen through a hallway or waiting room and appreciate a paper bag for disguising the container. The presence of menses may be an embarrassment or a concern to teenage girls; therefore it is a good idea to ask them about this and make adjustments as necessary. The specimen can be delayed, or a notation made on the laboratory slip to explain the presence of red blood cells.

Preschoolers and toddlers are usually unable to void on request. It is often best to offer them water or other liquids that they enjoy and wait about 30 minutes until they are ready to void voluntarily.

Children better understand what is expected if the nurse uses familiar terms such as "pee-pee," "wee-wee," or "tinkle." Some have difficulty voiding in an unfamiliar receptacle. Potty chairs or a potty hat placed on the toilet is usually satisfactory. Toddlers who have recently acquired bladder control may be especially reluctant because they undoubtedly have been admonished for "going" in places other than those approved by parents. Enlisting the parents' help usually leads to success. For infants and toddlers who are not toilet trained, special urine collection bags with self-adhering material around the opening at the point of attachment are used. To prepare the infant, the genitalia, perineum, and surrounding skin are washed and dried thoroughly because the adhesive does not stick to a moist, powdered, or oily skin surface. The collection bag is easiest to apply if attached first to the perineum, progressing to the symphysis pubis (Fig. 39-10). With girls the perineum is stretched taut during application to ensure a leakproof fit. With boys the penis and sometimes the scrotum are placed inside the bag. The adhesive portion of the bag must be applied to the skin firmly all around the genital area to avoid leakage. The bag is checked frequently and removed as soon as the specimen is available because the moist bag may become loosened on an active child. For some types of urine testing such as specific gravity, ketones, glucose, and protein, the nurse can aspirate urine directly from the diaper. If the urine is not tested within 30 minutes, the specimen is refrigerated or placed in a sterile container with a preservative. Superabsorbent disposable diapers may absorb all urine and may also produce a false crystalluria. Specific gravity measurements are accurate for up to 4 hours provided that the disposable diapers are kept folded. Urine samples collected by the cotton-ball method were accurate for pH and specific gravity and were atraumatic to the skin of newborns (Burke, 1995).

! NURSING ALERT

When using a urine collection bag, cut a small slit in the diaper and pull the bag through to allow room for urine to collect and to facilitate checking on the contents. To obtain small amounts of urine use a syringe without a needle to aspirate urine directly from the diaper. If diapers with absorbent gelling material that trap urine are used, place a small gauze dressing, some cotton balls, or a urine collection device inside the diaper to collect urine and aspirate it with a syringe.

Clean-Catch Specimens

Clean-catch specimen traditionally refers to a urine sample obtained for culture after the urethral meatus is cleaned and the first few

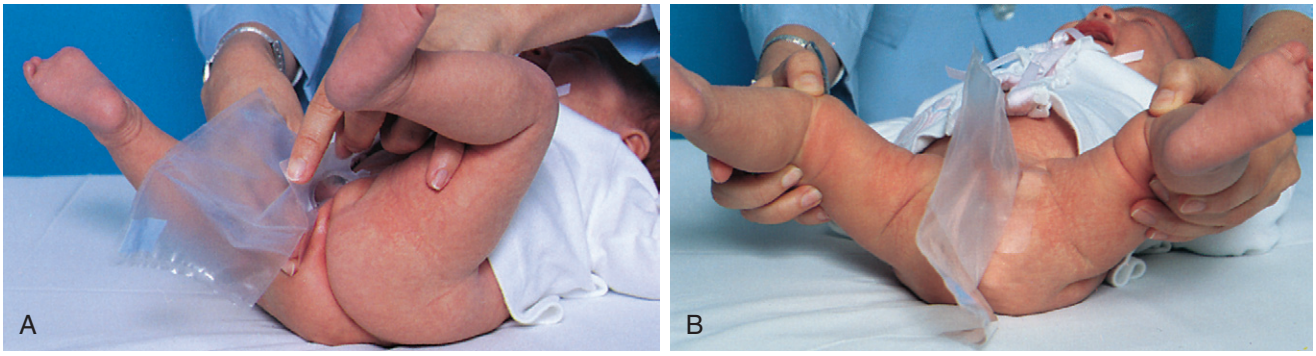

FIG 39-10 Application of urine collection bag. **A,** On female infants adhesive portion is applied to exposed and dried perineum first. **B,** Bag adheres firmly around the perineal area to prevent urine leakage.

milliliters of urine are voided (midstream specimen). In girls the perineum is wiped with an antiseptic pad from front to back. In boys the tip of the penis is cleansed.

Twenty-Four-Hour Collection

Collection bags are required in infants and small children for a 24-hour collection. Older children require special instruction about notifying someone when they need to void or have a bowel movement so urine can be collected separately and is not discarded. Some older school-age children and adolescents can take responsibility for collection of their own 24-hour specimens, keep output records, and transfer each voiding to the 24-hour collection container.

The collection period always starts and ends with an empty bladder. At the time the collection begins, instruct the child to void and discard the specimen. All urine voided in the subsequent 24 hours is saved in a container with a preservative or placed on ice. Twenty-four hours from the time that the precollection specimen was discarded, the child is again instructed to void, the specimen is added to the container, and the entire collection is taken to the laboratory.

Infants and small children who are bagged for 24-hour urine collection require a special collection bag. Frequent removal and replacement of adhesive collection devices can produce skin irritation. A thin coating of sealant such as Skin-Prep applied to the skin helps to protect it and aids adhesion (unless its use is contraindicated such as in premature infants or children with irritated skin). Plastic collection bags with collection tubes attached are ideal when the container must be left in place for a time. These can be connected to a collecting device or emptied periodically by aspiration with a syringe. When such devices are not available, a regular bag with a feeding tube inserted through a puncture hole at the top of the bag serves as a satisfactory substitute. However, take care to empty the bag as soon as the infant urinates to prevent leakage and loss of contents. An indwelling catheter may also be placed for the collection period.

Bladder Catheterization and Other Techniques

Bladder catheterization or suprapubic aspiration is used when a specimen is urgently needed or a child is unable to void or otherwise provide an adequate specimen. In infants younger than 3 months of age who are febrile, urine specimens should be collected by bladder catheterization (McGillivray, Mok, Mulrooney, et al., 2008). The AAP recommends that urine collected by the bag can be used to determine whether it is necessary to obtain a catheterized urine specimen for culture (Wald, 2005).

TABLE 39-5 STRAIGHT CATHETER OR FOLEY CATHETER*

	SIZE (LENGTH OF INSERTION [CM]) FOR GIRLS	SIZE (LENGTH OF INSERTION [CM]) FOR BOYS
Term neonate	5-6 (5)	5-6 (6)
Infant-3 yr	5-8 (5)	5-8 (6)
4-8 yr	8 (5-6)	8 (6-9)
8 yr-prepubertal	10-12 (6-8)	8-10 (10-15)
Pubertal	12-14 (6-8)	12-14 (13-18)

*Foley catheters are approximately 1 Fr size larger because of the circumference of the balloon. Example: 10-Fr Foley catheter = ≈12-Fr calibration.

Preparation for catheterization includes instruction on pelvic muscle relaxation whenever possible. The toddler, preschooler, or younger child should blow on a pinwheel and press the hips against the bed or procedure table during catheterization to relax the pelvic and periurethral muscles. The nurse describes the location and function of the pelvic muscles briefly to the older child or adolescent. The patient then contracts and relaxes the pelvic muscles, and the relaxation procedure is repeated during catheter insertion. If the patient vigorously contracts the pelvic muscles when the catheter reaches the striated sphincter (proximal urethra in boys and midurethra in girls), catheter insertion is stopped temporarily. The catheter is neither removed nor advanced; instead the child is helped to press the hips against the bed or examining table and relax the pelvic muscles. The catheter is then gently advanced into the bladder (Gray, 1996).

Catheterization is a sterile procedure, and Standard Precautions for body substance protection should be followed. If the catheter is to remain in place, a Foley catheter is used. Table 39-5 lists guidelines for choosing the appropriate-size catheter and length of insertion. The supplies needed for this procedure include sterile gloves, sterile lubricant anesthetic, the appropriate-size catheter, povidone-iodine (Betadine) swabs or an alternative cleansing agent and 4 × 4–inch gauze squares, a sterile drape, and a syringe with sterile water if a Foley catheter is used. Test the balloon of the Foley catheter by injecting sterile water before catheter insertion.

Adolescent boys and children with a history of urethral surgery may be catheterized with a coudé-tipped catheter. Children with

myelodysplasia and those who have been identified as being sensitive or allergic to latex are catheterized with catheters manufactured from an alternative material. When an indwelling catheter is indicated for urinary drainage, a lubricious-coated or silicone catheter is selected because these materials produce less irritation of the urethral mucosa compared with Silastic or latex catheters when left in place for more than 72 hours.

A 2% lidocaine lubricant with applicator is assembled according to manufacturer instructions, and several drops of the lubricant are placed at the meatus. The child is advised that the lubricant is used to reduce any discomfort associated with inserting the catheter and that introduction of the catheter into the urethra will produce a sensation of pressure and a desire to urinate (Gray, 1996).

In male patients grasp the penis with the nondominant hand and retract the foreskin. In uncircumcised newborns and infants the foreskin may be adhered to the shaft; use care when retracting. If the penis is pendulous, place a sterile drape under the penis. Using the sterile hand, swab the glans and meatus 3 times with povidone-iodine. Gently introduce the tip of the lidocaine jelly applicator into the urethra 1 to 2 cm (0.4 to 0.8 inch) so the lubricant flows only into the urethra; insert 5 to 10 mL 2% lidocaine lubricant into the urethra and hold it in place for 2 to 3 minutes by gently squeezing the distal penis. Lubricate the catheter and insert it into the urethra while gently stretching the penis and lifting it to a 90-degree angle to the body. Resistance may occur when the catheter meets the urethral sphincter. Ask the patient to inhale deeply and advance the catheter. Do not force a catheter that does not easily enter the meatus, particularly if the child has had corrective surgery. For indwelling catheters, after urine is obtained, advance the catheter to the hub, inflate the balloon with sterile water, pull it back gently to test inflation, and connect it to the closed drainage system. Cleanse the glans and meatus and replace retracted foreskin. If blood is seen at any time during the procedure, discontinue the procedure and notify the practitioner.

In female patients place a sterile drape under the buttocks. Use the nondominant hand to gently separate and pull up the labia minora to visualize the meatus. Swab the meatus from front to back 3 times using a different povidone-iodine swab each time. Place 1 to 2 mL 2% lidocaine lubricant on the periurethral mucosa and insert the lubricant 1 to 2 mL into the urethral meatus. Delay catheterization for 2 to 3 minutes to maximize absorption of the anesthetic into the periurethral and intraurethral mucosa. Add lubricant to the catheter and gently insert it into the urethra until urine returns; then advance the catheter an additional 2.5 to 5 cm (1 to 2 inches). When using an indwelling Foley catheter, inflate the balloon with sterile water and gently pull back; then connect to a closed drainage system. Cleanse the meatus and labia (see Cultural Competence box). Because the use of lidocaine jelly can increase the volume of intraurethral lubricant, urine return may not be as rapid as when minimal lubrication is used.

CULTURAL COMPETENCE

Bladder Catheterization

Parents may be upset when their child is catheterized. Aside from the trauma the child experiences, some parents may fear that the procedure affects the daughter's virginity. To correct this misconception, the family may benefit from a detailed explanation of the genitourinary anatomy, preferably with a model that shows the separate vaginal and urethral openings. The nurse can also indicate that catheterization has no effect on virginity.

SAFETY ALERT

Do not advance the catheter too far into the bladder. Knotting of catheters and tubes within the bladder has been reported in several case studies. Feeding tubes should not be used for urinary catheterization because they are more flexible, longer, and prone to knotting compared with commercially designed urinary catheters (Foster, Ritchey, and Bloom, 1992; Gonzalez and Palmer, 1997; Kilbane, 2009; Levison and Wojtulewicz, 2004; Lodha, Ly, Brindle, et al., 2005; Turner, 2004).

Suprapubic aspiration is mainly used when the bladder cannot be accessed through the urethra (e.g., with some congenital urologic birth defects) or to reduce the risk of contamination that may be present when passing a catheter. With the advent of small catheters (5- and 6-Fr straight catheters), the need for suprapubic aspiration has decreased. Access to the bladder via the urethra has a much higher success rate than suprapubic aspiration, in which success depends on the practitioner's skill at assessing the location of the bladder and the amount of urine in the bladder.

Suprapubic aspiration involves aspirating bladder contents by inserting a 20- or 21-gauge needle in the midline approximately 1 cm (0.4 inch) above the symphysis pubis and directed vertically downward. The nurse prepares the skin as for any needle insertion, and the bladder should contain an adequate volume of urine. This can be assumed if the infant has not voided for at least 1 hour or the bladder can be palpated above the symphysis pubis. This technique is useful for obtaining sterile specimens from young infants because the bladder is an abdominal organ and easily accessed. Suprapubic aspiration is painful; therefore pain management during the procedure is important (see Atraumatic Care box).

Stool Specimens

Stool specimens are frequently collected from children to identify parasites and other organisms that cause diarrhea, assess gastrointestinal function, and check for occult (hidden) blood. Ideally stool should be collected without contamination with urine, but in children wearing diapers this is difficult unless a urine bag is applied. Children who are toilet trained should urinate first, flush the toilet, and then defecate into the toilet or a bedpan (preferably one that is placed on the toilet to avoid embarrassment) or a commercial potty hat.

Stool specimens should be large enough to obtain an ample sampling, not merely a fecal fragment. Specimens are placed in an

ATRAUMATIC CARE

Bladder Catheterization or Suprapubic Aspiration

- Use distraction to help the child relax (e.g., blowing bubbles, deep breathing, singing a song).
- Use lidocaine jelly to anesthetize the area before insertion of the catheter. EMLA cream (a eutectic mix of lidocaine and prilocaine) or LMX cream (lidocaine) may lessen an infant's discomfort as the needle passes through the skin for suprapubic aspiration, but care should be taken that the site is thoroughly cleaned and prepped before the procedure.
- Children often become agitated at being restrained for either procedure. Use comfort measures through touch and voice, both during and after the procedure, to help reduce the child's distress.

appropriate container, which is covered and labeled. If several specimens are needed, mark the containers with the date and time and keep them in a specimen refrigerator. Exercise care in handling the specimen because of the risk of contamination.

Blood Specimens

Whether the specimen is collected by the nurse or others, the nurse is responsible for making certain that specimens such as serial examinations and fasting specimens are collected on time and that the proper equipment is available. Collecting, transporting, and storing specimens can have a major impact on laboratory results.

Venous blood samples can be obtained by venipuncture or by aspiration from a peripheral or central access device. Withdrawing blood specimens through peripheral lock devices in small peripheral veins has varying degrees of success. Although it avoids an additional venipuncture for the child, attempting to aspirate blood from the peripheral lock may shorten the life of the device. However, the nurse can use central lines to withdraw blood samples (see Atraumatic Care box). When using an IV infusion site for specimen collection, consider the type of fluid being infused. For example, a specimen collected for glucose determination would be inaccurate if removed from a catheter through which glucose-containing solution was being administered.

The needed specimens are collected quickly, and pressure is applied to the puncture site with dry gauze until bleeding stops. The arm should be extended, not flexed, while pressure is applied for a few minutes after venipuncture in the antecubital fossa to reduce bruising. The nurse then covers the site with an adhesive bandage. In young children adhesive bandages pose an aspiration hazard; thus avoid using them or remove the adhesive bandage as soon as the bleeding stops. Applying warm compresses to ecchymotic areas increases circulation, helps remove extravasated blood, and decreases pain.

Arterial blood samples are sometimes needed for blood gas measurement, although noninvasive techniques such as **transcutaneous oxygen monitoring** and pulse oximetry are used frequently. Arterial samples may be obtained by arterial puncture using the radial, brachial, or femoral arteries or from indwelling arterial catheters. Assess adequate circulation before arterial puncture by observing capillary refill or performing the Allen test, a procedure that assesses the circulation of the radial, ulnar, or brachial arteries. Because unclotted blood is required, use only heparinized collection tubes or syringes. In addition, no air bubbles should enter the tube because they can alter blood gas concentration. Crying, fear, and agitation affect blood gas values; therefore make every effort to comfort the child. Pack the blood samples in

ATRAUMATIC CARE

Guidelines for Skin and Vessel Punctures

To Reduce the Pain Associated with Heel, Finger, Venous, or Arterial Punctures

- Apply EMLA (a eutectic mix of lidocaine and prilocaine) topically over the site if time permits (>60 minutes). LMX cream (lidocaine) also may be used and requires a shorter application time (30 minutes). To remove the transparent dressing atraumatically, grasp opposite sides of the film and pull the sides away from one another to stretch and loosen the film. After the film begins to loosen, grasp the other two sides and pull. Use iontophoresis (Numby Stuff) over the site if time permits (8 to 20 minutes, depending on the amount of current), a vapocoolant spray, or buffered lidocaine (injected intradermally near the vein with a 30-gauge needle) to numb the skin.
- Use nonpharmacologic methods of pain and anxiety control (e.g., ask the child to take a deep breath when the needle is inserted and again when the needle is withdrawn, to exhale a large breath or blow bubbles to "blow hurt away," or to count slowly and then faster and louder if pain is felt).
- Keep all equipment out of sight until used.
- Enlist parents' presence or assistance if they wish.
- Restrain child *only as needed* to perform the procedure safely; use therapeutic holding (see p. 1150).
- Allow the skin preparation to dry completely before penetrating the skin.
- Use the smallest gauge needle (e.g., 25 gauge) that permits free flow of blood; a 27-gauge needle can be used for obtaining 1 to 1.5 mL of blood and for prominent veins (needle length is only 1.25 cm [0.5 inch]).
- If possible, avoid putting an IV line in the dominant hand or the hand the child uses to suck the thumb.
- Use an automatic lancet device for precise puncture depth of the finger or heel; press the device lightly against the skin; avoid steadying the finger against a hard surface.
- Have a "two-try" only policy to reduce excessive insertion attempts (i.e., two operators each have two insertion attempts). If insertion is not successful after four punctures, consider alternative venous access such as a PICC; have a policy for identifying children with difficult access and appropriate interventions (e.g., most experienced operator for the first attempt, use transilluminator or ultrasonography for insertion guidance).

For Multiple Blood Samples

- Use an intermittent infusion device (saline lock) to collect additional samples from an existing IV line; consider PICC lines early, not as a last resort.
- Coordinate care to allow several tests to be performed on one blood sample using micromethods of testing.
- Anticipate tests (e.g., drug levels, chemistry, immunoglobulin levels) and ask the laboratory to save blood for additional testing.

For Heel Lancing in Newborns

- Heel lancing has shown to be more painful than venipuncture (Shah and Ohlsson, 2007); consider venipuncture when the amount of blood from the heel would require much squeezing (e.g., genetic screening tests).
- The effectiveness of EMLA is controversial, although application of 0.5 g for 30 minutes 4 times a day in preterm infants was found to be safe (Essink-Tebbes, Wuis, Liem, et al., 1999).
- Place diapered newborn against mother's bare chest in skin-to-skin contact 10 to 15 minutes before and during heel lance (Gray, Watt, and Blass, 2000).
- During the procedure administer sucrose and encourage the newborn to suck a pacifier. When commercially manufactured 24% sucrose solution is unavailable, add 1 tsp of table sugar to 4 tsp of sterile water. Use this solution to coat the pacifier or administer 2 mL to the tongue 2 minutes before the procedure. (See Evidence-Based Practice Box, Reduction of Minor Procedural Pain in Infants, p. 842.)
- One study found that breastfeeding during a neonatal heel lance was more effective than sucrose in reducing pain (Codipietro, Ceccarelli, and Ponzone, 2008).

IV, Intravenous; *PICC,* peripherally inserted central catheter.

ice to reduce blood cell metabolism and take it to the laboratory immediately.

Take capillary blood samples from children by fingerstick. A common method for taking peripheral blood samples from infants younger than 6 months of age is by a heelstick. Before the blood sample is taken, warm the heel for 3 minutes and cleanse the area with alcohol. Holding the infant's foot firmly with the free hand, the nurse then punctures the heel with an automatic lancet device. An automatic device delivers a more precise puncture depth and is less painful than using a lance (Vertanen, Fellman, Brommels, et al., 2001). A surgical blade of any kind is contraindicated. An example of a safe device is the BD Quickheel Safety Lancet. The Tenderfoot Preemie device* was compared with the Monolet lancet and was found to be safer than the lancet and required fewer heel punctures, less collection time, and lower recollection rates (Kellam, Sacks, Wailer, et al., 2001). Shepherd, Glenesk, Niven, and others (2005) reported that the Tenderfoot device was more effective and safer than a lancet for newborn screening tests. Although obtaining capillary blood gases is a common practice, these measures may not reflect arterial values accurately.

The most serious complications of infant heel puncture are necrotizing osteochondritis from lancet penetration of the underlying calcaneus bone, infection, and abscess of the heel. To avoid osteochondritis the puncture should be no deeper than 2 mm and should be made at the outer aspect of the heel. The boundaries of the calcaneus can be marked by an imaginary line extending posteriorly from a point between the fourth and fifth toes and running parallel with the lateral aspect of the heel and another line extending posteriorly from the middle of the great toe and running parallel with the medial aspect of the heel (Fig. 39-11). Repeated trauma to the walking surface of the heel can cause fibrosis and scarring that may interfere with locomotion.

No matter how or by whom the specimen is collected, children, even some older ones, fear the loss of their blood. This is particularly true for children whose condition requires frequent blood specimens. They mistakenly believe that blood removed from their body is a threat to their lives. Explaining to them that their body continuously produces blood provides them a measure of reassurance. When the blood is drawn, a comment such as, "Just look how red it is. You're really making a lot of nice red blood," confirms this information and affords them an opportunity to express their concern.

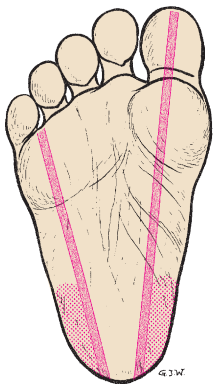

FIG 39-11 Puncture site (colored stippled area) on sole of infant's foot.

*The Tenderfoot Preemie device is manufactured by ITC, Edison, NJ, www.itcmed.com/products/tenderfoot-heel-incision-device.

An adhesive bandage gives them added assurance that the vital fluids will not leak out through the puncture site.

Children also dislike the discomfort associated with venous, arterial, and capillary punctures. They have identified these procedures as the ones most frequently causing pain during hospitalization and an arterial puncture as being one of the most painful of all procedures experienced. Toddlers are most distressed by venipuncture followed by school-age children and then adolescents. Consequently nurses need to institute pain-reduction techniques to lessen the discomfort of these procedures. (See Pain Management, Chapter 30.)

Respiratory Secretion Specimens

Collection of sputum or nasal discharge is sometimes required for the diagnosis of respiratory infections, especially tuberculosis and respiratory syncytial virus (RSV). Older children and adolescents are able to cough as directed and supply sputum specimens when given proper directions. The nurse must make it clear to them that a coughed specimen, not mucus cleared from the throat, is needed. It is helpful to demonstrate a deep cough. Infants and small children are unable to follow directions to cough and will swallow any sputum produced; therefore gastric washings (lavage) may be used to collect a sputum specimen. Sometimes a satisfactory specimen can be obtained using a suction device such as a mucus trap if the catheter is inserted into the trachea and the cough reflex elicited. A catheter inserted into the back of the throat is not sufficient. For children with a tracheostomy, a specimen is easily aspirated from the trachea or major bronchi by attaching a collecting device to the suction apparatus.

Nasal washings are usually obtained to diagnose an infection of RSV. The child is placed supine, and 1 to 3 mL of sterile normal saline is instilled with a sterile syringe (without needle) into one nostril. The contents are aspirated using a small, sterile bulb syringe and placed in a sterile container. Another method uses a syringe with 5 cm (2 inches) of 18- to 20-gauge tubing. The saline is instilled quickly and then aspirated to recover the nasal specimen. To prevent any additional discomfort, all of the equipment should be ready before beginning the procedure.

Other respiratory secretion collection methods include nasopharyngeal swabs to diagnose *Bordetella* pertussis and throat cultures. The nurse swabs both the tonsils and the posterior pharynx when obtaining a throat culture. The swab stick is inserted into the culture tube. Some culture kits require squeezing an ampule to release the culture medium.

ADMINISTRATION OF MEDICATION

Determination of Drug Dosage

Nurses must have an understanding of the safe dosages of medications they administer to children and the expected actions, possible side effects, and signs of toxicity. Unlike with adult medications, there are few standardized pediatric dosage ranges; and with a few exceptions drugs are prepared and packaged in average adult-dosage strengths.

Factors related to growth and maturation significantly alter an individual's capacity to metabolize and excrete drugs. Immaturity or defects in any of the important processes of absorption, distribution, biotransformation, or excretion can significantly alter the effects of a drug. Newborn and premature infants with immature enzyme systems in the liver (where most drugs are broken down and detoxified), lower plasma concentrations of protein for binding with drugs, and immaturely functioning kidneys (where most drugs are

excreted) are particularly vulnerable to the harmful effects of drugs. Beyond the newborn period many drugs are metabolized more rapidly by the liver, necessitating larger doses or more frequent administration. This is particularly important in pain control, when the dosage of analgesics may need to be increased or the interval between doses decreased.

Various formulas involving age, weight, and body surface area (BSA) as the basis for calculations have been devised to determine children's drug dosages. Because the administration of medication is a nursing responsibility, nurses need to have not only knowledge of drug action and patient responses but also resources for estimating safe dosages for children. Children's dosages are most often expressed in units of measure per body weight (mg/kg). Some medications such as chemotherapy are more precisely dosed using BSA. The ratio of BSA to weight varies inversely with length; therefore an infant who is shorter and weighs less than an older child or adult has relatively more BSA than would be expected from the weight. BSA is based on the West nomogram and is easily determined using conversion programs widely available on the Internet.

Checking Dosage

Administering the correct dosage of a drug is a shared responsibility between the practitioner who orders the drug and the nurse who carries out that order. Children react with unexpected severity to some drugs, and ill children may be especially sensitive to drugs. When a dose is ordered that is outside the usual range or when there is some question regarding the preparation or the route of administration, the nurse should check with the prescribing practitioner before proceeding with the administration because the nurse is legally liable for any drug administered.

Even when it has been determined that the dosage is correct for a particular child, many drugs are potentially hazardous or lethal. Most facilities have regulations requiring specified drugs to be double checked by another nurse before giving them to the child. Among drugs that require such safeguards are antiarrhythmics, anticoagulants, chemotherapeutic agents, and insulin. Others frequently included are epinephrine, opioids, and sedatives. Even if this precaution is not mandatory, nurses are wise to take such precautions. Errors in decimal point placement may occur and result in a 10-fold or greater dosage error.

Identifying the Child

Before the administration of any medication, the child must be identified correctly using two identifiers (e.g., name and medical record number or birth date). With an infant, young child, or nonverbal child, the parent or guardian (if present) can verify the child's identity. After verbal verification of the child's identity (by the parent, guardian, or child), the ID band should be verified using two identifiers. Bedside computers to scan the ID bracelet for electronic record updating may also be used.

Preparing the Parents

Nearly all parents have given some type of medication to their child and can describe the approaches they have found successful. In some cases it is less traumatic for the child if a parent gives the medication, provided that the nurse prepares the medication and supervises its administration. Children being given daily medications at home are accustomed to the parent's functioning in this capacity and are less likely to fuss than if a stranger administers the medication. Individual decisions need to be made regarding parental presence and participation such as holding the child during injections.

Preparing the Child

Every child requires psychologic preparation for parenteral administration of medication and supportive care during the procedure (see p. 1137). Even if children have received several injections, they rarely become accustomed to the discomfort and have as much right as any other child to understanding and patience from those giving the injection.

Oral Administration

The oral route is preferred for administering medications to children because of the ease of administration. Most medications are dissolved or suspended in liquid preparations. Although some children are able to swallow or chew solid medications at an early age, solid preparations are not recommended for young children because of the danger of aspiration.

Most pediatric medications come in palatable and colorful preparations for added ease of administration. Some have a slightly unpleasant aftertaste, but most children swallow these liquids with little, if any, resistance. Complaints of dislike from the child can be accepted, and the taste camouflaged whenever possible. Most pediatric units have preparations available for this purpose (see Atraumatic Care box).

Preparation

The devices available to measure medicines are not always sufficiently accurate for measuring the small amounts needed in pediatric nursing practice. Molded plastic cups offer reasonable accuracy in measuring moderate doses of liquids; on the other hand, paper cups are likely to have irregularly shaped or crumpled bottoms and retain considerable amounts of thick medication. Measures less than 1 tsp are impossible to determine accurately with a medicine cup.

ATRAUMATIC CARE

Encouraging a Child's Acceptance of Oral Medication

- Give the child a flavored ice pop or small ice cube to suck to numb the tongue before giving the drug.
- Mix the drug with a small amount (≈1 tsp) of sweet-tasting substance such as honey (except in infants because of the risk of botulism), flavored syrups, jam, fruit purees, sherbet, or ice cream; avoid essential food items because the child may later refuse to eat them.
- Give a "chaser" of water, juice, soft drink, or ice pop or frozen juice bar after the drug.
- If nausea is a problem, give a carbonated beverage poured over finely crushed ice before or immediately after the medication.
- When medication has an unpleasant taste, have the child pinch the nose and drink the medicine through a straw. Much of what we taste is associated with smell.
- Flavorings such as apple, banana, and bubble gum (e.g., FLAVORx) can be added at many pharmacies at nominal additional cost. An alternative is to have the pharmacist prepare the drug in a flavored, chewable troche or lozenge.*
- Infants will suck medicine from a needleless syringe or dropper in small increments (0.25 to 0.5 mL) at a time. Use a nipple or special pacifier with a reservoir for the drug.

*For information about compounding drugs, contact Technical Staff, Professional Compounding Centers of America, 9901 S. Wilcrest Drive, Houston, TX 77099, 800-331-2498, www.pccarx.com.

The teaspoon is an inaccurate measuring device and is subject to error. Teaspoons vary greatly in capacity, and different persons using the same spoon pour different amounts. Therefore measure a drug ordered in teaspoons in milliliters; the established standard is 5 mL/tsp. A convenient hollow-handled medicine spoon is available to measure and administer the drug accurately. Household measuring spoons can also be used when other devices are not available. A device called the *Medibottle* has shown to be more effective in delivering oral medication to infants than an oral syringe (Kraus, Stohlmeyer, Hannon, et al., 2001).

Another unreliable device for measuring liquids is the dropper, which varies to a greater extent than the teaspoon or measuring cup. The volume of a drop varies according to the viscosity (thickness) of the liquid measured. Viscous fluids produce much larger drops than thin liquids. Many medications are supplied with caps or droppers designed for measuring each specific preparation. These are accurate when used to measure that specific medication but are not reliable for measuring other liquids. Emptying dropper contents into a medicine cup invites additional error. Because some of the liquid clings to the sides of the cup, a significant amount of the drug can be lost.

The most accurate means for measuring small amounts of medication is the plastic disposable syringe, especially the tuberculin syringe for volumes less than 1 mL. Not only does the syringe provide a reliable measure, but it also serves as a convenient means for transporting and administering the medication. The medication can be placed directly into the child's mouth from the syringe.

Young children and some older children have difficulty swallowing tablets or pills. Because a number of drugs are not available in pediatric preparations, tablets need to be crushed before being given to these children. Commercial devices* are available, or simple methods can be used for crushing tablets. Not all drugs can be crushed (e.g., medication with an enteric or protective coating or formulated for slow release).

The nurse can teach children who must take solid oral medication for an extended period to swallow tablets or capsules. Training sessions include using verbal instruction, demonstration, reinforcement for swallowing progressively larger candy or capsules, no attention for inappropriate behavior, and gradual withdrawal of guidance after children can swallow their medication.

Because pediatric doses often require dividing adult preparations of medication, the nurse may be faced with the dilemma of accurate dosage. Only tablets that are scored can be halved or quartered accurately. If the medication is soluble, the tablet or contents of a capsule can be mixed in a small premeasured amount of liquid, and the appropriate portion given. For example, if half a dose is required, the tablet is dissolved in 5 mL of water, and 2.5 mL is given.

Administration

Although administering liquids to infants is relatively easy, the nurse must take care to prevent aspiration. While holding the infant in a semireclining position, place the medication in the mouth from a spoon, plastic cup, dropper, or syringe (without a needle). It is best to place the dropper or syringe along the side of the infant's tongue and administer the liquid slowly in small amounts, waiting for the child to swallow between deposits.

Medicine cups can be used effectively for older infants who are able to drink from a cup. Because of the natural outward tongue thrust in infancy, medications may need to be retrieved from the lips or chin and refed. Allowing the infant to suck the medication that has been placed in an empty nipple or inserting the syringe or dropper into the side of the mouth parallel to the nipple while the infant nurses is another convenient method for giving liquid medications to infants. Medication is not added to the infant's formula feeding because the child may subsequently refuse the formula. Dispose of any plastic covers that may be on the ends of syringes because these covers are choking hazards.

Young children who refuse to cooperate or resist consistently despite explanation and encouragement may require mild physical coercion. If so, it is carried out quickly and carefully. Make every effort to determine why the child resists and explain the reasons for the coercion in such a way that the child knows that it is being carried out for his or her well-being and is not a form of punishment. There is always a risk in using even mild forceful techniques. A crying child can aspirate a medication, particularly when lying on the back. If the nurse holds the child in the lap with the child's right arm behind the nurse, the left hand firmly grasped by the nurse's left hand, and the head securely cradled between the nurse's arm and body, the medication can be poured into the mouth slowly (Fig. 39-12).

Intramuscular Administration

Selecting the Syringe and Needle

The volume of medication prescribed for small children and the small amount of tissue available for injection necessitate selection of a syringe that can measure small amounts of solution. For volumes less than 1 mL the tuberculin syringe calibrated in 0.01-mL increments is appropriate. Minute doses may require the use of a 0.5-mL, low-dose syringe. These syringes, along with specially constructed needles, minimize the possibility of inadvertently administering incorrect amounts of a drug because of dead space, which allows fluid to remain in the syringe and needle after the plunger is

FIG 39-12 Nurse partially restrains child for easy and comfortable administration of oral medication.

*Several styles of pill crushers are available from Trademark Medical, 449 Sovereign Court, St. Louis, MO 63011, 800-325-9044, www.trademarkmedical.com.

pushed completely forward. A minimum of 0.2 mL of solution remains in a standard needle hub; therefore, when very small amounts of two drugs are combined in the syringe such as mixtures of insulin, the ratio of the two drugs can be altered significantly. Measures that minimize the effect of dead space are (1) when two drugs are combined in the syringe, always draw them up in the same order to maintain a consistent ratio between the drugs; (2) use the same brand of syringe (dead space may vary between brands); and (3) use one-piece syringe units (needle permanently attached to the syringe).

Dead space is also an important factor to consider when injecting medication because flushing the syringe with an air bubble adds an additional amount of medication to the prescribed dose. This can be hazardous when very small amounts of a drug are given. Consequently, flushing is not recommended, especially when less than 1 mL of medication is given. Syringes are calibrated to deliver a prescribed drug dose, and the amount of medication left in the hub and needle is not part of the syringe barrel calibrations. Certain drugs such as iron dextran and diphtheria and tetanus toxoid may cause irritation when tracked into the subcutaneous tissue. The Z-track method is recommended for use in infants and children rather than an air bubble. Changing the needle after withdrawing the fluid from the vial is another technique to minimize tracking.

The needle length must be sufficient to penetrate the subcutaneous tissue and deposit the medication into the body of the muscle. The needle gauge should be as small as possible to deliver the fluid safely. Smaller-diameter (25- to 30-gauge) needles cause the least discomfort, but larger gauges are needed for viscous medication and prevention of accidental bending of longer needles (see Evidence-Based Practice box).

Determining the Site

Factors to consider when selecting a site for an intramuscular (IM) injection on an infant or child include the following:

- The amount and character of the medication to be injected
- The amount and general condition of the muscle mass
- The frequency or number of injections to be given during the course of treatment
- The type of medication being given
- Factors that may impede access to or cause contamination of the site
- The child's ability to assume the required position safely

Older children and adolescents usually pose few problems in selecting a suitable site for IM injections; but infants, with their small and underdeveloped muscles, have fewer available sites. It is sometimes difficult to assess the amount of fluid that can be injected into a single site safely. Usually 1 mL is the maximum volume that should

EVIDENCE-BASED PRACTICE

Appropriate Site, Technique, Needle Size, and Dose for Intramuscular Injections in Infants, Toddlers, and Small Children

Ask the Question

In infants, toddlers, and small children, which site, technique, needle size and gauge, and dosage are best for intramuscular (IM) injections?

Search the Evidence

Search Strategies

Literature from 1990 to 2011 was reviewed to obtain clinical research studies related to this issue.

Databases Used

CINAHL, PubMed

Critically Analyze the Evidence

Searches reviewed were small studies. There were no randomized trials, double-blind trials, or large clinical studies addressing the subject of IM injections in children.

Infants and Toddlers

- A 16-mm needle is sufficient to penetrate the anterolateral thigh muscle if the needle is inserted at a 90-degree angle without pinching the muscle in children ages 2, 4, 6, and 18 months (Cook and Murtagh, 2002).
- A 25-mm needle is necessary to penetrate the thigh muscle when a 45-degree injection technique was used. Longer needle length is needed to fully deposit the medication into the muscle in children ages 2, 4, 6, and 18 months (Cook and Murtagh, 2002).
- For diphtheria–tetanus–pertussis (DTP) immunizations administered to infants 7 months of age and younger, 84.6% of injections were administered at the correct site (anterior thigh); 5.1% dorsogluteal and 2.6% deltoid muscles were administered at the incorrect sites (Daly, Johnston, and Chung, 1992).
- Vaccines containing adjuvant such as aluminum (e.g., DTaP, hepatitis A and B, diphtheria-tetanus [DT or Td]) should be given deep into the muscle to prevent local reactions (AAP Committee on Infectious Diseases and Pickering, 2009; CDC, 2002; Petousis-Harris, 2008; Taddio, Ilersich, Ipp, et al., 2009).
- Injecting adjuvant-containing vaccines into subcutaneous tissue increases the incidence of local reactions (Taddio, Ilersich, Ipp, et al., 2009; Zuckerman, 2000).
- Infants 4 months old experienced fewer local side effects (redness, tenderness, and swelling) when immunizations were administered into the anterior aspect of the thigh with a 25-mm (1-inch) needle vs. shorter 16-mm (⅝-inch) needle (Diggle and Deeks, 2000).
- Localized vaccine reactions were significantly reduced when long needles (25 mm) were used for infant immunizations (Diggle, Deeks, and Pollard 2006, Petousis-Harris, 2008).
- A 16-mm needle may be adequate for injections in small infants, and a 22- to 25-mm (⅞- to 1-inch) needle can be used in infants 2 months and older (AAP Committee on Infectious Diseases and Pickering, 2009).
- A 22- to 32-mm (⅞- to 1¼-inch) needle is recommended for injections in toddlers if deltoid muscle size is adequate (CDC, 2002).
- A minimum of a 25-mm-long needle is recommended for anterolateral thigh injection in toddlers (CDC, 2002).
- Dorsogluteal muscle should be avoided in infants, toddlers, and smaller preschoolers with smaller muscle mass because of the possibility of damaging the sciatic nerve (AAP Committee on Infectious Diseases and Pickering, 2009).
- In children older than age 1 year, deltoid muscle is recommended for IM injections. When multiple vaccines are given, two may be given in the thigh (anterior and lateral) because of its larger size (Diggle, 2003).
- Injections in the anterolateral thigh should be given at least 2.5 cm (1 inch) apart so local reactions are less likely to overlap (AAP Committee on Infectious Diseases and Pickering, 2009).

EVIDENCE-BASED PRACTICE

Appropriate Site, Technique, Needle Size, and Dose for Intramuscular Injections in Infants, Toddlers, and Small Children—cont'd

- No research or supportive data were found regarding the amount of medication to be given at the different sites in infants and toddlers.
- Small and preterm infants may only tolerate up to 0.5 mL in each muscle to prevent local complications, and 1 mL of medication is recommended for infants less than 12 months; no data can be found to refute or support such a recommendation.

Children and Adolescents

- A 22- to 25-gauge needle for all IM childhood immunizations is recommended (AAP Committee on Infectious Diseases and Pickering, 2009; CDC, 2002).
- Deltoid muscle may be used for immunizations in toddlers, older children, and adolescents (AAP Committee on Infectious Diseases and Pickering, 2009; CDC, 2002).
- 16-mm for children <60 kg and 25-mm needle for children 60-70 kg are appropriate for IM injections in the deltoid injection site (Koster, Stellato, Kohn, et al., 2009).
- Ventrogluteal site is relatively free of important nerves and vascular structures and is the site of choice for pediatric IM injections in children of all ages; no complications at this site were reported (Beecroft and Kongelbeck, 1994).
- Longer needles (25 mm) were preferred for injection when bunching the skin and injecting; shorter needles (16 mm) were perceived as causing fewer localized reactions when the injection was administered with the skin held taut (Groswasser, Kahn, Bouche, et al., 1997).
- Needle length was found to be the most significant variable for local reactions in children after injection: 25-mm needle was associated with fewer localized reactions vs. 16-mm needle (Davenport, 2004).
- In children older than age 1 year deltoid muscle is recommended for IM injections. When multiple vaccines are given, two may be given in the thigh (anterior and lateral) because of its larger size (Diggle, 2003).
- Injections in the anterolateral thigh should be given at least 2.5 cm (1 inch) apart so local reactions are less likely to overlap (AAP Committee on Infectious Diseases and Pickering, 2009).
- IM injections in the buttocks with longer needles using a 90-degree angle are associated with less reactogenicity (Petousis-Harris, 2008).

Apply the Evidence: Nursing Implications

There is *low-quality evidence with strong recommendation* (Guyatt, Oxman, Vist, et al., 2008) to continue administering IM injections to children in the anterolateral thigh (up to 12 months old), deltoid (12 months and older), and ventrogluteal site.. Needle length is an important factor in decreasing local reactions; the length should be adequate to deposit the medication into the muscle for IM injections. Recommendations are for a 25-mm (1-inch) needle in infants, a 25- to 32-mm (1- to 1¼-inch) needle for toddlers, and a 38- to 51-mm (1½- to 2-inch) needle for older children; preterm and small emaciated infants may require a shorter needle (16 to 25 mm [⅝ to 1 inch]) based on weight and muscle mass size.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries

Describe various methods for identifying the appropriate site, technique, needle size, and dose for IM injections in infants, toddlers, and small children.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence

Integrate evidence into practice by using the techniques for IM injections in clinical care.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice

Appreciate the strengths and weakness of evidence for identifying appropriate site, technique, needle size, and dose for IM injections in infants, toddlers, and small children.

TABLE 39-6 INTRAMUSCULAR INJECTION SITES IN CHILDREN

SITE	DISCUSSION
Vastus Lateralis  	***Location**** Palpate to find greater trochanter and knee joints; divide vertical distance between these two landmarks into thirds; inject into middle third. ***Needle Insertion and Size*** Insert needle perpendicular to knee in infants and young children or perpendicular to thigh or slightly angled toward anterior thigh. 22-25 gauge (⅝-1 inch†). ***Advantages*** Large, well-developed muscle that can tolerate larger quantities of fluid (0.5 mL [infant] to 2 mL [child]) Easily accessible if child is supine, side lying, or sitting ***Disadvantages*** Thrombosis of femoral artery from injection in midthigh area Sciatic nerve damage from long needle injected posteriorly and medially into small extremity More painful than deltoid or gluteal sites
Ventrogluteal  	***Location**** Palpate to locate greater trochanter, anterior superior iliac tubercle (found by flexing thigh at hip and measuring up to 1-2 cm [0.4-0.8 inch] above crease formed in groin), and posterior iliac crest; place palm of hand over greater trochanter, index finger over anterior superior iliac tubercle, and middle finger along crest of ileum posteriorly as far as possible; inject into center of V formed by fingers. ***Needle Insertion and Size*** Insert needle perpendicular to site but angled slightly toward iliac crest. 22-25 gauge (½-1 inch†) ***Advantages*** Free of important nerves and vascular structures Easily identified by prominent bony landmarks Thinner layer of subcutaneous tissue than in dorsogluteal site; thus less chance of depositing drug subcutaneously rather than intramuscularly Can accommodate larger quantities of fluid (0.5 mL [infant] to 2.0 mL [child]) Easily accessible if child is supine, prone, or side lying Less painful than vastus lateralis ***Disadvantages*** Health professionals' unfamiliarity with site

be administered in a single site to small children and older infants. The muscles of small infants may not tolerate more than 0.5 mL. As the child approaches adult size, the nurse can use volumes approaching those given to adults. However, the larger the amount of solution, the larger the muscle at the injection site must be.

Injections must be placed in muscles large enough to accommodate the medication while avoiding major nerves and blood vessels. The IM immunization site recommended by the Centers for Disease Control and Prevention (CDC), World Health Organization, and AAP for infants is the anterolateral thigh or vastus lateralis (Table 39-6). However, in two studies immunizations at the ventrogluteal site have been found to have fewer local reactions and fever (Cook and Murtagh, 2003; Junqueira, Tavares, Martins, et al., 2010). Cook and Murtagh (2003) also found fewer systemic reactions (irritability and persistent crying or screaming) and greater parental acceptance for the ventrogluteal site. It is relatively free of major nerves and blood vessels, is a relatively large muscle with less subcutaneous tissue than the dorsal site, has well-defined landmarks for safe site location, and is easily accessible in several positions. Distraction and prevention of unexpected movement may be more easily achieved by placing the child supine on a parent's lap for ventrogluteal site use (Cook and Murtagh, 2006).

TABLE 39-6 INTRAMUSCULAR INJECTION SITES IN CHILDREN—cont'd

SITE	DISCUSSION
Deltoid  	***Location**** Locate acromion process; inject only into upper third of muscle that begins about two finger breadths below acromion. ***Needle Insertion and Size*** Insert needle perpendicular to site but angled slightly toward shoulder. 22-25 gauge (½-1 inch). ***Advantages*** Faster absorption rates than gluteal sites Easily accessible with minimal removal of clothing Less pain and fewer local side effects from vaccines compared with vastus lateralis ***Disadvantages*** Small muscle mass; only limited amounts of drug can be injected (0.5-1 mL) Small margins of safety with possible damage to radial nerve and axillary nerve (not shown; lies under deltoid at head of humerus)

*Locations are indicated by asterisks on illustrations.
†Research has shown that a 1-inch needle is needed for adequate muscle penetration in infants 4 months old and possibly in infants as young as 2 months old. (From Cook IF, Murtagh J: Needle length required for intramuscular vaccination of infants and toddlers: an ultrasonographic study, *Austral Fam Phys* 31(3):295-297, 2002.)

The deltoid muscle, a small muscle near the axillary and radial nerves, can be used for small volumes of fluid in children as young as 18 months of age. Its advantages are less pain and fewer side effects from the injectate (as observed with immunizations) compared with the vastus lateralis. Table 39-6 summarizes the three major injection sites and illustrates the location of the preferred IM injection sites for children.

Administration

Although injections that are executed with care seldom cause trauma to children, there have been reports of serious disability related to IM injections in children. Repeated use of a single site has been associated with fibrosis of the muscle with subsequent muscle contracture. Injections close to large nerves such as the sciatic nerve have been responsible for permanent disability, especially when potentially neurotoxic drugs are administered. One of the difficulties in administering the opaque preparations such as penicillin G (Bicillin) is that aspirated blood cannot be detected at the bottom of the syringe, thus increasing the risk of injecting into a blood vessel. When such drugs are injected, use great care in locating the correct site. When aspirating, the nurse should look for blood at the top of the syringe near the plunger because blood may be drawn up through the column of penicillin. One study of IM injection techniques revealed that the straighter the path of needle insertion (e.g., 90-degree angle), the less displacement and shear to tissue, causing less discomfort (Katsma and Smith, 1997).

A reported potential hazard with medication in glass ampules is the presence of glass particles in the ampule after the container is broken. When the medication is withdrawn into the syringe, the glass particles are also withdrawn and subsequently injected into the patient. As a precaution medication from glass ampules is only drawn through a needle with a filter.

Most children are unpredictable, and few are totally cooperative when receiving an injection. Even children who appear to be relaxed and constrained can lose control under the stress of the procedure. It is advisable to have someone available to help hold the child if needed. Because children often jerk or pull away unexpectedly, the nurse should carry an extra needle to exchange for the contaminated one so the delay is minimal. The child, even a small one, is told that he or she is receiving an injection (preferably using a phrase such as "putting the medicine under the skin"); the procedure then is carried out as quickly and skillfully as possible to avoid prolonging the stressful experience. Invasive procedures such as injections are especially anxiety provoking in young children, who may associate any assault to the "behind" with punishment. Because injections are painful, the nurse should use excellent injection techniques and effective pain reduction measures to reduce discomfort (see Guidelines box).

GUIDELINES

Intramuscular Administration of Medication

- Apply EMLA (a eutectic mix of lidocaine and prilocaine) or LMX cream (lidocaine) topically over site if time permits. (See Pain Management, Chapter 30.)
- Prepare medication.
  - Select appropriate-size needle and syringe.
  - If withdrawing medication from an ampule, use a needle equipped with a filter that removes glass particles; then use a new, nonfilter needle for injection.
  - Maximum volume to be administered in a single site is 1 mL for older infants and small children.
  - Have medication at room temperature before injection.
- Determine site of injection (see Table 39-6); make certain that muscle is large enough to accommodate volume and type of medication.
  - For infants and small or debilitated children use the vastus lateralis or ventrogluteal muscles; the dorsogluteal muscle is insufficiently developed to be a safe site for infants and small children.
- Obtain sufficient help in restraining child.
- Explain briefly what is to be done and, if appropriate, what child can do to help.
- Expose injection area for unobstructed view of landmarks.
- Select a site where skin is free of irritation and danger of infection; palpate for and avoid sensitive or hardened areas.
- With multiple injections rotate sites.
- Place child in a lying or sitting position; child is not allowed to stand because landmarks are more difficult to assess, restraint is more difficult, and the child may faint and fall.
  - *Ventrogluteal*—On side with upper leg flexed and placed in front of lower leg
  - *Vastus lateralis*—Supine, lying on side, or sitting
- Use a new, sharp needle (not one that has pierced rubber stopper on vial) with smallest diameter that permits free flow of the medication.
- Grasp muscle firmly between thumb and fingers to isolate and stabilize it for deposition of drug in its deepest part; in obese children spread skin with thumb and index finger to displace subcutaneous tissue and grasp muscle deeply on each side.
- Allow skin preparation to dry completely before penetrating skin.
- Decrease perception of pain.
  - Distract child with conversation.
  - Give child something on which to concentrate (e.g., squeezing a hand or side rail, pinching own nose, humming, counting, yelling "Ouch!").
  - Spray vapocoolant (e.g., ethyl chloride or fluoromethane) on site before injection, place a cold compress or wrapped ice cube on site about 1 minute before injection, or apply cold to contralateral site.
  - Have child hold a small adhesive bandage and place it on puncture site after intramuscular injection is given.
- Insert needle quickly using a dartlike motion at a 90-degree angle unless contraindicated.
- Avoid tracking any medication through superficial tissues:
  - Replace needle after withdrawing medication.
  - Use Z-track or air-bubble technique as indicated.
  - Avoid any depression of plunger during insertion of needle.
- Aspirate for blood.
  - If blood is found, remove syringe from site, change needle, and reinsert into new location.
  - If no blood is found, inject medication slowly into a relaxed muscle.
- Remove needle quickly; hold gauze firmly against skin near needle when removing it to avoid pulling on tissue.
- Apply firm pressure to site after injection; massage site to hasten absorption unless contraindicated, as with irritating drugs.
- Place a small adhesive bandage on puncture site; with young children decorate it by drawing a smiling face or other symbol of acceptance.
- Hold and cuddle young child and encourage parents to comfort him or her; praise older child.
- Allow expression of feelings.
- Discard syringe and uncapped, uncut needle in puncture-resistant container located near site of use.
- Record time of injection, drug, dose, and injection site.

Small infants offer little resistance to injections. Although they squirm and may be difficult to hold in position, they can usually be restrained without assistance. A larger infant's body can be securely restrained between the nurse's arm and body. To inject into the body of a muscle, the nurse firmly grasps the muscle mass between the thumb and fingers to isolate and stabilize the site (Fig. 39-13). However, in obese children it is preferable to first spread the skin with the thumb and index finger to displace subcutaneous tissue and then grasp the muscle deeply on each side.

If medication is given around the clock, the nurse must wake the child. Although it may seem easier to surprise the sleeping child and do it quickly, this can cause him or her to fear going back to sleep. When awakened first, children will know that nothing will be done to them unless they are forewarned. The Guidelines box above summarizes administration techniques that maximize safety and minimize the discomfort often associated with injections.

A needleless injection system (e.g., Biojector) delivers IM or subcutaneous injections without the use of a needle and eliminates the risk of accidental needle puncture. This needle-free injection system uses a carbon dioxide cartridge to power the delivery of medication through the skin. Although it is not painless, it may reduce pain and the anxiety of seeing the needle.

FIG 39-13 Holding small child for intramuscular injection. Note how nurse isolates and stabilizes muscle.

Subcutaneous and Intradermal Administration

Subcutaneous and intradermal injections are administered to children frequently, but the technique differs little from the method used with adults. Examples of subcutaneous injections include insulin, hormone replacement, allergy desensitization, and some vaccines. Tuberculin testing, local anesthesia, and allergy testing are examples of frequently administered intradermal injections.

Techniques to minimize the pain associated with these injections include changing the needle if it pierced a rubber stopper on a vial, using 26- to 30-gauge needles (only to inject the solution), and injecting small volumes (≤0.5 mL). The angle of the needle for the subcutaneous injection is typically 90 degrees. In children with little subcutaneous tissue, some practitioners insert the needle at a 45-degree angle. However, the benefit of using the 45-degree angle rather than the 90-degree angle remains controversial.

Although subcutaneous injections can be given anywhere there is subcutaneous tissue, common sites include the center third of the lateral aspect of the upper arm, the abdomen, and the center third of the anterior thigh. Some practitioners believe that it is not necessary to aspirate before injecting subcutaneously (e.g., this is an accepted practice in the administration of insulin). Automatic injector devices do not aspirate before injecting.

When giving an intradermal injection into the volar surface of the forearm, the nurse should avoid the medial side of the arm where the skin is more sensitive.

Intravenous Administration

The IV route for administering medications is frequently used in pediatric therapy. For some drugs it is the only effective route. This method is used for giving drugs to children who:

- Have poor absorption as a result of diarrhea, vomiting, or dehydration.
- Need a high serum concentration of a drug.
- Have resistant infections that require parenteral medication over an extended time.
- Need continuous pain relief.
- Require emergency treatment.

The nurse needs to consider several factors in relation to IV medication. When a drug is administered intravenously, the effect is almost instantaneous, and further control is limited. Most drugs for IV administration require a specified minimum dilution, rate of flow, or both; and many drugs are highly irritating or toxic to tissues outside the vascular system. In addition to the precautions and nursing observations commonly related to IV therapy, factors to consider when preparing and administering drugs to infants and children by the IV route include the following:

- Amount of drug to be administered
- Minimum dilution of drug and whether child is fluid restricted
- Type of solution in which drug can be diluted
- Length of time over which drug can be safely administered
- Rate limitations of child, vascular system, and infusion equipment
- Time that this or another drug is to be administered
- Compatibility of all drugs that child is receiving intravenously
- Compatibility with infusion fluids

Before any IV infusion check the site of insertion for patency. Never administer medications with blood products. Only one antibiotic should be administered at a time. Extra fluids needed to administer IV medications can be problematic for infants and fluid-restricted children. Syringe pumps are often used to deliver IV medication because they minimize fluid requirements and more precisely deliver small volumes of medication compared with large-volume infusion pumps. Regardless of the technique, the nurse must know the minimum dilutions for safe administration of IV medications to infants and children.

TABLE 39-7 INTRAVENOUS CATHETER FLUSHES FOR LINES WITHOUT CONTINUOUS FLUID INFUSIONS

TYPE OF LINE	TYPE OF FLUSH
Peripheral lines (Hep-Lock or saline locks)	NS* after medications or every 8 hr for dormant lines; instill 2½ times tubing volume 24-g catheters: NS* or heparin 2 units/mL 2 mL
Midline	Heparin 10 units/mL; 3 ml in a 10-mL syringe† after medications or every 8 hours if dormant Newborns: heparin 1-2 units/mL to run continuously at ordered rate
External central line (nonimplanted, nontunneled, tunneled, or PICC)	Heparin 10 units/mL; 3 mL in a 10-mL syringe† after medications or once daily if dormant Newborns: heparin 2 units/mL; 2-3 ml after medications or to check line patency *or* heparin 1-2 units/mL to run continuously at ordered rate
Totally implanted central line (TIVAS, implanted port)	Heparin 10 units/mL; 5 mL after medications or once daily if dormant and accessed; if not accessed, heparin 100 units/mL; 5 mL every month
Arterial and central venous pressure continuous monitored lines	Heparin 2 units/mL in 55-mL syringe to run continuously at 1 mL/hr

NS, Normal saline; *PICC,* peripherally inserted central catheter; *TIVAS,* totally implantable venous access device.
*Use 5% dextrose in water when medication is incompatible with saline.
†Smaller syringes may be used when flush is delivered by a pump.

Peripheral Intermittent Infusion Device

The peripheral lock, also known as an intermittent infusion device or saline or heparin lock, is an alternative to a keep-open infusion when extended access to a vein is required without the need for continuous fluid. It is most frequently used for intermittent infusion of medication into a peripheral venous route. A short, flexible catheter is used as the lock device, and a site is selected where there will be minimal movement such as the forearm. The catheter is inserted and secured in the same manner as for any IV infusion device, but the hub is occluded with a stopper or injection cap.

The type of device used may vary, and the care and use of the peripheral lock are carried out according to the protocol of the institution or unit. However, the general concept is the same. The catheter remains in place and is flushed with saline after infusion of the medication. See the Evidence-Based Practice box and Table 39-7 on flushing with normal saline or heparin.

EVIDENCE-BASED PRACTICE

Normal Saline or Heparinized Saline Flush Solution in Pediatric Intravenous Lines

Ask the Question

Is there a significant difference in the longevity of IV intermittent infusion locks in children when NS is used as a flush instead a HS solution?

Search for the Evidence

Search Strategies

Selection criteria included evidence during the years 1992 to 2011 with the following terms: saline vs. heparin intermittent flush, children's heparin lock flush, heparin lock patency, peripheral venous catheter in children.

Databases Used

CINAHL, PubMed

Critically Analyze the Evidence

- In trials of HS administration vs. NS, placebo, or no treatment in neonates, no strong evidence regarding the effectiveness and safety of heparin in prolonging catheter life was found (Shah, Ng, and Sinha, 2005)
- No significant statistical difference was found between HS and NS flushes for maintaining catheter patency in children (Hanrahan, Kleiber, and Berends, 2000; Hanrahan, Kleiber, and Fagan, 1994; Heilskov, Kleiber, Johnson, et al., 1998; Kotter, 1996; Mok, Kwong, and Chan, 2007; Schultz, Drew, and Hewitt, 2002).
- Increased incidence of pain or erythema was associated with HS flushing of infusion devices (Hanrahan, Kleiber, and Fagan, 1994; McMullen, Fioravanti, Pollack, et al., 1993; Nelson and Graves, 1998; Robertson, 1994).
- Increased patency or longer dwell times were found with HS solutions vs. NS in 24-gauge catheters (Beecroft, Bossert, Chung, et al., 1997; Danek and Noris, 1992; Gyr, Burroughs, Smith, et al., 1995; Hanrahan, Kleiber, and Berends, 2000; Mudge, Forcier, and Slattery, 1998; Tripathi, Kaushik, and Singh, 2008).
- Younger children and preterm neonates with lower gestational ages were associated with shorter patency of IV catheters (McMullen, Fioravanti, Pollack, et al., 1993; Paisley, Stamper, Brown, et al., 1997; Robertson, 1994; Tripathi, Kaushik, and Singh, 2008).
- Infusion devices flushed with NS lasted longer than those flushed with HS (Goldberg, Sankaran, Givelichian, et al., 1999; Le Duc, 1997; Nelson and Graves, 1998).
- When measured and reported, the length of time between flushing peripheral devices affected the dwell time (Crews, Gnann, Rice, et al., 1997; Gyr, Burroughs, Smith, et al., 1995).
- Preterm neonates are at higher risk for development of clotting problems as a result of heparin; none of the studies cited anticoagulation-associated complications with HS (Klenner, Fusch, Rakow, et al., 2003).
- 0.9% sodium chloride injection is safe for maintaining patency of peripheral locks in adults and children older than age 12 years (American Society of Hospital Pharmacists, 2006).
- Either preservative-free heparin or preservative-free 0.9% sodium chloride may be used to flush a peripheral IV line; however, catheter patency may be maintained by flushing with saline when converting from continuous to intermittent use (Infusion Nurses Society, 2006).
- After each catheter use peripheral catheters should be locked with preservative-free 0.9% sodium chloride (Infusion Nurses Society, 2011).
- No recommendation is made for use of preservative-free 0.9% sodium chloride vs. heparin for locking peripheral catheters (Infusion Nurses Society, 2011).

Apply the Evidence: Nursing Implications

There is *low-quality evidence with a weak recommendation* (Guyatt, Oxman, Vist, et al., 2008) for using NS vs. HS flush solution in pediatric IV lines. Further research is still needed with larger samples of children, especially preterm neonates, using small-gauge catheters (24 gauge) and other gauge catheters flushed with NS and HS as intermittent infusion devices only (no continuous infusions). Variables to be considered include catheter dwell time; medications administered; period between regular flushing and flushing associated with medication administration; pain, erythema, and other localized complications; concentration and amount of HS used; flush method (positive-pressure technique vs. no specific technique); reason for IV device removal; and complications associated with either solution. NS is a safe alternative to HS flush in infants and children with intermittent IV locks larger than 24 gauge; smaller neonates may benefit from HS flush (longer dwell time), but the evidence is inconclusive for all weight ranges and gestational ages.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries

Describe methods for using NS or HS flush solution in pediatric IV lines.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence

Integrate evidence into practice on NS or HS flush solution in pediatric IV lines.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice

Appreciate the strengths and weakness of evidence for NS or HS flush solution in pediatric IV lines.

Children may be discharged with a peripheral lock in place to continue receiving medications without hospitalization; this is usually reserved for children who require medications on a short-term basis and are referred to a home-based infusion company. Those with chronic illnesses who require repeated blood sampling or medications, long-term chemotherapy, or frequent hyperalimentation or antibiotic therapy are best managed with a central venous catheter.

Central Venous Access Device

Central venous access devices (CVADs) have several different characteristics. Factors that can influence the type of CVAD include the reason for placement of the catheter (diagnosis), length of therapy, risk to the patient in placement of the catheter, and availability of resources to help the family maintain the catheter.

Short-term or nontunneled catheters are used in acute care, emergency, and intensive care units. These catheters are made of polyurethane and placed in large veins such as the subclavian, femoral, or jugular. Insertion is by surgical incision or large percutaneous threading. A chest x-ray film should be taken to verify placement of the catheter tip before administration of fluids or medications.

Peripherally inserted central catheters (PICCs) can be used for short-term to moderate-length therapy. These catheters consist of silicone or polymer material and are placed by specially trained nurses, physicians, or interventional radiologists (Gamulka, Mendoza, and Connolly, 2005). The most common insertion site is above the antecubital area using the median, cephalic, or basilic vein. The catheter is threaded either with or without a guidewire into the superior vena cava. PICCs can be trimmed before insertion; and the decision can be made to insert the catheter midline, which is considered between the insertion site and the axilla. If the catheter is threaded midline, total parenteral nutrition (TPN) or any other drug known to irritate a peripheral vein (e.g., chemotherapy drugs) should not be administered. The high concentration of glucose in TPN makes it irritating to the vessel; it should be infused through a central catheter.

The decision to insert a PICC needs to be made before several attempts at IV insertion are made. When the antecubital veins have been punctured repeatedly, they are not considered candidates for this type of catheter. Because it is the least costly and has less chance of complications than other CVADs, it is an excellent choice for many pediatric patients.

! NURSING ALERT

Most PICC lines are not sutured into place; thus care is needed when changing the dressing.

Long-term CVADs include tunneled catheters and implanted infusion ports (Table 39-8 and Fig. 39-14). They may have single, double, or triple lumens. Several lumens (multilumen) catheters allow more than one therapy to be administered at the same time. Reasons to use multilumen catheters include repeated blood sampling, TPN, administration of blood products or infusion of large quantities or concentrations of fluids, administration of incompatible drugs or fluids at the same time (through different lumens), and central venous pressure monitoring.

TABLE 39-8 COMPARISON OF LONG-TERM CENTRAL VENOUS ACCESS DEVICES

DESCRIPTION	BENEFITS	CARE CONSIDERATIONS
Tunneled Catheter (e.g., Hickman or Broviac Catheter)		
Silicone, radiopaque, flexible catheter with open ends or VitaCuffs (biosynthetic material impregnated with silver ions) on catheter(s) enhances tissue ingrowth May have more than one lumen	Reduced risk of bacterial migration after tissue adheres to cuff One or two Dacron cuff Easy to use for self-administered infusions Removal requires pulling catheter from site (nonsurgical procedure)	Requires daily heparin flushes Must be clamped or have clamp nearby at all times Must keep exit site dry Heavy activity restricted until tissue adheres to cuff Water sports may be restricted (risk of infection) Risk of infection still present Protrudes outside body; susceptible to damage from sharp instruments and may be pulled out; may affect body image More difficult to repair Patient or family must learn catheter care
Groshong Catheter		
Clear, flexible, silicone, radiopaque catheter with closed tip and two-way valve at proximal end Dacron cuff or VitaCuff on catheter enhances tissue ingrowth May have more than one lumen	Reduced time and cost for maintenance care; no heparin flushes needed Reduced catheter damage; no clamping needed because of two-way valve Increased patient safety because of minimal potential for blood backflow or air embolism Reduced risk of bacterial migration after tissue adheres to cuff Easily repaired Easy to use for self-administered intravenous infusions	Requires weekly irrigation with normal saline Must keep exit site dry Heavy activity restricted until tissue adheres to cuff Water sports may be restricted (risk of infection) Risk of infection still present Protrudes outside body; susceptible to damage from sharp instruments and may be pulled out; can affect body image Patient or family must learn catheter care
Implanted Ports (e.g., Port-A-Cath, Infus-A-Port, Mediport, Norport, Groshong Port)		
Totally implantable metal or plastic device that consists of self-sealing injection port with top or side access with preconnected or attachable silicone catheter that is placed in large blood vessel	Reduced risk of infection Placed completely under skin and therefore much less likely to be pulled out or damaged No maintenance care and reduced cost for family Heparinized monthly and after each infusion to maintain patency (only Groshong port requires saline) No limitations on regular physical activity, including swimming Dressing needed only when port accessed with Huber needle that is not removed No or only slight change in body appearance (slight bulge on chest)	Must pierce skin for access; pain with insertion of needle; can use local anesthetic (EMLA, LMX) or intradermal buffered lidocaine before accessing port Special noncoring needle (Huber) with straight or angled design must be used to inject into port Skin preparation needed before injection Difficult to manipulate for self-administered infusions Catheter may dislodge from port, especially if child "plays" with port site (twiddler syndrome) Vigorous contact sports generally not allowed Removal requires surgical procedure

EMLA, Eutectic mix of lidocaine and prilocaine; *LMX,* lidocaine.

With any of the central venous catheters, medication is easily instilled through the injection cap. Maintenance of the catheter includes dressing changes, flushing to maintain patency, and prevention of occlusion or dislodgment.

! NURSING ALERT

When working with tunneled catheters, PICCs, and peripheral intravenous (PIV) catheters, avoid the use of any scissors around the tubing or dressing. Removal is best accomplished using fingers and much patience. In the event that a tunneled catheter is cut, use a padded clamp to clamp the catheter proximal to the exit site to avoid blood loss. Repair kits are available, which may save the catheter and avoid surgery to replace a cut catheter.

With the implanted device the port must be palpated for placement and stabilized; the overlying skin cleansed; and only special noncoring Huber needles used to pierce the diaphragm of the port on the top or side, depending on the style. To avoid repeated skin punctures a special infusion set with a Huber needle and extension tubing with a Luer connection can be used (see Fig. 39-14). With this attached the injection procedure is the same as for an intermittent infusion device or a central venous catheter. To prevent infection, meticulous aseptic technique must be used any time the devices are entered, including instillation of heparin or saline to prevent clotting. There should be a protocol stating that the Huber needle needs to be changed at established intervals, usually 5 to 7 days.

The children and parents are taught the procedure for care of the CVAD before discharge from the hospital, including preparation

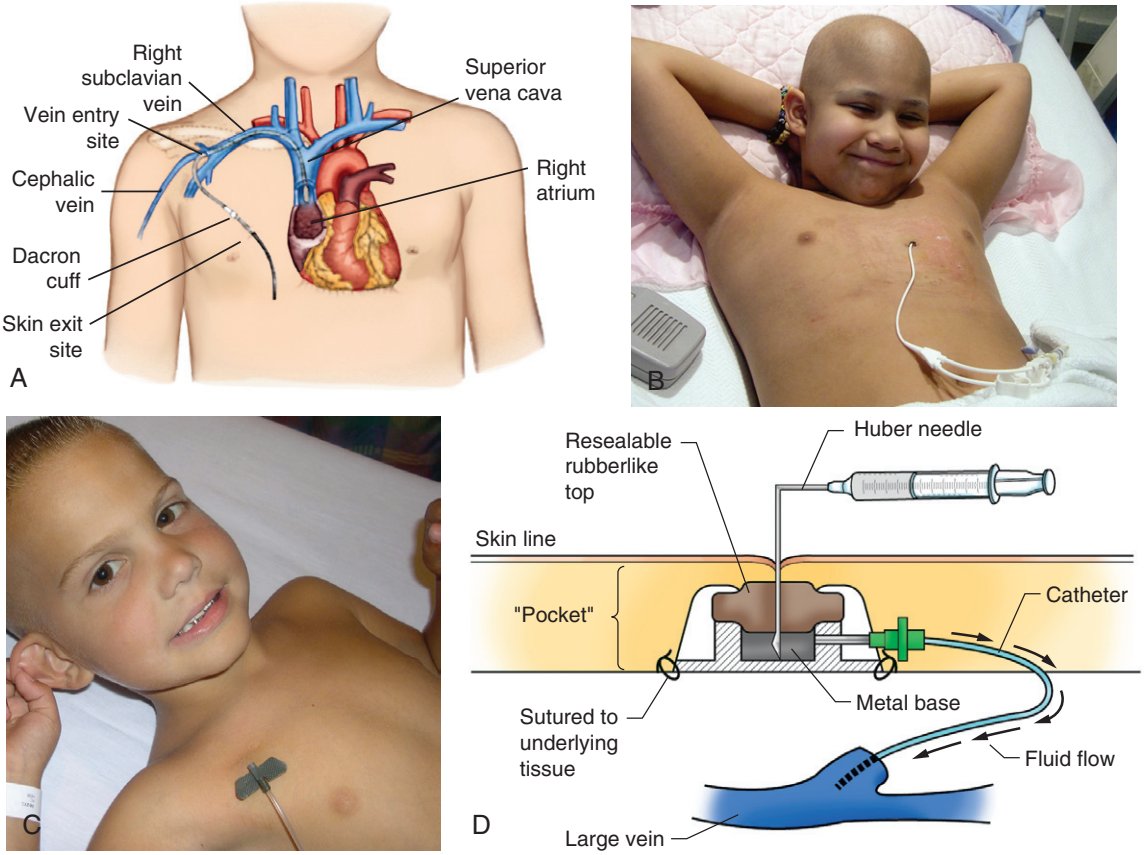

FIG 39-14 Venous access devices. **A,** External central venous catheter insertion and exit site. **B,** Child with external central venous catheter (dressing removed for photo). **C,** Child with implanted port with Huber needle in place (dressing removed for photo). **D,** Side view of implanted port.

and injection of the prescribed medication, the flush, and dressing changes. A protective device may be recommended for some active children to prevent their accidentally dislodging the needle. Many children take responsibility for preparing and administering medications. Both verbal and written step-by-step instructions are provided for the learners. See the Evidence-Based Practice box for CVAD site care.

Infection and catheter occlusion are two of the most common complications of central venous catheters. They require treatment with antibiotics for infection and a fibrinolytic agent such as alteplase for thrombus formation (Blaney, Shen, Kerner, et al., 2006; Fisher, Deffenbaugh, Poole, et al., 2004; Kerner, Garcia-Careaga, Fisher, et al., 2006; Shen, Li, Murdock, et al., 2003). Uncapping can be prevented by taping the cap securely to the catheter and the clamped line to the dressing. Leaks can be prevented by using a smooth-edged clamp only. The parents are cautioned to keep scissors away from the child to prevent accidental cutting of the catheter. If the catheter leaks, the parents are instructed to tape it above the leak and then clamp it at the taped site. The child should be taken to the practitioner as soon as possible to prevent infection or clotting after a catheter leak.

! NURSING ALERT

If a central venous catheter is removed accidentally, apply pressure to the entry site to the vein, not the exit site on the skin.

Nasogastric, Orogastric, and Gastrostomy Administration

When a child has an indwelling feeding tube or a gastrostomy, oral medications are usually given via that route. An advantage of this method is the ability to administer oral medications around the clock without disturbing the child. A disadvantage is the risk of occluding, or clogging, the tube, especially when giving viscous solutions through small-bore feeding tubes. The most important preventive measure is adequate flushing after the medication is instilled (see Guidelines box on p. 1170).

Rectal Administration

The rectal route for administration is less reliable but is sometimes used when the oral route is difficult or contraindicated. It is also used when oral preparations are unsuitable to control vomiting. Some of the drugs available in suppository form are acetaminophen, aspirin, sedatives, analgesics (morphine), and antiemetics. The difficulty in using the rectal route is that, unless the rectum is empty at the time of insertion, the absorption of the drug may be delayed, diminished, or prevented by the presence of feces. Sometimes the drug is evacuated later, securely surrounded by stool.

Remove the wrapping on the suppository and lubricate the suppository with warm water (water-soluble jelly may affect medication absorption). Rectal suppositories are traditionally inserted with the apex (pointed end) foremost. Reverse contractions or the pressure gradient of the anal canal may help the suppository slip higher into the canal. Using a glove or finger cot, quickly but gently insert the

EVIDENCE-BASED PRACTICE

Central Venous Catheter Site Care

Ask the Question

In children with CVCs, is chlorhexidine gluconate a more effective antiseptic solution than povidone-iodine in preventing CVC-related site infections and bacteremia?

Search the Evidence

Search Strategies

Search selection criteria included English language publications within the past 10 years and research-based articles on catheter site care and chlorhexidine.

Databases Used

The National Guideline Clearinghouse (AHRQ), Centers for Disease Control and Prevention (CDC), Cochrane Collaboration, Joanna Briggs Institute, PubMed, Infusion Nurses Society, Oncology Nurses Society, MD Consult, BestBETs, TRIP Database Plus

Critically Analyze the Evidence

Chlorhexidine Gluconate vs. Povidone-Iodine

- Use of 2% chlorhexidine for disinfecting catheter site before insertion (allowing it to dry) is preferred; but tincture of iodine, an iodophor, or 70% alcohol can be used. Iodine needs to remain on the skin for at least 2 minutes or until dry (Infusion Nurses Society, 2011a, 2011b; O'Grady, Alexander, Dellinger, et al., 2002).
- No recommendations can be made for the use of chlorhexidine in infants younger than 2 months of age, use of topical antibiotic ointments or creams because of the potential to promote fungal infections and antimicrobial resistance, or use of impregnated catheters and chlorhexidine sponge dressings to reduce the incidence of infection (Infusion Nurses Society, 2011a, 2011b; O'Grady, Alexander, Dellinger, et al., 2002).
- Avoid use of sponges in infants younger than 7 days old and 26 weeks' gestation. Replace the catheter-site dressing when it becomes damp, loosened, or soiled or when inspection of the site is necessary (O'Grady, Alexander, Dellinger, et al., 2002).
- Replace dressings used on short-term CVC sites every 2 days for gauze dressings and at least every 7 days for transparent dressings except in pediatric patients in whom the risk for dislodging the catheter outweighs the benefit of changing the dressing (Infusion Nurses Society, 2011a; O'Grady, Alexander, Dellinger, et al., 2002)
- Use of alcohol, chlorhexidine gluconate, povidone-iodine, and tincture of iodine (allow to dry) is recommended. If using povidone-iodine, do not apply alcohol as a second antiseptic (Infusion Nurses Society, 2006, 2011a, 2011b; Marlowe, Mistry, Coffin, and others, 2010).
- Dress the vascular access site with sterile gauze and cover it with sterile transparent dressings. Gauze dressings should be changed every 48 hours (Camp-Sorrell, 2004; Infusion Nurses Society, 2006, 2011a, 2011b).
- Semipermeable transparent dressings should be changed at least every 5 to 7 days; the interval depends on the dressing material, age and condition of the patient, infection rate reported by the organization, environmental conditions, and manufacturer labeled uses and directions (Infusion Nurses Society, 2006, 2011a, 2011b)
- Chlorhexidine for preinsertion and postinsertion site catheter care was found superior to alcohol and povidone-iodine (Camp-Sorrell, 2004; Carson 2004; Chaiyakunapruk, Veenstra, Lipsky, et al., 2002).
- Routine application of antibiotic ointment is not recommended because of the risk of fungal infections and antimicrobial resistance.
- For bone marrow transplant recipients, chlorhexidine is the recommended antisepsis for prevention of catheter-related infection (Zitella, 2003).
- In pediatric hemopoietic stem cell transplant patients, use of 2% chlorhexidine in 70% isopropanol resulted in a sustained decrease in catheter-related infections (Soothill, Bravery, Ho, et al., 2009).
- Neonates weighing 1500 g or more and 7 days of age or older tolerated use of chlorhexidine-gluconate; however, some chlorhexidine-gluconate was absorbed cutaneously (Garland, Alex, Uhing, et al., 2009).
- Neonates and infants with Biopatch (chlorhexidine sponge dressings) had a substantial decrease in colonized catheter tips compared with the group that used standard dressings. Biopatch was associated with localized contact dermatitis in infants of very low birth weight (Garland, Alex, Mueller, et al., 2001).
- Skin disinfection before CVC insertion and daily dressing changes with propanol-chlorhexidine followed by povidone-iodine was associated with the lowest rate of microbial catheter colonization (Langgartner, Linde, Lehn, et al., 2004).
- Patients with chlorhexidine-impregnated CVC dressing (Biopatch) had a significantly reduced risk of CVC colonization compared with patients with transparent dressing alone (Levy, Katz, Solter, et al., 2005; Onder, Chandar, Coakley, et al., 2009).
- In children older than 2 years of age, use of chlorhexidine-impregnated dressing should be considered as an extra prevention measure for catheter-related bloodstream infection (Infusion Nurses Society, 2011a).

Other Antiseptics

- Use of ethanol locks in children on parental nutrition (median age, 18.3 months) significantly decreased the rate of CVC infections (9.9 per 1000 to 2.1 per 1000 catheter days) (Jones, Hull, Richardson, et al., 2010).
- In pediatric patients with hemophilia (3, 11, and 13 years of age), ethanol lock therapy cleared catheter-related infection (Rajpurkar, Boldt-Macdonald, Mclenon, et al., 2009).
- In pediatric cancer patients, taurolidine/citrate (TauroLock) reduced catheter-related blood infections (Simon, Ammann, Wiszniewsky, et al., 2008).

Apply the Evidence: Nursing Implications

There is *moderate-quality evidence with a strong recommendation* (Guyatt, Oxman, Vist, et al., 2008) for CVC care. Two percent chlorhexidine should be used for catheter site antisepsis. Two percent chlorhexidine should be used with caution in premature and low-birth-weight infants. Chlorhexidine-impregnated sponges (Biopatch) should be used around the catheter site except in low-birth-weight infants in the first 2 weeks of life.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries

Describe methods for CVC care.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence

Integrate evidence into practice by using appropriate CVC care.

EVIDENCE-BASED PRACTICE

Central Venous Catheter Site Care—cont'd

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice

Appreciate the strengths and weakness of evidence for CVC care.

suppository into the rectum beyond both of the rectal sphincters. Then hold the buttocks together firmly to relieve pressure on the anal sphincter until the urge to expel the suppository has passed, which occurs within 5 to 10 minutes. Sometimes the amount of drug ordered is less than the dose available. The irregular shape of most suppositories makes the process of dividing them into a desired dose difficult if not dangerous. If it must be halved, it should be cut lengthwise. However, there is no guarantee that the drug is evenly dispersed throughout the petrolatum base.

If medication is administered via a retention enema, the same procedure is used. Drugs given by enema are diluted in the smallest amount of solution possible to minimize the likelihood of being evacuated.

Optic, Otic, and Nasal Administration

There are few differences in administering eye, ear, and nose medication to children and adults. The major difficulty is gaining children's cooperation. Older children need only an explanation and direction. Although the administration of optic, otic, and nasal medication is not painful, these drugs can cause unpleasant sensations, which can be eliminated with various techniques.

To instill eye medication place the child supine or sitting with the head extended and ask him or her to look up. Use one hand to pull the lower eyelid downward; the hand that holds the dropper rests on the head so it may move synchronously with the child's head, thus reducing the possibility of trauma to a struggling child or dropping medication on the face (Fig. 39-15). When the lower eyelid is pulled down, a small conjunctival sac is formed; apply the solution or ointment to this area rather than directly on the eyeball. Another effective technique is to pull the lower eyelid down and out to form a cup effect, into which the medication is dropped. Gently close the eyelids to prevent expression of the medication. Wipe excess medication from the inner canthus outward to prevent contamination to the contralateral eye.

! NURSING ALERT

To reduce unpleasant sensations when administering medications:

- *Eye*—Apply finger pressure to the lacrimal punctum at the inner aspect of the eyelid for 1 minute to prevent drainage of medication to the nasopharynx and the unpleasant "tasting" of the drug.
- *Ear*—Allow medications stored in the refrigerator to warm to room temperature before instillation.
- *Nose*—Position the child with the head hyperextended to prevent strangling sensations caused by medication trickling into the throat rather than up into the nasal passages.

GUIDELINES

Nasogastric, Orogastric, or Gastrostomy Medication Administration in Children

- Use elixir or suspension (rather than tablet) preparations of medication whenever possible.
- Dilute viscous medication or syrup with a small amount of water if possible.
- If administering tablets, crush tablet to a fine powder and dissolve drug in small amount of warm water.
- Never crush enteric-coated or sustained-release tablets or capsules.
- Avoid oily medications because they tend to cling to side of tube.
- Do not mix medication with enteral formula unless fluid is restricted. If adding a drug:
  - Check with pharmacist for compatibility.
  - Shake formula well and observe for any physical reaction (e.g., separation, precipitation).
  - Label formula container with name of medication, dosage, date, and time infusion started.
- Check for correct placement of nasogastric or orogastric tube (see Evidence-Based Practice box, pp. 1185-1186).
- Attach syringe (with adaptable tip but without plunger) to tube.
- Pour medication into syringe.
- Unclamp tube and allow medication to flow by gravity.
- Adjust height of container to achieve desired flow rate (e.g., increase height for faster flow).
- As soon as syringe is empty, pour in water to flush tubing.
  - Amount of water depends on length and gauge of tubing.
  - Determine amount before administering any medication by using a syringe to fill completely an unused nasogastric or orogastric tube with water. Amount of flush solution is usually 1.5 times this volume.
  - With certain drug preparations (e.g., suspensions), more fluid may be needed.
- If administering more than one drug at the same time, flush tube between each medication with clear water.
- Clamp tube after flushing unless it is left open.

Instilling eyedrops in infants can be difficult because they often clench the eyelids tightly closed. One approach is to place the drops in the nasal corner where the eyelids meet. The medication pools in this area; and, when the child opens the eyelids, the medication flows onto the conjunctiva. For young children playing a game can be helpful such as instructing the child to keep the eyes closed to the count of three and then open them, at which time the drops are quickly instilled. Ointment can be applied by gently pulling down the lower eyelid and placing the ointment in the lower conjunctival sac.

MEDICATION ALERT

If both eye ointment and drops are ordered, give drops first, wait 3 minutes, and then apply the ointment to allow each drug to work. When possible, administer eye ointments before bedtime or naptime because the child's vision will be blurred temporarily.

Ear drops are instilled with the child in the prone or supine position and the head turned to the appropriate side. For children younger than 3 years of age, the external auditory canal is straightened by gently pulling the pinna downward and straight back. The pinna is pulled upward and back in children older than 3 years of age. To place the drops deep into the ear canal without contaminating the tip of the dropper, place a disposable ear speculum in the canal and administer the drops through the speculum. Position the bottle so the drops fall against the side of the ear canal. After instillation the child should remain lying on the unaffected side for a few minutes. Gentle massage of the area immediately anterior to the ear facilitates the entry of drops into the ear canal. The use of cotton pledgets prevents medication from flowing out of the external canal. However, they should be loose enough to allow any discharge to exit from the ear. Premoistening the cotton with a few drops of medication prevents the wicking action from absorbing the medication instilled in the ear.

FIG 39-15 Administering eyedrops.

FIG 39-16 Proper position for instilling nose drops.

Nose drops are instilled in the same manner as in the adult patient. Remove mucus from the nose with a clean tissue or washcloth. Unpleasant sensations associated with medicated nose drops are minimized when care is taken to position the child with the head extended well over the edge of the bed or pillow (Fig. 39-16). Depending on size, infants can be positioned in the football hold

(see Fig. 39-5, *B*), in the nurse's arm with the head extended and stabilized between the nurse's body and elbow and the arms and hands immobilized with the nurse's hands, or with the head extended over the edge of the bed or a pillow. After instillation of the drops, the child should remain in position for 1 minute to allow the drops to come in contact with the nasal surfaces. Insert nasal spray dispensers into the naris vertically and then angle them to avoid trauma to the septum and direct medication toward the inferior turbinate.

Aerosol Therapy

Aerosol therapy can be effective in depositing medication directly into the airway. The value of aerosolized water, or "mist therapy," is controversial. This route of administration can be useful in avoiding the systemic side effects of certain drugs and reducing the amount of drug necessary to achieve the desired effect. Bronchodilators, steroids, mucolytics, and antibiotics suspended in particulate form can be inhaled so the medication reaches the small airways. Aerosol therapy is particularly challenging in children who are too young to cooperate with controlling the rate and depth of breathing. Administration of this therapy requires skill, patience, and creativity.

MEDICATION ALERT

Medications can be aerosolized or nebulized with air or oxygen-enriched gas. The metered-dose inhaler (MDI) is a self-contained, handheld device that allows for intermittent delivery of a specified amount of medication. Many bronchodilators are available in this form and are used successfully by children with asthma. For children younger than the age of 5 or 6 years, a spacer device attached to the MDI can help with coordination of breathing and aerosol delivery. It also allows the aerosolized particles to remain in suspension longer. Handheld nebulizers discharge a medicated mist into a small plastic mask, which the child holds over the nose and mouth. To avoid particle deposition in the nose and pharynx, the child is instructed to take slow, deep breaths through an open mouth during the treatment. For home use an air compressor is necessary to force air through the liquid medication to form the aerosol. Compact, portable units can be obtained from health equipment companies.

Breath sounds and work of breathing should be assessed before and after treatments. Young children who become upset by having a mask held close to the face may become fatigued with fighting the procedure and actually appear worse during and immediately after the therapy. It may be necessary to spend a few minutes calming the child and allowing the vital signs to return to baseline to accurately assess changes in breath sounds and work of breathing.

Family Teaching and Home Care

The nurse usually assumes responsibility for preparing families to administer medications at home. The family should understand why the child is receiving the medication; the effects that might be expected; and the amount, frequency, and length of time the drug is to be administered. Instruction should be carried out in an unhurried, relaxed manner, preferably in an area away from a busy ward or office.

Instruct the caregiver carefully regarding the correct dosage. Some people have difficulty understanding medical terminology; the nurse should not assume that the message is clear just because they nod or otherwise indicate that they understand. For example, it is important to ascertain their interpretation of a teaspoon and be certain that they have acceptable devices for measuring the drug. If the drug is packaged with a dropper, syringe, or plastic cup, the nurse should show or mark the point on the device that indicates the prescribed dose and demonstrate how the dose is drawn up into a dropper or syringe, measured, and the bubbles eliminated. If the nurse has any doubts about the parent's ability to administer the correct dose, the parent should give a return demonstration. This is essential when a drug such as insulin or digoxin has potentially serious consequences from incorrect dosage or when more complex administration such as parenteral injections is required. When teaching a parent to give an injection, the nurse must allot adequate time for instruction and practice.

Home modifications are often necessary because the availability of equipment or assistance can differ from the hospital setting. For example, the parent may need guidance in devising methods that allow one person to hold the child and safely give the drug.

! NURSING ALERT

To administer oral, nasal, or optic medication when only one person is available to hold the child, use the following procedure:

- Place child supine on a flat surface (bed, couch, floor).
- Sit facing child so his or her head is between operator's thighs and child's arms are under operator's legs.
- Place lower legs over child's legs to restrain lower body if necessary.
- To administer oral medication, place a small pillow under child's head to reduce risk of aspiration.
- To administer nasal medication, place a small pillow under child's shoulders to aid flow of liquid through nasal passages.

The nurse should clarify with parents the time that the drug is to be administered. For instance, when a drug is prescribed in association with meals, the number of meals that the family is accustomed to eating influences the amount of drug the child receives. Does the family have meals twice a day or 5 times a day? When a drug is to be given several times during the day, together the nurse and parents can work out a schedule that accommodates the family's routine. This is particularly significant if a drug must be given at equal intervals throughout a 24-hour period. For example, telling parents that the child needs 1 tsp of medicine 4 times a day is subject to misinterpretation because the parents may routinely schedule the doses at incorrect times. Instead a preplanned schedule based on 6-hour intervals should be set up with the number of days required for the therapeutic dosage listed. Modification should also be made to accommodate sleep schedules. Written instructions should accompany all drug prescriptions.

! NURSING ALERT

If parents have difficulty reading or understanding English, use colors to convey instructions. For example, mark each drug with a color and place the appropriate color on a calendar chart or on a drawing of a clock to identify when the drug needs to be given. If a liquid medication and syringe are used, also mark the syringe at the place the plunger needs to be with color-coded tape.

MAINTAINING FLUID BALANCE

Measuring Intake and Output

Accurate measurements of fluid intake and output (I&O) are essential to the assessment of fluid balance. Measurements from all sources—including gastrointestinal and parenteral I&O from urine,

stools, vomitus, fistulas, NG suction, sweat, and drainage from wounds—must be taken and considered. Although the practitioner usually indicates when I&O measurements are to be recorded, it is a nursing responsibility to keep an accurate I&O record on certain children, including those:

- Receiving IV therapy.
- Who underwent major surgery.
- Receiving diuretic or corticosteroid therapy.
- With severe thermal burns or injuries.
- With renal disease or damage.
- With congestive heart failure.
- With dehydration.
- With diabetes mellitus.
- With oliguria.
- In respiratory distress.
- With chronic lung disease.

Infants and small children who are unable to use a bedpan and those who have bowel movements with every voiding require the application of a collecting device. If collecting bags are not used, wet diapers or pads are carefully weighed to ascertain the amount of fluid lost, including liquid stool, vomitus, and other losses. The volume of fluid in milliliters is equivalent to the weight of the fluid measured in grams. The specific gravity as a measure of osmolality helps to assess the degree of hydration.

For infants with diapers weigh all dry diapers to be used and note in an indelible marker the dry weight of the diaper; when there is fluid (urine or liquid stool) in the diaper, the amount of output can be approximated by subtracting the weight of the dry diaper from the weighed amount of the wet diaper.

Disadvantages of the weighed-diaper method of fluid measurement include (1) an inability to differentiate one type of loss from another because of admixture, (2) loss of urine or liquid stool from leakage or evaporation (especially if the infant is under a radiant warmer), and (3) additional fluid in the diaper (superabsorbent disposable type) from absorption of atmospheric moisture (in high-humidity incubators).

Special Needs When the Child Is NPO

Infants or children who are unable or not permitted to take fluids by mouth (NPO) have special needs. To ensure that they do not receive fluids, a sign can be placed in some obvious place such as over their beds or on their shirts to alert others to the NPO status. To prevent the temptation to drink, fluids should not be left at the bedside.

Oral hygiene, a part of routine hygienic care, is especially important when fluids are restricted or withheld. For young children who cannot brush their teeth or rinse their mouth without swallowing fluid, the mouth and teeth can be cleaned and kept moist by swabbing with saline-moistened gauze.

The child who is fluid restricted presents an equal challenge. Limiting fluids is often more difficult for the child than being NPO, especially when IV fluids are also eliminated. To make certain that the child does not drink the entire amount allowed early in the day, the daily allotment is calculated to provide fluids at periodic intervals throughout his or her waking hours. Serving the fluids in small containers gives the illusion of larger servings. No extra liquid is left at the bedside.

Parenteral Fluid Therapy

Site and Equipment

The site selected for PIV infusion depends on accessibility and convenience. Although it is possible to use any accessible in older children, the child's developmental, cognitive, and mobility needs must be considered when selecting a site. Ideally in older children the superficial veins of the forearm should be used, leaving the hands free. An older child can help select the site and thereby maintain some measure of control. For veins in the extremities it is best to start with the most distal site and avoid the child's favored hand to reduce the disability related to the procedure. Restrict the child's movements as little as possible; avoid a site over a joint in an extremity such as the antecubital space. In small infants a superficial vein of the hand, wrist, forearm, foot, or ankle is usually most convenient and most easily stabilized (Fig. 39-17). Foot veins should be avoided in children learning to walk and those already walking. Superficial veins of the scalp have no valves, insertion is easy, and they can be used in infants up to about 9 months of age; but they should be used only when other site attempts have failed. A transilluminator (Fig. 39-18) can aid in finding and evaluating veins for access.

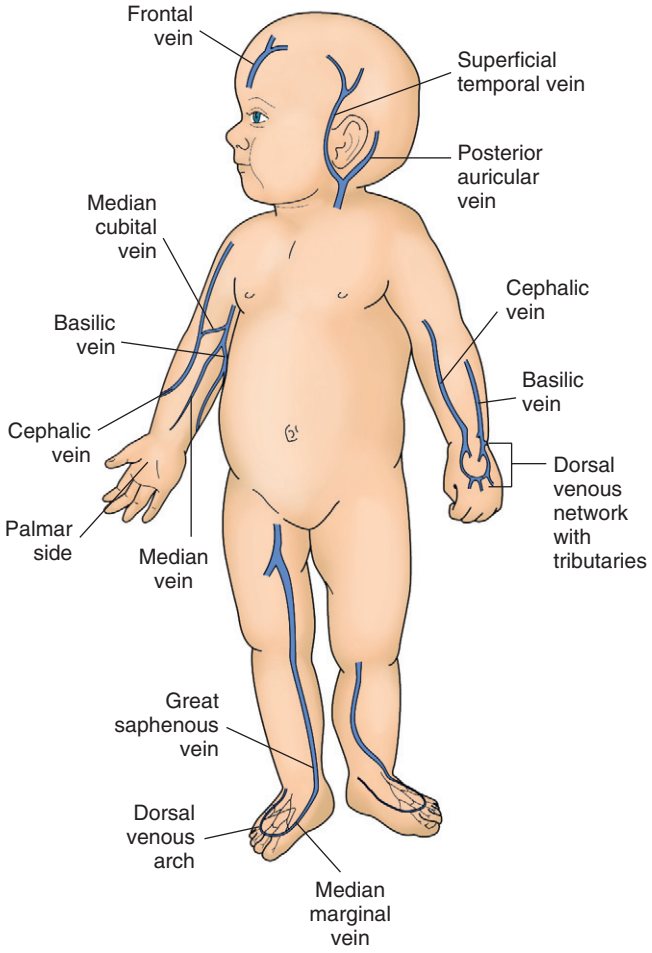

FIG 39-17 Preferred sites for venous access in infants.

Selection of a scalp vein may require clipping the area around the site to better visualize the vein and provide a smoother surface on which to tape the catheter hub and tubing. Clipping a portion of the infant's hair is upsetting to parents; therefore they should be told what to expect and reassured that the hair will grow in again rapidly (save the hair because parents often wish to keep it). Remove as little as possible directly over the insertion site and taping surface. A rubber band slipped onto the head from brow to occiput usually suffices as a tourniquet; although, if the vessel is visible, a tourniquet may not be necessary.

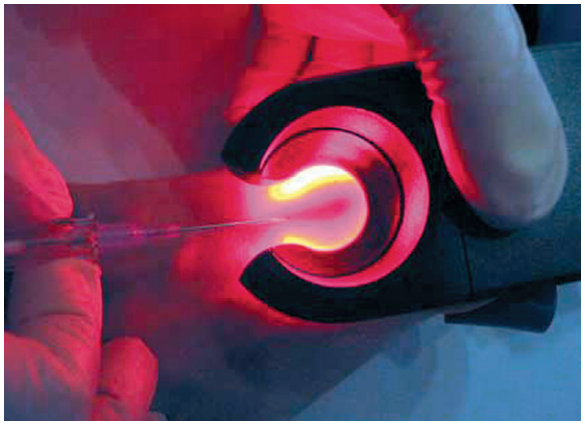

FIG 39-18 Transilluminator: low-heat light-emitting diode (LED) light placed on skin to illuminate veins; an opening allows cannulation of vein. (Courtesy Professor Mark Waltzman, Children's Hospital, Boston, MA.)

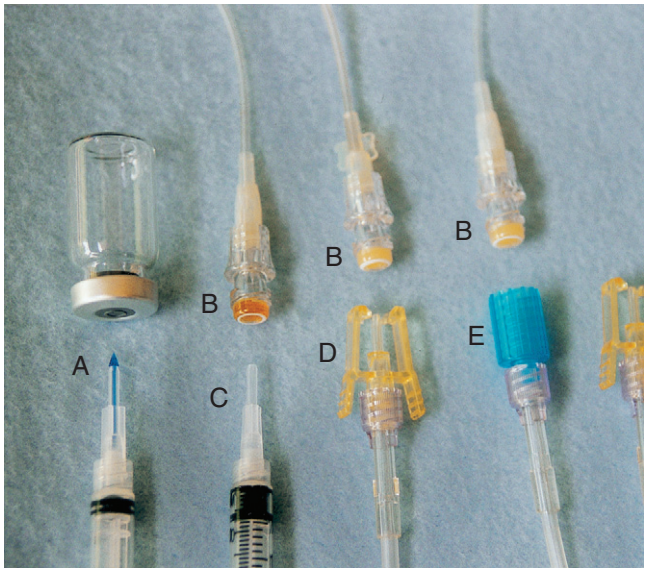

FIG 39-19 Interlink intravenous access systems. **A,** Blue spike syringe. **B,** Preslit injection port (needleless). **C,** Blunt plastic cannula syringe. **D,** Lever lock cannula. **E,** Threaded lock cannula.

Situations may occur in which rapid establishment of systemic access is vital; and venous access may be hampered by peripheral circulatory collapse, hypovolemic shock (secondary to vomiting or diarrhea, burns, or trauma), cardiopulmonary arrest, or other conditions (de Caen, Reis, and Bhutta, 2008; Hazinski, Zaritsky, Nadkarni, et al., 2002). Intraosseous infusion provides a rapid, safe, and lifesaving alternate route for administration of fluids and medications until intravascular access can be attained, especially in children who are 6 years of age and younger.

A large-bore needle such as a bone marrow aspiration needle (e.g., Jamshidi) or an intraosseous needle (e.g., Cook), is inserted into the medullary cavity of a long bone, most often the proximal tibia. This procedure is usually reserved for children who are unconscious or for those who are receiving analgesia because the procedure is painful. Local anesthesia should be used for semiconscious patients. Observe the dependent tissue closely for swelling because extravasation may be hidden under the leg and compartment syndrome may result.

For most IV infusions in children a 22- to 24-gauge catheter may be used if therapy is expected to last less than 5 days. The smallest-gauge and shortest-length catheter that will accommodate the prescribed therapy should be chosen. The length of the catheter may be directly related to infection or embolus formation (i.e., the shorter the catheter, the fewer the complications). The gauge of the catheter should maintain adequate flow of the infusate into the cannulated vein while allowing adequate blood flow around the catheter walls to promote proper hemodilution of the infusate.

Determining the best catheter for the patient early in the therapy provides the best chance of avoiding catheter-related complications. As the length of therapy increases, decisions regarding the type of infusion device (short peripheral, midline, PICC, or central venous catheter) should be explored. Guidelines such as flow charts and algorithms are available to help in these decisions.

Safety Catheters and Needleless Systems

Over-the-needle IV catheters with hollow-bore needles carry a high risk for transmission of bloodborne pathogens from needlestick injuries. Safety catheters prevent accidental needlesticks with the use of over-the-needle IV catheters (Whitby, McLaws, and Slater, 2008).

Needleless IV systems are designed to prevent needlestick injuries during administration of IV push medications and IV piggyback medications. Some needleless devices can be used with any tubing, but others require use of the entire IV delivery system for compatibility. Needleless IV systems rely on prepierced septa that are accessed by blunted plastic cannulas or systems that use valves that open and close a fluid path when activated by insertion of a syringe.

Blunt plastic cannulas and preslit injection port sites (Fig. 39-19) eliminate the need for steel needles and conventional injection port sites but remain accessible via hypodermic needles, a drawback except in emergent situations. Systems that do not permit needled access enhance safety by preventing health care workers from attempting to use needles. A syringe with a blue spike is available to access a single-dose vial (Fig. 39-19, *A*). The preslit injection port sites are identified by a white ring surrounding the port; this ring alerts users that the system is needleless (Fig. 39-19, *B*). Syringes are available with the blunt plastic cannula for accessing these sites (Fig. 39-19, *C*). A lever lock (Fig. 39-19, *D*) or threaded lock cannula (Fig. 39-19, *E*) attaches to an IV line, IV Y site, or peripheral intermittent infusion device. A preslit universal vial adapter (not pictured) provides access to standard multiple-dose vials, and syringe cannulas are then used to access the adapter. Valve technology allows syringes and IV tubing to connect directly in-line without the use of an adapter.

! NURSING ALERT

Misconnections of tubing have occurred, resulting in patient deaths. Many needleless IV systems allow other types of tubing such as blood pressure and oxygen tubing to connect and instill air directly into the IV line. Before tubing is connected or reconnected to a patient, trace it completely from the patient to the point of origin for verification.

Infusion Pumps

A variety of infusion pumps are available and used in nearly all pediatric infusions to accurately administer medication and minimize the possibility of overloading the circulation. It is important

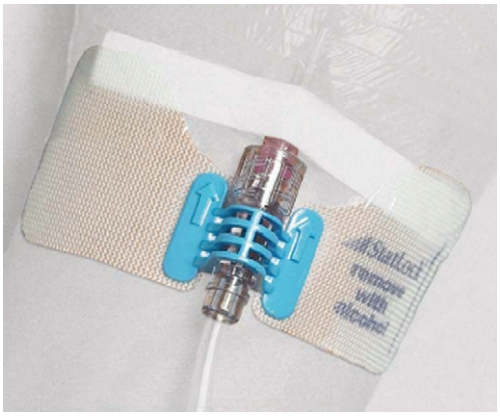

FIG 39-20 StatLock securement devices enhance peripheral intravenous line dwell time and decrease phlebitis.

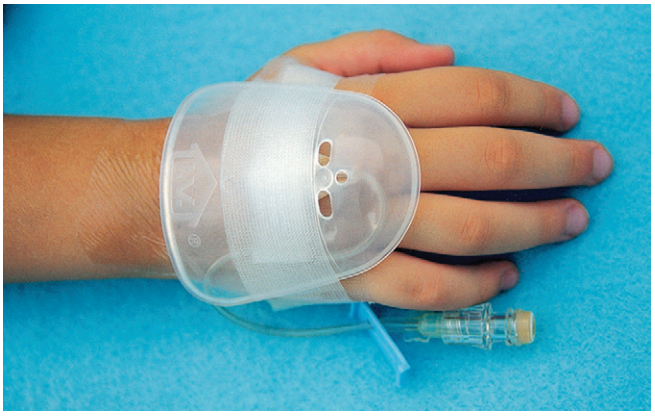

FIG 39-21 I.V. House used to protect intravenous site.

to calculate the amount to be infused in a given length of time, set the infusion rate, and monitor the apparatus frequently (at least every 1 to 2 hours) to make certain that the desired rate is maintained, the integrity of the system remains intact, the site remains intact (free of redness, edema, infiltration, or irritation), and the infusion does not stop. Continuous infusion pumps, although convenient and efficient, are not without risks. Overreliance on the accuracy of the machine can cause either too much or too little fluid to be infused; therefore its use does not eliminate careful periodic assessment by the nurse. Excess pressure can build up if the machine is set at a rate faster than the vein is able to accommodate (or continues to pump when the needle is out of the lumen).

Securing a Peripheral Intravenous Line

To maintain the integrity of the IV line, adequate protection of the site is required. The catheter hub is secured firmly at the puncture site with a transparent dressing and commercial securement device (e.g., StatLock) (Fig. 39-20) or clear nonallergenic tape. Transparent dressings are ideal because the insertion site is easily observed. Minimal tape should be used at the puncture site and on about 1 to 2 inches (2.54 to 5.08 cm) of skin beyond the site to avoid obscuring the insertion site for early detection of infiltration.

A protective cover is applied directly over the catheter insertion site to protect the infusion site. Easy access to the IV site for frequent (hourly) assessments must be considered (Infusion Nurses Society, 2006). Improvised plastic cups that are cut in half with the ridged edges covered with tape should not be used because they have injured patients. A commercial site protector, I.V. House, is available in different sizes (Fig. 39-21). Its ventilation holes prevent moisture from accumulating under the dome. This device is designed to protect the IV site and allows for visibility of the site. It also minimizes use of padded boards, splints, or other restraints and tape and maintains skin integrity. The connector tubing or extension tubing can be looped to make it small enough to fit under the protective cover to prevent accidental snagging of the catheter. It is important to secure the IV tubing safely to prevent infants and children from becoming entangled in it and from accidentally pulling the catheter or needle out. Securing the tubing in this manner also eliminates movement of the catheter hub at the insertion site (mechanical manipulation). A colorful and interesting sticker can be applied to the protecting device to add a positive note to the procedure.

Finger and toe areas are left unoccluded by dressings or tape to allow for assessment of circulation. The thumb is never immobilized because of the danger of contractures with limited movement later on. An extremity should never be encircled with tape. The use of roll gauze, self-adhering stretch bandages (Coban), and Ace bandages can cause the same constriction and hide signs of infiltration.

! NURSING ALERT

Opaque covering should be avoided; however, if any type of opaque covering is used to secure the IV line, the insertion site and extremity distal to the site should be visible to detect an infiltration. If these sites are not visible, they must be checked frequently to detect problems early.

Traditionally padded boards and splints have been used to partially immobilize the IV site. Padded boards and splints and restraints were appropriate when metal needles were inserted into the vein to prevent the sharp end from puncturing the vessel, especially at a joint. With the more recent use of soft, pliable catheters, arm or leg boards may not be necessary and have several disadvantages. They obscure the IV site, can constrict the extremity, may excoriate the underlying tissue and promote infection, can cause a contracture of a joint, restrict useful movement of the extremity, and are uncomfortable. Unfortunately no research has been conducted to demonstrate their proposed benefit of increasing dwell time (patency of the IV line). Adequate securement should eliminate the need for padded boards in most circumstances. Older children who are alert and cooperative can usually be trusted to protect the IV site (see Evidence-Based Practice box).

Removing a Peripheral Intravenous Line

When it is time to discontinue an IV infusion, many children are distressed by the thought of catheter removal. Therefore they need a careful explanation of the process and suggestions for helping. Encouraging children to remove or help remove the tape from the site provides them with a measure of control and often fosters their cooperation. The procedure consists of turning off any pump apparatus, occluding the IV tubing, removing the tape, pulling the catheter out of the vessel in the opposite direction of insertion, and exerting firm pressure at the site. A dry dressing (adhesive bandage strip) is placed over the puncture site. The use of adhesive-removal pads can decrease the pain of tape removal, but the skin should be washed after use to avoid irritation. To remove transparent dressings (e.g., OpSite, Tegaderm), pull the opposing edges parallel to the skin

EVIDENCE-BASED PRACTICE

Peripheral Intravenous Care

Ask the Question

What site preparation and stabilization measures for PIV catheters are optimum for preventing complications and extending dwell time in children?

Search for Evidence

Search Strategies

Search selection criteria included English language and research-based publications within the past 20 years on PIV catheter site care.

Databases Used

National Guidelines Clearinghouse (AHQR), Cochrane Collaboration, Joanna Briggs Institute, PubMed, TRIP Database Plus, MD Consult, PedsCCM, BestBETs

Critically Analyze the Evidence

Site Preparation

- The skin should be disinfected with an appropriate antiseptic before PIV catheter insertion; allow it to dry before catheter insertion (Infusion Nurses Society, 2011a, 2011b; O'Grady, Alexander, Dellinger, et al., 2002; Registered Nurses' Association of Ontario, 2008).
- A 2% chlorhexidine-based preparation is preferred; but tincture of iodine, an iodophor, or 70% alcohol can be used. There is no recommendation for the use of chlorhexidine in infants younger than 2 months old (Infusion Nurses Society, 2011a; O'Grady, Alexander, Dellinger, et al., 2002).
- Cleansing the skin with a preparation that combines alcohol with either chlorhexidine gluconate or povidone-iodine before PIV catheter insertion is recommended (Infusion Nurses Society, 2006, 2011a, 2011b).
- All disinfectants have risks for neonates. Chlorhexidine gluconate with alcohol should not be used in neonates; aqueous chlorhexidine or povidone-iodine should be used in premature infants. Remove cleansers from infants using sterile water or normal saline to prevent absorption of the disinfectant (AWHONN, 2007).

Stabilization or Securement Devices

- PIV catheters must be stabilized for easy monitoring and evaluation of the access site; to promote delivery of therapy; and to prevent damage, dislodgement, or migration of the catheter (Infusion Nurses Society, 2011a; Registered Nurses' Association of Ontario, 2008).
- To avoid catheter movement and damage, the catheter and hub should be secured firmly with Steri-Strips and clear occlusive dressing; tape should not be placed directly to the catheter (Infusion Nurses Society, 2011a; Paulson and Miller, 2008).
- The catheter site should be assessed every 7 to 8 hours to ensure that the catheter has not migrated (Infusion Nurses Society, 2011a; Paulson and Miller, 2008).
- The traditional transparent dressing (Tegaderm) and tape group had a 65% complication rate (dislodgments, infiltration, and phlebitis) vs. a 20% complication rate in the transparent dressings and a catheter securement device (StatLock) group, indicating a 45% reduction in overall PIV therapy complications in the StatLock group (Wood, 1997).
- When comparing tape, StatLock, and Hub-Guard for a 96-hour PIV protocol change, it was found that PIV catheters with StatLock produced a statistically significant improved survival rate (52%) compared with tape (8%) or HubGuard (9%) (Smith, 2006).

Dwell Time

- In pediatric patients PIV catheters may remain in place until a complication occurs or the therapy is complete (O'Grady, Alexander, Dellinger, et al., 2002).
- In pediatric patients with PIV catheters the overall risk of PIV catheter complications was extremely low and would not be reduced substantially by routine catheter replacement (Shimandle, Johnson, Baker, et al., 1999).
- Evidence is insufficient regarding the effect of heparin use for extending PIV catheter use in neonates (Shah, Ng, and Sinha, 2005).
- An increase in complications and obstructions of PIV catheters was related to younger patient age, insertion into the wrist and scalp, and use of a 24-gauge catheter (Tripathi, Kaushik, and Singh, 2008).

Apply the Evidence: Nursing Implications

There is *low-quality evidence with strong recommendation* (Guyatt, Oxman, Vist, et al., 2008) for site preparation and stabilization measures for PIV catheters in children. For children older than 2 months of age chlorhexidine is the preferred skin cleanser. For younger infants non–alcohol-based cleansers are preferred and should be removed with sterile water or sterile normal saline to prevent absorption. The most distal vein on the extremity that allows the child optimum movement (avoid over the joint) should be selected. Veins on the scalp may be used in infants. Subsequent PIV catheters should be proximal to the previous IV site. If the child is mobile, consider using a securement or protection device (e.g., StatLock, HubGuard, Ray-Marshall Shield, IV House, IV Shield, IV Pro). Discontinue the PIV catheter if complications occur or when it is no longer needed.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries

Describe methods for site preparation and stabilization measures of PIV catheters for preventing complications and extending dwell time in children.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence

Integrate evidence into practice by using techniques for site preparation and stabilization measures for PIV catheters in children.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice

Appreciate the strengths and weakness of evidence for site preparation and stabilization measures for PIV catheters in children.

to loosen the bond. Inspect the catheter tip to ensure that the catheter is intact and that no portion remains in the vein.

! NURSING ALERT

Consider the child's age, development, and neurologic status and his or her predictability (i.e., how the child responds to painful treatments) when determining the need for assistance to maintain safety. Manual removal of tape is the preferred method. Only if absolutely necessary should a small cut be made in the tape, using bandage scissors, to facilitate its removal. Before cutting the tape:

- Ensure that all digits are visible.
- Remove any barrier that hinders visibility, such as a protective covering.
- Protect the child's skin and digits by sliding own finger(s) between the tape and the child's skin so the scissors do not touch the patient.
- Cut on the tape on the medial aspect (thumb side) of the extremity.

Complications

The same precautions regarding maintenance of asepsis, prevention of infection, and observation for infiltration are carried out with patients of any age. However, infiltration is more difficult to detect in infants and small children than in adults. The increased amount of subcutaneous fat and the amount of tape used to secure the catheter often obscure the early signs of infiltration. When the fluid appears to be infusing too slowly or ceases, the usual assessment for obstruction within the apparatus (i.e., kinks, screw clamps, shutoff valve, and positioning interference [e.g., a bent elbow]) often locates the difficulty. When these actions fail to detect the problem, it may be necessary to carefully remove some of the dressing to obtain a clear view of the venipuncture site. Dependent areas such as the palm and undersides of the extremity or the occiput and behind the ears are examined.

Whenever possible the IV infusion should be placed in an extremity to which the ID band (or bracelet) is not attached. Serious circulatory impairment can result from infiltrated solution distal to the band, which acts as a tourniquet preventing adequate venous return. To check for return blood flow through the catheter, the tubing is removed from the infusion pump, and the bag is lowered below the level of the infusion site. Resistance during flushing or aspiration for blood return also indicates that the IV infusion may have infiltrated surrounding tissue. A good blood return or lack thereof is not always an indicator of infiltration in small infants. Flushing the catheter and observing for edema, redness, or streaking along the vein are appropriate for assessment of the IV.

IV therapy in pediatrics tends to be difficult to maintain because of mechanical factors such as vascular trauma resulting from the catheter, the insertion site, vessel size, vessel fragility, pump pressure, the patient's activity level, operator skill and insertion technique, forceful administration of boluses of fluid, and infusion of irritants or vesicants through a small vessel. These factors cause infiltration and extravasation injuries. Infiltration is defined as inadvertent administration of a nonvesicant solution or medication into surrounding tissue. Extravasation is defined as inadvertent administration of vesicant solution or medication into surrounding tissue (Infusion Nurses Society, 2006). A vesicant or sclerosing agent causes varying degrees of cellular damage when even minute amounts escape into surrounding tissue. Guidelines are available for determining the severity of tissue injury by staging characteristics such as the amount of redness, blanching, the amount of swelling, pain, the quality of pulses below infiltration, capillary refill, and warmth or coolness of the area (Infusion Nurses Society, 2006).*

Treatment of infiltration or extravasation varies according to the type of vesicant. Guidelines are available outlining the sequence of interventions and specific treatment of infiltration or extravasation with antidotes.

! NURSING ALERT

When infiltration or extravasation is observed (signs include erythema, pain, edema, blanching, streaking on the skin along the vein, and darkened area at the insertion site), immediately stop the infusion, elevate the extremity, notify the practitioner, and initiate the ordered treatment as soon as possible. Remove the IV line when it is no longer needed (e.g., after infusing an antidote).

*Guidelines for determining tissue injury severity are available from the Infusion Nurses Society, 315 Norwood Park South, Norwood, MA 02062, 781-440-9408, www.ins1.org.

FIG 39-22 Oxygen administered to infant by means of a plastic hood. Note oxygen analyzer (blue machine).

Phlebitis, or inflammation of the vessel wall, may also develop in children who require IV therapy. Lamagna and MacPhee (2004) describe three types of phlebitis: mechanical (caused by rapid infusion rate, manipulation of the IV), chemical (caused by medications), and bacterial (caused by staphylococcal organisms). The initial sign of phlebitis is erythema (redness) at the insertion site. Pain may or may not be present.

PIV catheters are the most commonly used intravascular device. Heavy cutaneous colonization of the insertion site is the single most important predictor of catheter-related infection with all types of short-term, percutaneously inserted catheters. Phlebitis, largely a mechanical rather than infectious process, remains the most important complication associated with the use of peripheral venous catheters.*

! NURSING ALERT

The most effective ways to prevent infection of an IV site are to cleanse hands between each patient, wear gloves when inserting a catheter, and inspect the insertion site and physical condition of the dressing closely. Proper education of the patient and family regarding signs and symptoms of an infected site can help prevent infections from going unnoticed.

PROCEDURES FOR MAINTAINING RESPIRATORY FUNCTION

Inhalation Therapy

Oxygen Therapy

Oxygen is administered for hypoxemia and may be delivered by mask, nasal cannula, face tent, hood, face mask, or ventilator. The mode of delivery is selected on the basis of the concentration needed and the child's ability to cooperate in its use. Oxygen therapy is frequently administered in the hospital, although increasing numbers of children are receiving oxygen in the home. Oxygen is dry and therefore must be humidified.

Oxygen delivered to infants is well tolerated by using a plastic hood (Fig. 39-22). At least 4 to 5 L/min of flow is necessary to maintain oxygen concentrations and remove the exhaled carbon dioxide. The humidified oxygen should not be blown directly into the infant's face. Older cooperative infants and children can use a nasal cannula or prongs, which can supply a concentration of oxygen of about 50%.

Oxygen masks are available in pediatric sizes but may not be tolerated well in children because a snug fit is required to ensure adequate oxygen delivery. A face tent or bucket is often tolerated better because this soft piece of plastic sits beneath the child's chin and allows oxygen to be directed to the mouth and nose without enclosure (Curley and Moloney-Harmon, 2001). Oxygen tents (croup tents) are rarely used today in developed countries. Oxygen concentration is difficult to control, and the child's clothing can become saturated with water from the humidification and cause hypothermia.

MEDICATION ALERT

Prolonged exposure to high oxygen tensions can damage some body tissues and functions. The organs most vulnerable to the adverse effects of excessive oxygenation are the retinas of extremely preterm infants and the lungs of people at any age.

! NURSING ALERT

Inspect all toys for safety and suitability (e.g., vinyl or plastic, not stuffed items that absorb moisture and are difficult to keep dry). The high-level oxygen environment makes any source of sparks (e.g., mechanical or electrical toys) a potential fire hazard.

Oxygen-induced carbon dioxide narcosis is a physiologic hazard of oxygen therapy that may occur in people with chronic pulmonary disease such as cystic fibrosis. In these patients the respiratory center has adapted to the continuously higher arterial carbon dioxide tension ($PaCO_2$) levels; therefore hypoxia becomes the more powerful stimulus for respiration. When the arterial oxygen tension (PaO_2) level is elevated during oxygen administration, the hypoxic drive is removed, causing progressive hypoventilation and increased $PaCO_2$ levels, and the child rapidly becomes unconscious. Carbon dioxide narcosis can also be induced by the administration of sedation in these patients.

Monitoring Oxygen Therapy

Pulse oximetry is a continuous, noninvasive method of determining oxygen saturation (SaO_2) to guide oxygen therapy. A sensor composed of a light-emitting diode (LED) and a photodetector is placed in opposition around a foot, hand, finger, toe, or earlobe, with the LED placed on top of the nail when digits are used (Fig. 39-23). The diode emits red and infrared lights that pass through the skin to the photodetector. The photodetector measures the amount of each type of light absorbed by functional hemoglobins. Hemoglobin saturated with oxygen (oxyhemoglobin) absorbs more infrared light than does hemoglobin not saturated with oxygen (deoxyhemoglobin). Pulsatile blood flow is the primary physiologic factor that influences accuracy of the pulse oximeter. In infants reposition the probe at least every 3 to 4 hours to prevent pressure necrosis; poor perfusion and very sensitive skin may necessitate more frequent repositioning.

Another noninvasive method is transcutaneous monitoring (TCM), which provides continuous monitoring of transcutaneous partial pressure of oxygen in arterial blood ($tcPaO_2$) and with some

*Guidelines for prevention of health care–associated infections are available from the CDC, 1600 Clifton Road, Atlanta, GA 30333, 800-232-4636 or 404-639-1515, www.cdc.gov/hai.

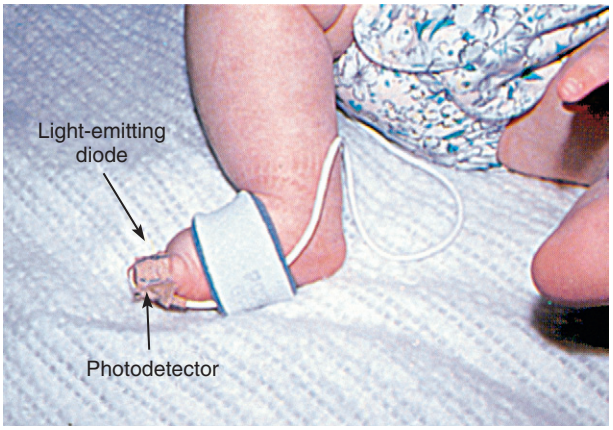

FIG 39-23 Oximeter sensor on great toe. Note that sensor is positioned with a light-emitting diode (LED) opposite photodetector. Cord is secured to foot to minimize movement of sensor.

devices of carbon dioxide in arterial blood ($tcPaCO_2$). An electrode is attached to the warmed skin to facilitate arterialization of cutaneous capillaries. The site of the electrode must be changed every 3 to 4 hours to avoid burning the skin, and the machine must be calibrated with every site change. TCM is used frequently in neonatal intensive care units, but it may not reflect PaO_2 in infants with impaired local circulation or older infants whose skin is thicker.

Oximetry is insensitive to hyperoxia because hemoglobin approaches 100% saturation for all PaO_2 readings greater than approximately 100 mm Hg, which is a dangerous situation for preterm infants at risk for developing retinopathy of prematurity (see Chapter 25). Therefore preterm infants being monitored with oximetry should have their upper limits identified such as 90% to 95%, and a protocol should be established for decreasing oxygen when saturations are high.

Oximetry offers several advantages over TCM. It (1) does not require heating the skin, thus reducing the risk of burns; (2) eliminates a delay period for transducer equilibration; and (3) maintains an accurate measurement regardless of the patient's age or skin characteristics or the presence of lung disease.

! NURSING ALERT

It is important to make certain that sensor connectors and oximeters are compatible. Wiring that is incompatible can generate considerable heat at the tip of the sensor, causing second- and third-degree burns under the sensors. Pressure necrosis can also occur from sensors attached too tightly. Therefore inspect the skin under the sensor frequently.

Applying the sensor correctly is essential for accurate SaO_2 measurements. Because the sensor must identify every pulse beat to calculate the SaO_2, movement can interfere with sensing. Some devices synchronize the SaO_2 reading with the heartbeat, thereby reducing the interference caused by motion. Sensors are not placed on extremities used for blood pressure monitoring or with indwelling arterial catheters because pulsatile blood flow may be affected.

Ambient light from ceiling lights and phototherapy and high-intensity heat and light from radiant warmers can interfere with readings. Therefore the sensor should be covered to block these light sources. IV dyes; green, purple, or black nail polish; nonopaque synthetic nails; and possibly ink used for footprinting can also cause inaccurate SaO_2 measurements. The dyes should be removed; or, in the case of porcelain nails, a different area used for the sensor. Skin color, thickness, and edema do not affect the readings.

Blood gas measurements are sensitive indicators of change in respiratory status in acutely ill patients. They provide valuable information regarding lung function, lung adequacy, and tissue perfusion. The pH, $PaCO_2$, HCO_3, and PaO_2 levels can provide information about whether the child is compensating and guide critical treatment decisions.

End-Tidal Carbon Dioxide Monitoring

End-tidal CO_2 ($ETCO_2$) monitoring measures exhaled carbon dioxide noninvasively. Capnometry provides a numeric display, and capnography provides a graph over time. Continuous capnometry is available in many bedside physiologic and stand-alone monitors. $ETCO_2$ differs from pulse oximetry in that it is more sensitive to the mechanics of ventilation rather than oxygenation. Hypoxic episodes can be prevented through the early detection of hypoventilation, apnea, or airway obstruction.

Children who are experiencing an asthma exacerbation, receiving procedural sedation, or mechanically ventilated may have $ETCO_2$ monitoring. Special sampling cannulas are used for nonintubated patients, and a small device is placed between the endotracheal (ET) tube and the ventilator tubing in intubated patients. Although $ETCO_2$ monitoring is not a substitute for arterial blood gases, it does provide ventilation information continuously and noninvasively. Normal $ETCO_2$ values are 30 to 43 mm Hg, which is slightly lower than normal arterial PCO_2 of 35 to 45 mm Hg. During CPR, $ETCO_2$ values consistently below 15 mm Hg indicate ineffective compressions or excessive ventilation. Changes in waveform and numeric display follow changes in ventilation by a very few seconds and precede changes in respiratory rate, skin color, and pulse oximetry values.

For years disposable colormetric $ETCO_2$ detectors have been used to assess ET tube placement. A color change with each exhaled breath when there is adequate systemic perfusion indicates that the tube is in the lungs. These devices do not provide numbers or graphic representation and the same early detection of hypoventilation as the continuous quantitative monitors.

Additional uses of $ETCO_2$ monitoring have limited supporting research. Although waveform analysis does not yet have standardized nomenclature, some clinicians use the angles of the waveform coupled with the quantitative value of $ETCO_2$ to classify the severity of asthma exacerbations. The severity of diabetic ketoacidosis (Fearon and Steele, 2002) and acidosis from gastroenteritis (Nagler, Wright, and Krauss, 2006) has also been researched in children and is used in some facilities.

When there is a change in the $ETCO_2$ value or waveform, assess the patient quickly for adequate airway, breathing, and circulation. Sedated patients may be hypoventilating and need stimulation. Intubated patients may need suctioning, have self-extubated or dislodged the tube, or have equipment failure or disconnection. Patients with asthma may have a worsening condition. Problems with the $ETCO_2$ monitoring system can include a kink in the sample line or disconnection. In general check the patient first and then the equipment.

Bronchial (Postural) Drainage

Bronchial drainage is indicated whenever excessive fluid or mucus in the bronchi is not being removed by normal ciliary activity and cough. Positioning the child to take maximum advantage of gravity facilitates removal of secretions. Postural drainage can be effective

in children with chronic lung disease characterized by thick mucus such as cystic fibrosis.

Postural drainage is carried out 3 or 4 times daily and is more effective when it follows other respiratory therapy such as bronchodilator or nebulization medication. Bronchial drainage is generally performed before meals (or 1 to 1½ hours after meals) to minimize the chance of vomiting and is repeated at bedtime. The duration of treatment depends on the child's condition and tolerance; it usually lasts 20 to 30 minutes. Several positions facilitate drainage from all major lung segments.

Chest Physical Therapy

Chest physical therapy (CPT) usually refers to the use of postural drainage in combination with adjunctive techniques that are thought to enhance the clearance of mucus from the airway. These techniques include manual percussion, vibration, and squeezing of the chest; cough; forceful expiration; and breathing exercises. Special mechanical devices are also currently used to perform CPT (e.g., vest-type percussors). Postural drainage in combination with forced expiration has been shown to be beneficial.

Common techniques used in association with postural drainage include manual percussion of the chest wall and percussion with mechanical devices such as a high-frequency handheld chest compression device. A "popping," hollow sound, not a slapping sound, should be the result. The procedure should be done over the rib cage only and should be painless. Percussion can be performed with a soft circular mask (adapted to maintain air trapping) or a percussion cup marketed especially for the purpose of aiding in loosening secretions. CPT is contraindicated when patients have pulmonary hemorrhage, pulmonary embolism, end-stage renal disease, increased intracranial pressure, osteogenesis imperfecta, or minimal cardiac reserves.

Intubation

Rapid-sequence intubation (RSI) is commonly performed in pediatric (and some neonatal) patients to induce an unconscious, neuromuscular blocked condition to avoid the use of positive-pressure ventilation and the risk of possible aspiration (Bottor, 2009). Atropine, fentanyl, and vecuronium or rocuronium are drugs commonly used during RSI. In neonates ET tube intubation is often a stressful event, and hypoxia and pain are commonly associated with it; RSI in neonates may serve to prevent such adverse events (Bottor, 2009).

Indications for intubation include the following:

- Respiratory failure or arrest, agonal or gasping respirations, apnea
- Upper airway obstruction
- Significant increase in work of breathing, use of accessory muscles
- Potential for developing partial or complete airway obstruction—respiratory effort with no breath sounds, facial trauma, and inhalation injuries
- Potential for or actual loss of airway protection, increased risk for aspiration
- Anticipated need for mechanical ventilation related to chest trauma, shock, increased intracranial pressure
- Hypoxemia despite supplemental oxygen
- Inadequate ventilation

In preparation for intubation the child should be preoxygenated with 100% oxygen using an appropriate-size bag and mask. Only uncuffed ET tubes should be used in children younger than 8 years of age (Curley and Moloney-Harmon, 2001). Air or gas delivered directly to the trachea must be humidified. During intubation the cardiac rhythm, heart rate, and oxygen saturation should be monitored continuously with audible tones. ET tube placement should be verified by at least one clinical sign and at least one confirmatory technology:

- Visualization of bilateral chest expansion
- Auscultation over the epigastrium (breath sounds should not be heard) and the lung fields bilaterally in the axillary region (breath sounds should be equal and adequate)
- Water vapor in the tube (helpful; not definitive)
- Color change on end-tidal carbon dioxide detector during exhalation after at least 3 to 6 breaths or waveform/value verification with continuous capnography
- Chest radiography

Apply a protective skin barrier and secure the ET tube with tape or a securement device. An NG tube typically is inserted after intubation.

Mechanical Ventilation

ET intubation can be accomplished by the nasal (nasotracheal), oral (orotracheal), or direct tracheal (tracheostomy) routes. Although it is more difficult to place, nasotracheal intubation is preferred to orotracheal intubation because it facilitates oral hygiene and provides more stable fixation, which reduces the complication of tracheal erosion and the danger of accidental extubation.

Basic ongoing assessment of the mechanically ventilated patient includes observing the chest rise and fall for symmetry, bilateral breath sounds equal or unchanged from last assessment, level of consciousness, capillary refill and skin color, and vital signs. A heart rate that is too fast or too slow is a possible indication of hypoxemia, air leak, or low cardiac output. Pulse oximetry and end-tidal carbon dioxide monitoring is also routine along with periodic arterial blood gas analysis. If sudden deterioration of an intubated patient occurs, consider the following etiologies.

DOPE*

Displacement—Tube not in the trachea or has moved into a bronchus (right mainstream most common)

Obstruction—Secretions or kinking of the tube

Pneumothorax—Chest trauma, barotraumas, or noncompliant lung disease

Equipment failure—Check the oxygen source, Ambu bag, and ventilator

Verify placement again during each transport and when patients are moved to different beds

To maintain skin integrity in the mechanically ventilated patient, reposition the patient at least every 2 hours as the patient's condition tolerates. Apply a hydrocolloid barrier to protect the facial cheeks. Place gel pillows under pressure points such as occiput, heels, elbows, and shoulders. Allow no tubes, lines, wires, or wrinkles in bedding under the patient. Provide meticulous skin care.

Provide analgesia and sedation as needed. Use a system for communication that includes sign boards, pointing, and opening and closing eyes. To maintain safety use soft restraints if necessary to maintain a critical airway.

Ventilator-associated pneumonia is a complication that can be prevented through the use of aggressive hand hygiene, oral care, and elevation of the head of the bed between 30 and 45 degrees (unless contraindicated). Enteral nutrition is often provided to decrease the risk of bacterial translocation. Routinely assess the patient's intestinal motility (e.g., by auscultating for bowel sounds and measuring

*American Heart Association, 2010.

residual gastric volume or abdominal girth) and adjust the rate and volume of enteral feeding to avoid regurgitation. In high risk patients (decreased gag reflex, delayed gastric emptying, gastroesophageal reflux, severe bronchospasm), postpyloric (duodenal or jejunal) feeding tubes are often used. To prevent the aspiration of pooled secretions, suction the hypopharynx before suctioning the ET tube, before repositioning the ET tube, and before repositioning the patient. Prevent ventilator circuits' condensate from entering ET tube or in-line medication nebulizers.

Assess readiness to extubate daily. Indications that a child is ready to be extubated include an improvement in underlying condition, hemodynamic stability, and mechanical support no longer being necessary. Assess level of consciousness and ability to maintain a patent airway by mobilizing pulmonary secretions through effective coughing. Maintain NPO status 4 hours before extubation. After extubation monitor for respiratory distress, which may develop within minutes or hours. Signs of postintubation respiratory distress include stridor, hoarseness, increased work of breathing, unstable vital signs, and desaturations.

Tracheostomy

A tracheostomy is a surgical opening in the trachea; the procedure may be done on an emergency basis or elective, and it may be combined with mechanical ventilation. Pediatric tracheostomy tubes are usually made of plastic or Silastic (Fig. 39-24). The most common types are the Hollinger, Jackson, Aberdeen, and Shiley tubes. These tubes are constructed with a more acute angle than adult tubes; and they soften at body temperature, conforming to the contours of the trachea. Because these materials resist the formation of crusted respiratory secretions, they are made without an inner cannula.

Children who have undergone a tracheostomy must be monitored closely for complications such as hemorrhage, edema, aspiration, accidental decannulation, tube obstruction, and the entrance of free air into the pleural cavity. The focuses of nursing care are maintaining a patent airway, facilitating the removal of pulmonary secretions, providing humidified air or oxygen, cleansing the stoma, monitoring the child's ability to swallow, and teaching while simultaneously preventing complications.

Because the child may be unable to signal for help, direct observation and use of respiratory and cardiac monitors are essential. Respiratory assessments include breath sounds and work of breathing, vital signs, tightness of the tracheostomy ties, and the type and amount of secretions. Large amounts of bloody secretions are uncommon and should be considered a sign of hemorrhage. The practitioner should be notified immediately if this occurs.

The child is positioned with the head of the bed raised or in the position most comfortable to the child with the call light easily available. Suction catheters, suction source, gloves, sterile saline, sterile gauze for wiping away secretions, scissors, an extra tracheostomy tube of the same size with ties already attached, another tracheostomy tube one size smaller, and the obturator are kept at the bedside. A source of humidification is provided because the normal humidification and filtering functions of the airway have been bypassed. IV fluids ensure adequate hydration until the child is able to swallow sufficient amounts of fluids.

Suctioning

The airway must remain patent and may require frequent suctioning during the first few hours after a tracheostomy to remove mucus plugs and excessive secretions. Proper vacuum pressure and suction catheter size are important to prevent atelectasis and decrease hypoxia from the suctioning procedure. Vacuum pressure should range from 60 to 100 mm Hg for infants and children and from 40 to 60 mm Hg for preterm infants. Unless secretions are thick and tenacious, the lower range of negative pressure is recommended. Tracheal suction catheters are available in a variety of sizes. The catheter selected should have a diameter that is half the diameter of the tracheostomy tube. If it is too large, it can block the airway. The catheter is constructed with a side port so that it is introduced without suction and removed while simultaneous intermittent suction is applied by covering the port with the thumb (Fig. 39-25). It is inserted just to the end of the tracheostomy tube. The practice of instilling sterile saline in the tracheostomy tube before suctioning is not supported by research and is no longer recommended (see Evidence-Based Practice box).

The child is allowed to rest for 30 to 60 seconds after each aspiration to allow oxygen saturation to return to normal; then the process is repeated until the trachea is clear. Suctioning should be limited to

! NURSING ALERT

Suctioning should require no more than 5 seconds. Counting one one-thousand, two one-thousand, three one-thousand, and so on while suctioning is a simple means for monitoring the time. Without a safeguard the airway may be obstructed for too long. Hyperventilating the child with 100% oxygen before and after suctioning (using a bag-valve-mask or increasing the fraction of inspired oxygen concentration [FiO_2] ventilator setting) may be performed to prevent hypoxia. Closed tracheal suctioning systems that allow for uninterrupted oxygen delivery may also be used.

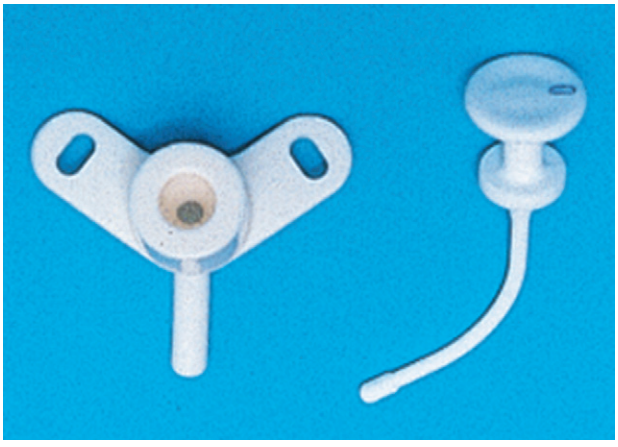

FIG 39-24 Silastic pediatric tracheostomy tube and obturator.

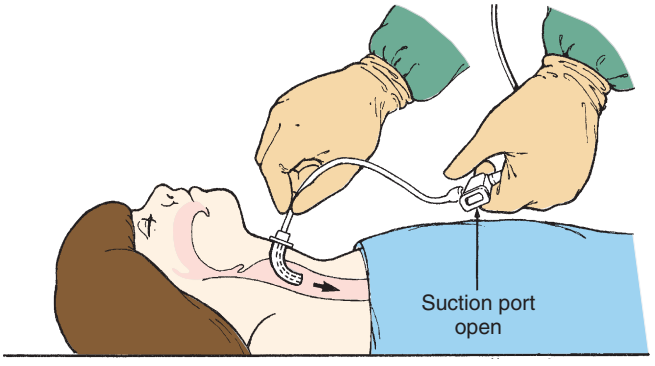

FIG 39-25 Tracheostomy suction catheter insertion. Note that catheter is inserted just to the end of the tracheostomy tube.

EVIDENCE-BASED PRACTICE

Normal Saline Instillation Before Endotracheal or Tracheostomy Suctioning—Helpful or Harmful?

Ask the Question

In intubated children and those with tracheostomy, is NS instillation before suctioning helpful or harmful?

Search for Evidence

Search Strategies

Searched all literature from 1980 to 2011.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, BestBETs, PedsCCM, AHRQ

Critically Analyze the Evidence

- Adult studies have found decreased oxygen saturation, increased frequency of nosocomial pneumonia, and increased intracranial pressure after instillation of NS before suctioning (Ackerman, 1993; Ackerman and Gugerty, 1990; Bostick and Wendelgass, 1987; Hagler and Traver, 1994; Kinlock, 1999; O'Neal, Grap, Thompson, et al., 2001; Reynolds, Hoffman, Schlichtig, et al., 1990).
- No significant differences in oxygenation, heart rate, or blood pressure were found before or after suctioning in a group of 27 intubated neonates (Shorten, Byrne, and Jones, 1991).
- No adverse effects on lung mechanics were found after NS instillation and suctioning in neonates (Beeram and Dhanireddy, 1992).
- Children ages 10 weeks to 14 years experienced significantly greater oxygen desaturation after suctioning if NS was instilled (Ridling, Martin, and Bratton, 2003).
- With tracheostomies NS should not be instilled before suctioning (American Thoracic Society, 2005).
- Evidence does not support routine instillation of NS in neonates; however, abundant evidence indicates the adverse effects of NS instillation (Gardner and Shirland, 2009).
- Evidence indicating the detriment of the use of saline for suctioning is lacking in the pediatric population. However, saline should not be used routinely for suctioning infants and children (Morrow and Argent, 2008).
- ET suctioning performed with saline solution was associated with an increase in episodes of bradycardia, desaturations, and need for increase in the fraction of inspired oxygen (Trevisanuto, Doglioni, and Zanardo, 2009).
- Potential harms that may be associated with use of NS installation include increased coughing, oxygen desaturation, bronchospasms, tachycardia, pain, anxiety, dyspnea, increased intracranial pressure, and loosened bacterial biofilm that may colonize the ET tube (American Association for Respiratory Care, 2010).
- Use of low-sodium solution for airway suctioning in neonates significantly decreased VAP and rates of chronic lung disease (Christensen, Henry, Baer, et al., 2010).

Apply the Evidence: Nursing Implications

There is *moderate-quality evidence with a strong recommendation* (Guyatt, Oxman, Vist, et al., 2008) that adverse effects of NS instillation before suctioning in children are similar to those found for adults. This technique causes a significant reduction in oxygen saturation that can last up to 2 minutes after suctioning. The evidence does not support the use of NS instillation before ET suctioning in children.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries

Describe methods for using NS instillation before ET or tracheostomy suctioning.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence

Integrate evidence into practice on NS instillation before ET or tracheostomy suctioning.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice

Appreciate the strengths and weakness of evidence for NS instillation before ET or tracheostomy suctioning.

about three aspirations in one period. Oximetry is used to monitor suctioning and prevent hypoxia.

! NURSING ALERT

Suctioning is carried out only as often as needed to keep the tube patent. Signs of mucus partially occluding the airway include an increased heart rate, a rise in respiratory effort, a drop in SaO_2, cyanosis, and an increase in the positive inspiratory pressure on the ventilator.

In the acute care setting aseptic technique is used during care of the tracheostomy. Secondary infection is a major concern because the air entering the lower airway bypasses the natural defenses of the upper airway. Gloves are worn during the aspiration procedure, although a sterile glove is needed only on the hand touching the catheter. A new tube, gloves, and sterile saline solution are used each time.

Routine Care

The tracheostomy stoma requires daily care. Assessments of the stoma area include observations for signs of infection and breakdown of the skin. The skin is kept clean and dry, and crusted secretions around the stoma may be gently removed with half-strength hydrogen peroxide. Hydrogen peroxide should not be used with sterling silver tracheostomy tubes because it tends to pit and stain the silver surface. The nurse should be aware of wet tracheostomy dressings, which can predispose the peristomal area to skin breakdown. Several products are available to prevent or treat excoriation. The Allevyn tracheostomy dressing is a hydrophilic sponge with a polyurethane back that is highly absorptive. Other possible barriers to help maintain skin integrity include the use of hydrocolloid wafers (e.g., DuoDERM CGF, Hollister Restore) under the tracheostomy flanges and extra-thin hydrocolloid wafers under the chin.

The tracheostomy tube is held in place with tracheostomy ties made of a durable, nonfraying material. The ties are changed daily and when soiled. Ties fastened with self-adhering Velcro closures are commonly used. If Velcro ties are not available, cotton ties are looped through the flanges and tied snugly in a triple knot at the side of the neck before the soiled ties are cut and removed. The ties should be tight enough to allow just a fingertip to be inserted between the ties and the neck (Fig. 39-26). It is easier to ensure a snug fit if the child's head is flexed rather than extended while the ties are being secured.

Routine tracheostomy tube changes are usually carried out weekly after a tract has been formed to minimize the formation of granulation tissue. The first change is usually performed by the surgeon; subsequent changes are performed by the nurse, and, if the child is discharged home with the tracheostomy, by either a parent or a visiting nurse. Ideally two caregivers participate in the procedure to help position the child.

FIG 39-26 Tracheostomy ties are snug but allow one finger to be inserted.

Changing the tracheostomy tube is accomplished using sterile technique. Tube changes should occur before meals or 2 hours after the last meal. Continuous feedings should be turned off at least an hour before a tube change. The new sterile tube is prepared by inserting the obturator and attaching new ties. The child may be suctioned if necessary before the procedure and then restrained and positioned with the neck slightly extended. One caregiver removes the old ties and removes the tube from the stoma. The new tube is inserted gently into the stoma (using a downward and forward motion that follows the curve of the trachea), the obturator is removed, and the ties are secured. The adequacy of ventilation must be assessed after a tube change because the tube can be inserted into the soft tissue surrounding the trachea; therefore, breath sounds and respiratory effort are monitored carefully.

Supplemental oxygen is always delivered with a humidification system to prevent drying of the respiratory mucosa. Humidification of room air for an established tracheostomy can be intermittent if secretions remain thin enough to be coughed or suctioned from the tracheostomy. Direct humidification via a tracheostomy mask can be provided during naps and at night so the child is able to be up and around unencumbered during much of the day. Room humidifiers are also used successfully.

If the inner cannula is used, it should be removed with each suctioning, cleaned with sterile saline and pipe cleaners to remove crusted material, dried thoroughly, and reinserted.

Emergency Care: Tube Occlusion and Accidental Decannulation

Occlusion of the tracheostomy tube is life threatening, and infants and children are at greater risk than adults because of the smaller diameter of the tube. Maintaining patency of the tube is accomplished with suctioning and routine tube changes to prevent the formation of crusts that can occlude it.

! NURSING ALERT

Life-threatening occlusion is apparent when the child displays signs of respiratory distress and a suction catheter cannot be passed to the end of the tube despite several attempts and instillation of saline. This situation requires an immediate tube change.

Accidental decannulation also requires immediate tube replacement. Some children have a fairly rigid trachea; thus the airway remains partially open when the tube is removed. However, others have malformed or flexible tracheal cartilage, which causes the airway to collapse when the tube is removed or dislodged. Because many infants and children with upper airway problems have little airway reserve, if replacement of the dislodged tube is impossible, a smaller-size tube should be inserted. If the stoma cannot be cannulated with another tracheostomy tube, oral intubation should be performed.

Chest Tube Procedures

A chest tube is placed to remove fluid or air from the pleural or pericardial space. Chest tube drainage systems collect air and fluid while inhibiting backflow into the pleural or pericardial space. Indications for chest tube placement include pneumothorax, hemothorax, chylothorax, empyema, pleural or pericardial effusion, and

prevention of accumulation of fluid in the pleural and pericardial space after cardiothoracic surgery. Nursing responsibilities include assisting with chest tube placement, managing chest tubes, and assisting with chest tube removal.

Before chest tube insertion assess hematologic and coagulation studies for any risk of bleeding during the procedure. Notify the health care provider of abnormal findings. Prepare the drainage system with sterile water as described in the package insert (some systems may not require this step). Administer pain and sedation medications as ordered. Monitor airway, breathing, circulation, and pulse oximetry throughout the procedure.

After the tube has been inserted and connected to the chest drainage system, secure the tubing so it does not become disconnected. If suction is required, use connection tubing to join the drainage system to a wall suction adapter and adjust suction on the drainage system as ordered (usually −10 to −20 cm H_2O). There should be gentle, continuous bubbling in the suction control chamber. Place occlusive dressing over the chest tube insertion site per hospital policy. Note the date, time, and your initials on the dressing. If gauze is used, use presplit gauze; "homemade" split gauze may leave loose threads in the wound. Ensure that the drainage system is positioned below the patient's chest and secured to the floor or bed. Keep the drainage tubing free of dependent loops. Obtain a chest radiograph to confirm placement of the chest tube. Ensure that daily chest radiographs are scheduled to monitor placement of the chest tube and resolution of the pneumothorax or effusion.

Disposable chest drainage systems typically consist of three chambers next to one another in one drainage unit (Fig. 39-27). The fluid collection chamber collects drainage from the patient's pleural or pericardial space. The water-seal chamber is connected directly to the fluid collection chamber and acts as a one-way valve, protecting patients from air returning to the pleural or pericardial space. The suction chamber may be a dry suction or calibrated water chamber. It is connected to external vacuum suction set to the amount of suction ordered and controls the amount of suction that patients experience.

Assess for blood clots and fibrin strands in tubes with sanguineous or serosanguineous drainage and ensure that there are no obstructions to drainage in the tube. Maintain chest tube clearance per hospital policy. Milking or stripping of chest tubes is not recommended for chest tube clearance because of the high negative intrathoracic pressure that is created. However, some special circumstances such as maintaining chest tube patency while a patient is bleeding warrant chest tube clearance with these methods. Notify the health care provider immediately if chest tube obstruction is suspected. Generally chest tubes should not be clamped. However, it may be necessary to clamp a chest tube when exchanging the collection chamber or determine the site of an air leak (see Guidelines box).

ALTERNATIVE FEEDING TECHNIQUES

Some children are unable to take nourishment by mouth because of anomalies of the throat, esophagus, or bowel; impaired swallowing capacity; severe debilitation; respiratory distress; or unconsciousness. These children are frequently fed by way of a tube inserted orally or nasally into the stomach (orogastric [OG] or NG gavage) or duodenum-jejunum (enteral gavage) or by a tube inserted directly into the stomach (gastrostomy) or jejunum (jejunostomy). Such feedings may be intermittent or by continuous drip. Feeding resistance, a problem that may result from any long-term feeding method that bypasses the mouth, is discussed in Chapter 25. During gavage or gastrostomy feedings infants are given a pacifier. Nonnutritive sucking has several advantages such as increased weight gain and decreased crying. However, only pacifiers with a safe design can be used to prevent the possibility of aspiration. Using improvised pacifiers made from bottle nipples is not a safe practice.

When a child is concurrently receiving continuous-drip gastric or enteral feedings and parenteral (IV) therapy, the potential exists for inadvertent administration of the enteral formula through the

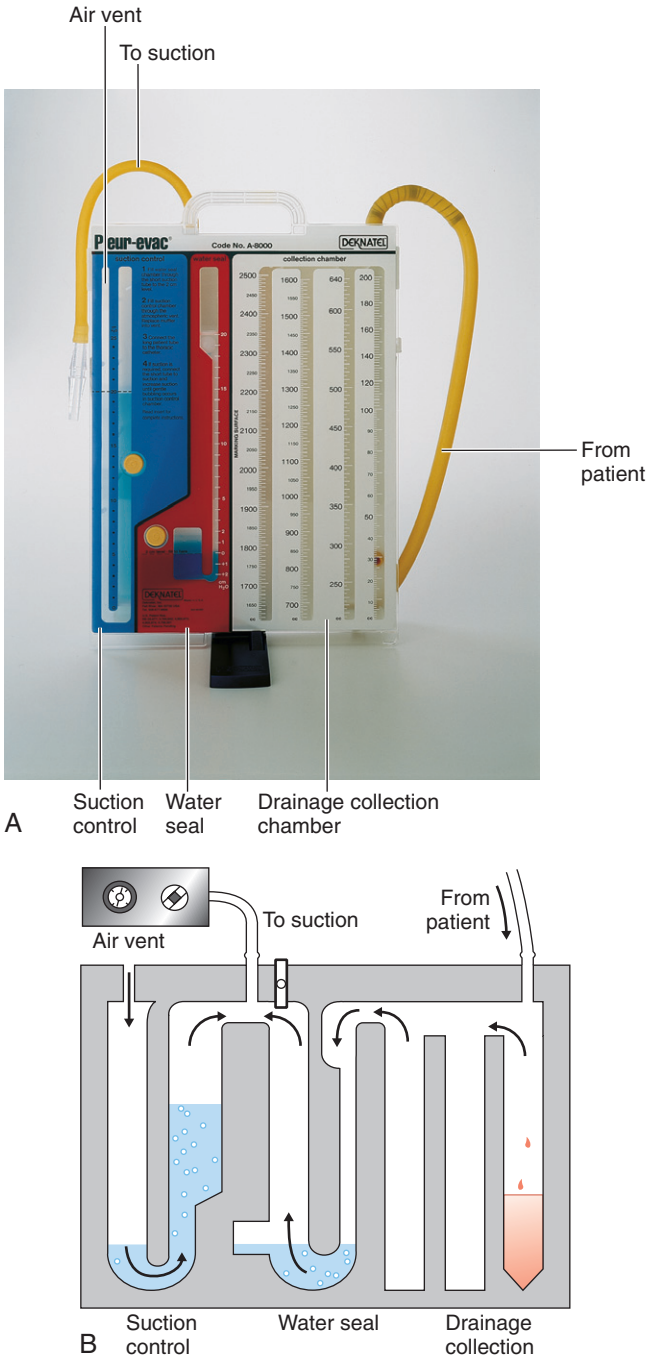

FIG 39-27 **A,** Pleur-Evac drainage system, a commercial three-bottle chest drainage device. **B,** Schematic of drainage device. (From Ignatavicius, DD, Workman, LM: *Medical-surgical nursing: patient-centered collaborative care*, ed 6, Philadelphia, 2010, Saunders.)

circulatory system. The possibility for error increases when the parenteral solution is a fat emulsion (i.e., a milky-appearing substance). Safeguards to prevent this potentially serious error include:

- Using a separate, specifically designed enteral feeding pump mounted on a separate pole for continuous-feeding solutions.
- Labeling all tubing of continuous enteral feeding with brightly colored tape or labels.
- Using specifically designed continuous-feeding bags to contain the solutions instead of parenteral equipment such as a burette.

GUIDELINES

Ongoing Patient and Chest Drainage System Assessment

- Determine drainage type (sanguinous, serosanguineous, serous, chylous, empyemic), color, amount, consistency. If there is a marked decrease in the amount of drainage, assess for drainage around chest tube insertion site.
- Dressing clean, dry, and intact.
- Chest tube sutures are intact.
- Prescribed amount of suction is applied.
- Water level is at 2 cm. If water column is too high, the flow of air from the chest may be impeded.
- Bubbling in water-seal chamber is normal if chest tube was placed to evacuate a pneumothorax. Bubbling will stop when the pneumothorax has resolved.
- Fluctuations may be seen in the water column because of changes in intrathoracic pressure. Substantial fluctuations may reflect changes in a patient's respiratory status.
- Note signs and symptoms of infection or skin breakdown.
- Palpate for presence of subcutaneous air.

Interventions

- Notify health care provider of any changes in the quantity or quality of drainage.
- If 3 mL/kg/hr or greater of sanguinous drainage occurs for 2 to 3 consecutive hours after cardiothoracic surgery, it may indicate active hemorrhaging and warrants immediate attention of the physician.
- Change dressing and perform site care per hospital policy. Typically a minimal, occlusive dressing is applied.
- When the collection chamber is almost full, exchange existing drainage system with a new one per manufacturer instructions using sterile technique.
- To lower the water column, depress the manual vent on the back of the unit until the water level reaches 2 cm. *Do not depress the filtered manual vent when the suction is not functioning or connected.*
- If evacuation of a pneumothorax was not the indication for placement of the chest tube, bubbling in the water-seal chamber may be the result of a break in the chest drainage system. Identify the break in the system by briefly clamping the system between the drainage unit and the patient. When the clamp is placed between the unit and the break in the system, the bubbling will stop. Tighten any loose connections. If the air leak is suspected to be at the patient's chest wall, notify the health care provider.
- Encourage patient ambulation. Secure chest tube drainage system to prevent chest tube dislodgment from patient or disconnection from drainage system.
- Whenever access or connections are made, tracing the tubing all the way from the patient to the bag to ensure that the correct tubing source is selected.

Gavage Feeding

Infants and children can be fed simply and safely by a tube passed into the stomach through either the nares or the mouth. The tube can be left in place or inserted and removed with each feeding. In older children it is usually less traumatic to tape the tube securely in place between feedings. When this alternative is used, the tube should be removed and replaced with a new tube according to hospital policy, specific orders, and the type of tube used. Meticulous hand washing is practiced during the procedure to prevent bacterial contamination of the feeding, especially during continuous-drip feedings.

Preparation

The equipment needed for gavage feeding includes the following:

- A suitable tube selected according to the child's size, the viscosity of the solution being fed, and anticipated duration of treatment
- A receptacle for the fluid; for small amounts a 10- to 30-mL syringe barrel or Asepto syringe is satisfactory; for larger amounts a 60-mL syringe with a catheter tip is more convenient
- A 10-mL barrel syringe to aspirate stomach contents after the tube has been placed
- Water or water-soluble lubricant to lubricate the tube; sterile water is used for infants
- Paper or nonallergenic tape to mark the tube and to attach the tube to the infant's or child's cheek (and nose if placed through the nares)
- pH paper to determine the correct placement in the stomach
- The solution for feeding

Not all feeding tubes are the same. Polyethylene and polyvinylchloride types lose their flexibility and need to be replaced frequently, usually every 3 or 4 days. Polyurethane and silicone tubes remain flexible; thus they can remain in place up to 30 days. Advantages of small-bore tubes include a reduced incidence of pharyngitis, otitis media, aspiration, and discomfort. Disadvantages include difficulty during insertion (may require a stylet or metal guidewire), collapse of the tube during aspiration of gastric contents to test for correct placement, dislodgment during forceful coughing, migration out of position, knotting, occlusion, and unsuitability for thick feedings.

Procedure

Infants are easier to control if they are first wrapped in a mummy restraint (see Fig. 39-6, *A*). Even tiny infants with random movements can grasp and dislodge the tube. Preterm infants do not ordinarily require restraint; but, if they do, a small blanket folded across the chest and secured beneath the shoulders is usually sufficient. Be careful so breathing is not compromised.

Whenever possible the infant should be held and provided with a means for nonnutritive sucking during the procedure to associate the comfort of physical contact with the feeding. When this is not possible, gavage feeding is carried out with the infant or child on the back or toward the right side and the head and chest elevated. Feeding the child in a sitting position helps maintain placement of the tube in the lowest position, thus increasing the likelihood of correct placement in the stomach.

Although the most accurate method for testing tube placement is radiography, this practice is not always possible before each

feeding. Research indicates that bedside assessment of gastrointestinal aspirate color and pH is useful in predicting feeding tube placement (see Evidence-Based Practice box below). If doubt exists regarding correct placement, consult the practitioner. The Guidelines box on p. 1187 describes the procedure for gavage feeding.

Studies evaluating NG and OG tube length in infants and children found that age-specific methods for predicting the distance based on height is a more accurate estimate of internal distance to the stomach (Beckstrand, Ellett, and McDaniel, 2007; Klasner, Luke, and Scalzo, 2002). The morphologic measure most commonly used by clinicians (i.e., nose-ear-xiphoid distance) is often too short to locate the entire tube pore span in the stomach. However, the nose-ear-midxiphoid umbilicus span approached the accuracy of the age-specific prediction equations and is easier to use in a clinical setting. The best option is to adapt the nose-ear-midxiphoid umbilicus measurement for NG or OG tube length (Fig. 39-28, *A*) (see Guidelines box on p. 1187).

Ellett and Beckstrand (1999) found significant tube placement errors (43.5%) in a study of 39 hospitalized children. Children who were comatose or semicomatose, were inactive, had swallowing difficulty, or had Argyle tubes experienced increased tube placement errors. Findings supported the effectiveness of radiographs in documenting tube placement.

In a survey of 113 level II and III nurseries, 98% of the nurseries measured from the nose or mouth to the earlobe and then to the xiphoid process to calculate the length of the feeding tube for

EVIDENCE-BASED PRACTICE

Confirming Nasogastric Tube Placement in Pediatric Patients

Ask the Question

In children how should correct placement of NG tubes be assessed during hospitalization?

Search for Evidence

Search Strategies

Search selection criteria included English, research-based articles, and children and adolescents requiring NG tube placement. Search areas included aspirate, auscultation and radiology methods, NG tube length prediction methods, age-related height based methods, and accurate NG tube placement. Searches excluded newborns and preterm infants.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Joanna Briggs Institute, AHRQ-National Guideline Clearinghouse, TRIP database Plus, PedsCCM, BestBETS

Critically Analyze the Evidence

Studies compared various methods used to evaluate correct placement of the NG tube.

Accurate NG Tube Length Measurement

- Children 8 years, 4 months of age or younger: use age-related height-based equation for NG length predictions.
- Children older than 8 years, 4 months of age, short stature, or when you cannot obtain accurate height: use nose-ear-midxiphoid-umbilicus (NEMU) (Beckstrand, 1990; Beckstrand, Cirgin-Ellett, and McDaniel, 2007; Ellett, Beckstrand, Welch, et al., 1992; Strobel, Byrne, Ament, et al., 1979).

Nonradiologic Verification Methods

- A pH of 6.0 or less supports that the tip of the tube is in the gastric location (Ellett and Beckstrand, 1999; Ellett, Croffie, Cohen, et al., 2005; Huffman, Pieper, Jarczyk, et al., 2004; Metheny and Stewart, 2002; Metheny, Reed, Wiersema, et al., 1993; Metheny, Stewart, Smith, et al., 1999; Metheny, Stewart, Smith, et al., 1997; Neumann, Meyer, Dutton, et al., 1995; Nyqvist, Sorell, and Ewald, 2005; Phang, Marsh, Barlows, et al., 2004; Westhus, 2004).
- A pH greater than 5.0 does not predict correct distal tip location reliably. This may indicate respiratory or esophageal placement or the presence of medications to suppress acid secretion. Gastric aspirate pH means are statistically significantly lower compared with means from intestinal and respiratory pH aspirates (Ellett, Croffie, Cohen, et al., 2005; Metheny and Stewart, 2002; Metheny, Stewart, Smith, et al., 1999; Metheny, Stewart, Smith, et al., 1997; Phang, Marsh, Barlows, et al., 2004; Westhus, 2004).

Visual Inspection of Aspirate

- Visual inspection is less accurate than pH to confirm placement. Aspirate colors are specific to the intended placement location. Gastric contents are clear, off-white, or tan or may be brown-tinged if blood is present. Respiratory secretions may look the same. Intestinal contents are often bile stained, light to dark yellow, or greenish-brown (Metheny, Reed, Berglund, et al., 1994; Metheny and Stewart, 2002; Metheny, Stewart, Smith, et al., 1999; Phang, Marsh, Barlows, et al., 2004; Westhus, 2004).

Enzyme Testing

- Aspirate testing of enzyme levels for bilirubin, pepsin, and trypsin is highly accurate but limited to laboratory assessment (Ellett, Croffie, Cohen, and Perkins, 2005; Metheny and Stewart, 2002; Metheny, Stewart, Smith, et al., 1999; Westhus, 2004).

CO_2 Monitoring

- CO_2 monitoring is a reliable method to determine incorrect tube placement in the respiratory tract; it requires a capnograph monitor (Ellett, Croffie, Cohen, and Perkins, 2005; Metheny and Stewart, 2002; Metheny, Stewart, Smith, et al., 1999).

Gastric Auscultation

- Auscultation as a verification tool is reliable only 60% to 80% of the time and should not be used without additional methods (Ellett and Beckstrand, 1999; Metheny, McSweeney, Wehrle, et al., 1990; Neumann, Meyer, Dutton, and Smith, 1995).
- Using aspirate and nonaspirate NG tube placement verification methods in combination increases the likelihood for accurate NG tube placement to 97% to 99%, similar to the radiologic chest radiography gold standard of 99% (Ellett and Beckstrand, 1999; Ellett, Croffie, Cohen, and Perkins, 2005; Metheny and Stewart, 2002; Metheny, Reed, Berglund, et al., 1994; Metheny, Reed, Wiersema, et al., 1993; Metheny, Stewart, Smith, et al., 1999; Neumann, Meyer, Dutton, et al., 1995; Phang, Marsh, Barlows, et al., 2004; Westhus, 2004).

Apply the Evidence: Nursing Implications

There is *good evidence with strong recommendations* (Guyatt, Oxman, Vist, et al., 2008) that a combination of verification methods to confirm NG tube placement reduces the required number of x-ray films in children (Cincinnati Children's Hospital Medical Center, 2011). These methods include pH testing and visual inspection of the pH aspirate. There is also good evidence that improving the accuracy of predicting NG tube length before insertion enhances the precision of successful NG tube placement. Auscultation is used in combination with other NG tube verification methods.

NG, Nasogastric.

placement in preterm infants. For very low–birth-weight infants, daily weight can be used to predict insertion length. Until more definitive data are available, no method that results in a shorter distance than these methods should be used.

Gastrostomy Feeding

Feeding by way of gastrostomy, or G tube, is often used for children in whom passage of a tube through the mouth, pharynx, esophagus, and cardiac sphincter of the stomach is contraindicated or impossible. It is also used to avoid the constant irritation of an NG tube in children who require tube feeding over an extended period. A gastrostomy tube may be placed with the child under general anesthesia or percutaneously using an endoscope with the patient sedated and under local anesthesia (percutaneous endoscopic gastrostomy [PEG]). The tube is inserted through the abdominal wall into the stomach about midway along the greater curvature and secured by a purse-string suture. The stomach is anchored to the peritoneum at the operative site. The tube used can be a Foley, wing-tip, or mushroom catheter. Immediately after surgery the catheter may be left open and attached to gravity drainage for 24 hours or more.

Direct postoperative care of the wound site toward prevention of infection and irritation. Cleanse the area at least daily or as often as needed to keep the area free of drainage. After healing, meticulous care is needed to keep the area surrounding the tube clean and dry to prevent excoriation and infection. Daily applications of antibiotic ointment or other preparations may be prescribed to aid in healing and prevent irritation. Exercise care to prevent excessive pull on the catheter that might cause widening of the opening and subsequent leakage of highly irritating gastric juices. Secure the tube to the abdomen, leaving a small loop of tubing at the exit site to prevent tension on the site (see Evidence-Based Practice box on p. 1188).

Granulation tissue may grow around a gastrostomy site (Fig. 39-29). This moist, beefy red tissue is not a sign of infection. However, if it continues to grow, the excess moisture can irritate the surrounding skin.

For children receiving long-term gastrostomy feeding, a skin-level device (e.g., MIC-KEY, Bard Button) offers several advantages.

GUIDELINES

Nasogastric Tube Feedings in Children

- Place child supine with head slightly hyperflexed or in a sniffing position (nose pointed toward ceiling).
- Measure the tube for approximate length of insertion and mark the point with a small piece of tape.
- Insert a tube that has been lubricated with sterile water or water-soluble lubricant through either the mouth or one of the nares to the predetermined mark. Because most young infants are obligatory nose breathers, insertion through the mouth causes less distress and helps stimulate sucking. In older infants and children the tube is passed through the nose and alternated between nostrils. An indwelling tube is almost always placed through the nose.
  - When using the nose, slip the tube along the base of the nose and direct it straight back toward the occiput.
  - When entering through the mouth, direct the tube toward the back of the throat (see Fig. 39-28, *B*).
  - If the child is able to swallow on command, synchronize passing the tube with swallowing.
- Confirm placement (see Evidence-Based Practice box, pp. 1185-1186).
- Stabilize the tube by holding or taping it to the cheek, not to the forehead, because of possible damage to the nostril. To maintain correct placement, measure and record the amount of tubing extending from the nose or mouth to the distal port when the tube is first positioned. Recheck this measurement before each feeding.
- Warm the formula to room temperature. Do not microwave! Pour formula into the barrel of the syringe attached to the feeding tube. To start the flow, give a gentle push with the plunger but then remove the plunger and allow the fluid to flow into the stomach by gravity. The rate of flow should not exceed 5 mL every 5 to 10 minutes in premature and very small infants and 10 mL/min in older infants and children to prevent nausea and regurgitation. The rate is determined by the diameter of the tubing and the height of the reservoir containing the feeding and is regulated by adjusting the height of the syringe. A usual feeding may take 15 to 30 minutes to complete.
- Flush the tube with sterile water (1 or 2 mL for small tubes to 5 to 15 mL or more for large ones) or see discussion of flushing for administering medication through nasogastric tubes in the Guidelines box on p. 1170 to clear it of formula.
- Cap or clamp indwelling tubes to prevent loss of feeding.
  - If the tube is to be removed, first pinch it firmly to prevent escape of fluid as the tube is withdrawn. Withdraw the tube quickly.
- Position the child with the head elevated 30 to 45 degrees or on the right side for 30 to 60 minutes in the same manner as after any infant feeding to minimize the possibility of regurgitation and aspiration. If the child's condition permits, bubble the youngster after the feeding.
- Record the feeding, including the type and amount of residual, the type and amount of formula, and how it was tolerated.
  - For most infant feedings any amount of residual fluid aspirated from the stomach is refed to prevent electrolyte imbalance, and the amount is subtracted from the prescribed amount of feeding. For example, if the infant is to receive 30 mL and 10 mL is aspirated from the stomach before the feeding, the 10 mL of aspirated stomach contents is refed along with 20 mL of feeding. Another method can be used in children. If residual fluid is more than one fourth of the last feeding, return the aspirate and recheck in 30 to 60 minutes. When residual fluid is less than one fourth of the last feeding, give the scheduled feeding. If large amounts of aspirated fluid persist and the child is due for another feeding, notify the practitioner.

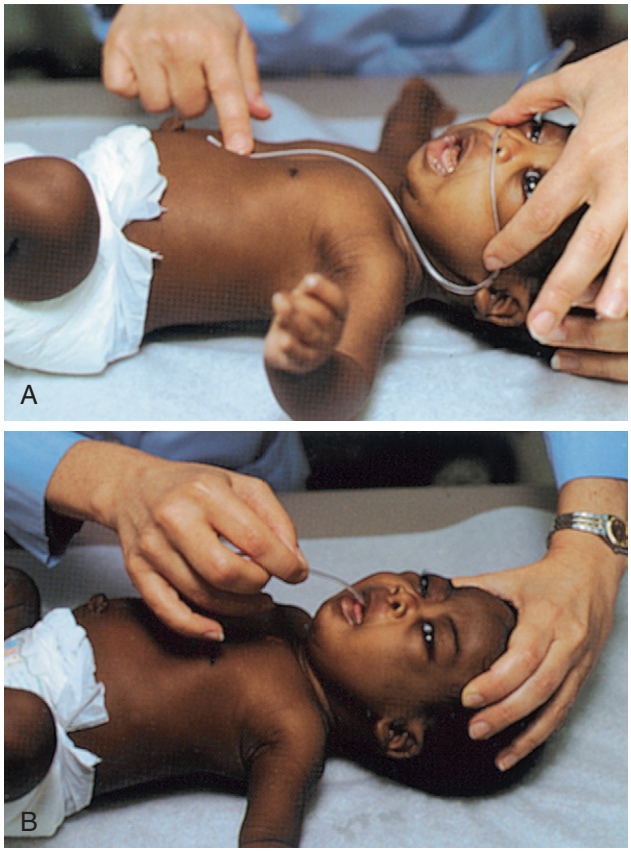

FIG 39-28 Gavage feeding. **A,** Measuring tube for orogastric feeding from tip of nose to earlobe and to midpoint between end of xiphoid process and umbilicus. **B,** Inserting tube.

The small, flexible silicone device protrudes slightly from the abdomen, is cosmetically pleasing, affords increased comfort and mobility to the child, is easy to care for, and is fully immersible in water. The one-way valve at the proximal end minimizes reflux and eliminates the need for clamping. However, the skin-level device requires a well-established gastrostomy site and is more expensive than the conventional tube. In addition, the valve may become clogged. When functioning, the valve prevents air from escaping; therefore the child may require frequent bubbling. With some devices, during feedings the child must remain fairly still because the tubing easily disconnects from the opening if the child moves. With other devices extension tubing can be attached securely to the opening (Fig. 39-30). The feeding is instilled at the other end of the tubing in a manner similar to that for a regular gastrostomy. The extension tubing may also have a separate medication port. Both the feeding and medication ports have plugs attached. Some skin-level devices require a special tube to be able to decompress the stomach (to check residual or decompress air).

Feeding of water, formula, or pureed foods is carried out in the same manner and rate as for gavage feeding. A mechanical pump may be used to regulate the volume and rate of feeding. After feedings the infant or child is positioned on the right side or in the Fowler position, and the tube may be clamped or left open and suspended between feedings, depending on the child's condition. A clamped tube allows more mobility but is only appropriate if the child can tolerate intermittent feedings without vomiting or prolonged backup of feeding into the tube. Sometimes a Y tube is used to allow for simultaneous decompression during feeding. If a Foley

EVIDENCE-BASED PRACTICE

Skin Care: Prevention and Management of Gastrostomy Button and Gastrostomy Tube Breakdown

Ask the Question

In children with skin breakdown around the gastrostomy device (tube or skin-level button), which interventions are recommended for management of skin issues?

Search for the Evidence

Search Strategies

Search selection criteria included English language publications on children and adults published on gastrostomy, care practice guidelines, and manufacturer product information.

Databases Used

Critically Analyze the Evidence

Skin Care of the Gastrostomy Tube

- The American Pediatric Surgical Nurses Association (2006) recommends cleaning the skin around the gastrostomy twice daily and as needed with warm soap and water and keeping the area dry. It is important to remove crusted areas around the G tube. Diluted half-strength hydrogen peroxide may be used to clean for the first 2 weeks.
- The Wound Ostomy and Continence Nurses Society clinical guidelines (2008) identify the use of hydrogen peroxide as one of the possible causes of hypergranulation tissue. The guidelines recommend routine assessment of the site and keeping the skin around the G tube dry to prevent complications.
- McClave and Neff (2006) suggest cleaning the skin around the G tube with mild antibacterial soap and water. The use of hydrogen peroxide is discouraged because it is corrosive to the skin and leads to excessive drying of the tissue. Prompt treatment of skin irritation is vital in preventing further skin breakdown.
- Borkowski (2004, 2005) discourages the use of hydrogen peroxide because it can cause skin irritation and may be cytotoxic, disrupting wound healing. The author recommends gently cleaning the skin with water and patting dry because aggressive cleaning around the G tube may also interfere with the healing process.
- Product information by the manufacturer of MIC-KEY (Kimberly-Clark, 2006) advises cleaning the skin around the G button with soap and water using a soft cotton tip applicator or washcloth. The document recommends inspecting the skin daily and reporting any complications to a health care provider.

Skin Barriers

- The Wound Ostomy and Continence Nurses Society clinical guidelines (2008) recommend the use of barrier ointments such as zinc oxide and nonalcohol skin barrier film to control leakage. If skin irritation is present, the guidelines recommend adding absorptive powders and skin barrier wafers to help manage leakage and promote healing.
- Borkowski (2004, 2005) uses protective barriers such as zinc oxide and petrolatum to provide skin protection. For maceration around the stoma, the use of a solid skin barrier (pectin-based wafer Stomahesive) to provide an environment for protection and healing of the skin is recommended.

Stabilization

- The Wound Ostomy and Continence Nurses Society (2008) recommends that the stabilizer be placed on the skin without excessive tension and pulling. If a long tube is not stabilized, it can increase the risk for infection, cause hyperplasia, and lead to skin breakdown.
- In three patients with peristomal irritation caused by G tube mobility, Borkowski (2004) successfully managed two patients by applying a stabilization method to the G tube. In the third patient, despite the author's recommendation, the family refused to stabilize the G tube and preferred to treat the irritation with protective barrier ointments only. This finding illustrates the need to individualize care. There was no follow-up reported in the article regarding the success of the family's methods.
- McClave and Neff (2006) reported on their experience with percutaneous endoscopic gastrostomy (PEG) tubes. PEG tubes have increased risk for mobility and migration, which leads to ulceration and enlargement of the stoma. This can be prevented by stabilizing the tube.
- Crawley-Coha (2004) strongly recommends the use of stabilizing techniques to promote healing after surgery and prevent dislodgment. In active children the use of additional products such as elastic wraps and flexible dressings to immobilize the gastrostomy device is recommended.

Hypergranulation

- In a longitudinal study of 40 children with G tubes, granulation tissue occurred 2 times more often in children with long tube devices than in those who had skin-level devices (Thorne, Radford, Onyskiw, et al., 1998).
- In a prospective study of eight patients, granulation tissue was the complication that prompted the most hospital and physician visits. Granulation tissue affected five patients (63%). Although families and caregivers were educated about the potential complications, this did not eliminate unscheduled health care contacts (Crosby and Duerksen, 2007).
- Borkowski (2004, 2005) recommends the use of triamcinolone (0.5%-0.1%) cream as a less painful alternative to the traditional silver nitrate sticks. Polyurethane foam may be used to absorb moisture and keep the skin dry to prevent further breakdown. One 2×2 gauze may be placed to create a snug fit for an ill-fitting low-profile device and help keep the skin dry. Stabilization of the tube is a priority to prevent the development of hypergranulation.
- In the experience of Crawley-Coha (2004) hypergranulation tissue can occur, regardless of the type of G tube placed and method of stabilization used. Treatment options include the application of silver nitrate, sharp debridement, and topical steroids. This author used triamcinolone cream (0.5%) 3 times a day with great success for the previous 6 years. In some patients polyurethane foam dressing is also used to manage hypergranulation tissue.
- The Wound Ostomy and Continence Nurses Society clinical guidelines (2008) recommend managing hypergranulation by stabilizing the tube, keeping the peristomal area dry by applying polyurethane foam, and using triamcinolone (0.5%) 3 times a day. Silver nitrate may also be used for hypergranulation.

Individualizing Care

- Borkowski (2004) acknowledges that, when children with G tube develop complications despite family education on alternative management options, families may have chosen to continue to use familiar techniques.

EVIDENCE-BASED PRACTICE

Skin Care: Prevention and Management of Gastrostomy Button and Gastrostomy Tube Breakdown—cont'd

The care plan for managing complications should consider the child's developmental age, activity level, and parental preferences.

- Crawley-Coha (2004) recommends providing parents with individualized written instructions before discharge. Ongoing support should be provided by the child's medical team. To help with transition to the home, information on support groups for patients with G tubes may be offered (e.g., Oley Foundation, www.oley.org).

Apply the Evidence: Nursing Implications

There is *very low evidence with strong recommendations* for the following (Guyatt, Oxman, Vist, et al., 2008):

1. Use mild soap and water to clean the peristomal area.
2. If skin irritation or breakdown is noted, use appropriate skin barriers:
   - Zinc oxide–based ointment, petrolatum-based ointment, or nonalcohol skin barrier for prevention or treatment of breakdown
   - Solid pectin-based wafer for maceration
3. Stabilize long G tube using one of the three methods: commercial stabilization device, polyurethane foam, or the H tape method.
4. Request an order for triamcinolone cream for short-term treatment of hypergranulation.
5. Individualize skin care management.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries

Recommend interventions for management of skin breakdown around the gastrostomy device (tube or skin-level button).

Skills

Base individualized care plan on patient values, clinical expertise, and evidence

Integrate evidence into practice by using recommended interventions for management of skin breakdown around the gastrostomy device (tube or skin-level button).

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice

Appreciate the strengths and weakness of evidence for using interventions for management of skin breakdown around the gastrostomy device (tube or skin-level button).

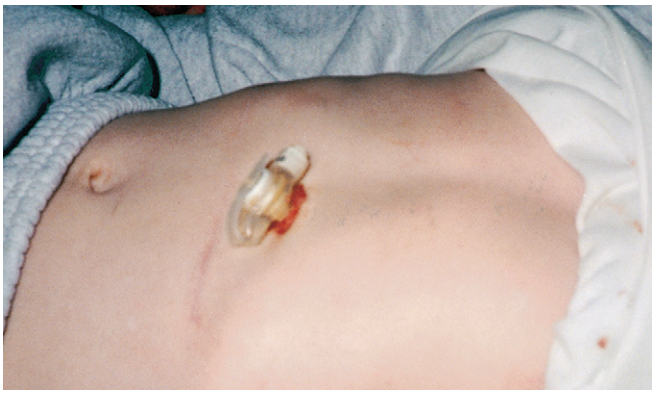

FIG 39-30 Child with skin-level gastrostomy device (MIC-KEY), which provides for secure attachment of extension tubing to gastrostomy opening.

catheter is used as the gastrostomy tube, apply very slight tension. The tube is securely taped to maintain the balloon at the gastrostomy opening and prevent leakage of gastric contents and the progression of the tube toward the pyloric sphincter, where it may occlude the stomach outlet. As a precaution the length of the tube is measured after surgery and measured again each shift to be certain that it has not slipped. The nurse can make a mark above the skin level to further ensure its placement. When the gastrostomy tube is no longer needed, it is removed; the skin opening usually closes spontaneously by contracture.

Nasoduodenal and Nasojejunal Tubes

Children at high risk for regurgitation or aspiration such as those with gastroparesis, mechanical ventilation, or brain injuries may require placement of a postpyloric feeding tube. A trained practitioner inserts the nasoduodenal or nasojejunal tube because of the risk of misplacement and potential for perforation in tubes requiring a stylet. Accurate placement is verified by radiography. Small-bore tubes may easily clog. Flush the tube when feeding is interrupted, before and after medication administration, and routinely every 4 hours or as directed by institutional policy. Tube replacement should be considered monthly to ensure optimal tube patency. Continuous feedings are delivered by a mechanical pump to regulate their volume and rate. Bolus feeds are contraindicated. Tube displacement is suspected in children showing signs of feeding intolerance such as vomiting. In these cases stop the feedings and notify the practitioner.

Total Parenteral Nutrition

TPN provides for the total nutritional needs of infants and children whose lives are threatened because feeding by way of the gastrointestinal tract is impossible, inadequate, or hazardous.

TPN therapy involves IV infusion of highly concentrated solutions of protein, glucose, and other nutrients. The solution is infused through conventional tubing with a special filter attached to remove particulate matter or microorganisms that may have contaminated the solution. The highly concentrated solutions require infusion into a vessel with sufficient volume and turbulence to allow for rapid dilution. The wide-diameter vessels selected are the superior vena cava and innominate or intrathoracic subclavian veins approached by way of the external or internal jugular veins. The highly irritating nature of concentrated glucose precludes the use of the small peripheral veins in most instances. However, diluted glucose-protein hydrolysates that are appropriate for infusing into peripheral veins are being used with increasing frequency. When peripheral veins are used, intralipid becomes the major calorie source. For long-term alimentation central venous catheters are usually used.

The infusion is maintained at a constant rate by means of an infusion pump to ensure the proper concentrations of glucose and amino acids. Accurate calculation of the rate is required to deliver a measured amount in a given length of time. Because alterations in flow rate are relatively common, the drip should be checked frequently to ensure an even, continuous infusion. The TPN infusion rate should not be increased or decreased without the practitioner being informed because alterations can cause hyperglycemia or hypoglycemia.

General assessments such as vital signs, input and output measurements, and checking results of laboratory tests facilitate early detection of infection or fluid and electrolyte imbalance. Additional amounts of potassium and sodium chloride are often required in hyperalimentation; therefore observation for signs of potassium or sodium deficit or excess is part of nursing care. This is rarely a problem except in children with reduced renal function or metabolic defects. Hyperglycemia may occur during the first day or two as the child adapts to the high-glucose load of the hyperalimentation solution. Although hyperglycemia occurs infrequently, insulin may be required to help the body adjust. When this occurs, nursing responsibilities include blood glucose testing. To prevent hypoglycemia when the hyperalimentation is disconnected, the rate of the infusion and the amount of insulin are decreased gradually.

TABLE 39-9 ADMINISTRATION OF ENEMAS TO CHILDREN

AGE	AMOUNT (mL)	INSERTION DISTANCE
Infant	120-240	2.5 cm (1 inch)
2-4 yr	240-360	5 cm (2 inch)
4-10 yr	360-480	7.5 cm (3 inch)
11 yr	480-720	10 cm (4 inch)

Family Teaching and Home Care

When alternative feedings are needed for an extended period, the family needs to learn how to feed the child with an NG, gastrostomy, or TPN feeding regimen. The same principles apply as discussed earlier in this chapter for compliance, especially in terms of education, and in Chapter 21 for discharge planning and home care. Plan ample time for the family to learn and perform the procedures under supervision before they assume full responsibility for the child's care. Refer the family to community agencies that provide support and practical assistance. The Oley Foundation* is a nonprofit research and education organization that assists persons receiving enteral nutrition and home TPN.

PROCEDURES RELATED TO ELIMINATION

Enema

The procedure for giving an enema to an infant or child does not differ essentially from that for an adult except for the type and amount of fluid administered and the distance for inserting the tube into the rectum (Table 39-9). Depending on the volume, use a syringe with rubber tubing, an enema bottle, or an enema bag.

An isotonic solution is used in children. Plain water is not used because, being hypotonic, it can cause rapid fluid shift and fluid overload. The Fleet enema (pediatric or adult sized) is not advised for children because of the harsh action of its ingredients (sodium biphosphate and sodium phosphate). Commercial enemas can be dangerous to patients with megacolon and dehydrated or azotemic children. The osmotic effect of the Fleet enema may produce diarrhea, which can lead to metabolic acidosis. Other potential complications are extreme hyperphosphatemia, hypernatremia, and hypocalcemia, which may lead to neuromuscular irritability and coma (Walton, Thomas, Aly, et al., 2000).

Because infants and young children are unable to retain the solution after it is administered, the buttocks must be held together for

*214 Hun Memorial, MC-28, Albany Medical Center, Albany, NY 12208, 800-776-OLEY, www.oley.org.

a short time to retain the fluid. The enema is administered and expelled while the child is lying with the buttocks over the bedpan and with the head and back supported by pillows. Older children are ordinarily able to hold the solution if they understand what to do and if they are not expected to hold it for too long. The nurse should have the bedpan handy or for ambulatory children ensure that the bathroom is available before beginning the procedure. An enema is an intrusive procedure and thus threatening to preschool children; therefore a careful explanation is especially important to ease possible fear.

A preoperative bowel preparation solution given orally or through an NG tube is being used increasingly instead of an enema. The polyethylene glycol–electrolyte lavage solution (GoLYTELY) mechanically flushes the bowel without significant absorption, thereby avoiding potential fluid and electrolyte imbalances. NuLYTELY, a modification of GoLYTELY, has the same therapeutic advantages as GoLYTELY and was developed to improve on the taste. Another effective oral cathartic is magnesium citrate solution.

Ostomies

Children may require stomas for various health problems. The most frequent causes in infants are necrotizing enterocolitis, imperforate anus, and less often Hirschsprung disease. In older children the most frequent causes are inflammatory bowel disease, especially Crohn disease (regional enteritis), and ureterostomies for distal ureter or bladder defects.

Care and management of ostomies in older children differ little from the care of ostomies in adult patients. The major emphasis in pediatric care is preparing the child for the procedure and teaching care of the ostomy to the child and family. The basic principles of preparation are the same as for any procedure (see p. 1131). Simple, straightforward language is most effective, together with the use of illustrations and a replica model (e.g., drawing a picture of a child with a stoma on the abdomen and explaining it as "another opening where bowel movements [or any other term the child uses] will come out"). At another time the nurse can draw a pouch over the opening to demonstrate how the contents are collected. Using a doll to demonstrate the process is an excellent teaching strategy, and special books are available.

Children with ileostomies are fitted immediately after surgery with an appliance to protect the skin from the proteolytic enzymes in the liquid stool. Infants may not be fitted with a pouch in the immediate postoperative period. When stomal drainage is minimal, as is often the case in small or preterm infants, a gauze dressing suffices. Give parents a choice of caring for the colostomy with or without an appliance. Pediatric appliances are available in a variety of sizes to ensure an adequate fit.*

Ostomy equipment consists of a one- or two-piece system with a hypoallergenic skin barrier to maintain peristomal skin integrity. The pouch should be large enough to contain a moderate amount of stool and flatus but not so large as to overwhelm the infant or child. A backing helps minimize the risk of skin breakdown from moisture trapped between the skin and pouch. Avoid small clips and rubber bands to prevent choking in young children.

Protection of the peristomal skin is a major aspect of stoma care. Well-fitting appliances are important to prevent leakage of contents. Before applying the appliance, prepare the skin with a skin sealant that is allowed to dry. Then apply stoma paste around the base of the stoma or to the back of the wafer. The sealant and paste work together to prevent peristomal skin breakdown.

In infants with a colostomy left unpouched, skin care is similar to that of any diapered child. However, protect the peristomal skin with a barrier substance (e.g., zinc oxide ointment [Sensi-Care] or a mixture of zinc oxide ointment and stoma powder [Stomahesive]). A diaper larger than the one usually worn may be needed to extend upward over the stoma and absorb drainage. If the skin becomes inflamed, denuded, or infected, the care is similar to the interventions used for diaper dermatitis. A zinc-based product helps protect healthy skin, heal excoriated skin, and minimize pain associated with skin breakdown. The skin protectant adheres to denuded, weeping skin. The nurse can apply zinc-based products over topical antifungal and antibacterial agents if infection is present. No-sting barrier film is a skin sealant that has no alcohol base and can be used on open skin without stinging.

Preventing young children from pulling off the pouch is also an important consideration. One-piece outfits keep exploring hands from reaching the pouch, and the loose waist avoids any pressure on the appliance. Keeping the child occupied with toys during the pouch change is also helpful. As children mature, encourage their participation in ostomy care. Even preschoolers can help by holding supplies, pulling paper backings from the appliance, and helping clean the stoma area. Toilet training for bladder control needs to begin at the appropriate time as for any other child.

Older children and adolescents should eventually have total responsibility for ostomy care just as they would for usual bowel function. During adolescence concerns for body image and the impact of the ostomy on intimacy and sexuality emerge. The nurse should stress to teenagers that the presence of a stoma need not interfere with their activities. These youngsters can choose which ostomy equipment is best suited to their needs. Attractively designed and decorated pouch covers are well liked by teenagers.

Children with familial adenomatous polyposis may require a colectomy with ileoanal reservoir to prevent or treat carcinoma of the colon. Peristomal skin care for these children is particularly challenging because of increased liquid stools, increased digestive enzymes that may cause skin breakdown, and the stoma being at skin level rather than raised. Additional care with this condition includes close monitoring of fluid and electrolyte status and increased incidence of bowel obstruction.

An enterostomal therapy nurse specialist is an important member of the health care team and will have additional suggestions and assistance with skin care information and ostomy pouching options. The nurse can obtain further information by contacting the Wound, Ostomy and Continence Nurses Society.*

Family Teaching and Home Care

Because these children are almost always discharged with a functioning colostomy, preparation of the family should begin as early as possible in the hospital. The nurse instructs the family in the application of the device (if used), care of the skin, and appropriate action in case skin problems develop. Early evidence of skin breakdown or stomal complication, such as ribbonlike stools, excessive diarrhea, bleeding, prolapse, or failure to pass flatus or stool is brought to the attention of the health care provider, nurse, or stoma specialist. The same principles are applied as discussed earlier in this chapter for compliance, especially in terms of education, and in Chapter 38 for discharge planning and home care.

KEY POINTS

- Informed consent is valid when the person is capable of giving consent (is over the age of majority and competent), is supplied with information needed to make an intelligent decision, and acts voluntarily when exercising freedom of choice.
- Informed consent is needed for major surgery, minor surgery, and diagnostic tests and medical treatments with an element of risk.
- The major principles in psychologic preparation of the child for surgery are to establish trust, provide support, and give an explanation in easy-to-understand terms.
- Preparation for procedures should be based on developmental characteristics of the child and family, emphasizing the importance of the parents' role.
- Most parents and children want to be together during stressful procedures and should be offered this opportunity, with guidance on how the parent can comfort the child.
- The use of play activities to provide teaching about necessary nursing and medical interventions is an effective tool for use with children.
- In the performance of a procedure, the nurse should expect success, involve the child when possible in the procedure, provide distraction, and allow for expression of feelings.
- Proper positioning of infants and small children for procedures is essential to minimize movement and discomfort.
- In giving postprocedural support, the nurse should encourage children to express their feelings and praise them for completion of the procedure.
- Stressful times before and after surgery that produce anxiety in children are admission, blood tests, injection of preoperative medication (if used), transportation to the operating room, and return from the PACU.
- Assessment of compliance entails measuring factors that affect compliance through clinical judgment, self-reporting, direct observation, monitoring of appointments and therapeutic response, pill counts, and chemical assay.
- Compliance strategies may be classified as organizational, educational, and behavioral.
- Knowledge of the ill child's eating habits and favorite foods can help maintain adequate nutrition.
- Skin care is essential to prevent skin breakdown.
- Control of fever may be accomplished by administration of antipyretics; hyperthermia is controlled by environmental means (minimum clothing, increased air circulation, hypothermia mattress, or cool compresses).
- Infection control is based on two systems. Standard Precautions provide protection when the infected person is undiagnosed. Transmission-based precautions add extra interventions for patients diagnosed with or suspected of having an infection.
- Ensuring safety in the hospital setting is a major concern and can be achieved through environmental measures, infection control measures, limit setting, and safe transportation.
- Restraints are used cautiously and require a medical order. Therapeutic hugging can avoid the use of restraints.
- Factors that affect drug dosage determination are growth and maturation, difficulty in evaluating drug response, and BSA.
- Family teaching regarding medication administration includes telling parents why the child is receiving the drug; its possible effects; and the amount, frequency, and length of time the drug is to be administered.
- The preferred sites for IM injection in children are the vastus lateralis and ventrogluteal areas.
- Intermittent venous access is accomplished by a peripheral intermittent infusion device, a PICC, a central venous catheter, or an implanted port.
- Several safety catheters and needleless device systems are available to reduce the risk of needlestick injuries in patients and caregivers.
- Nursing assessment of fluid and electrolyte disturbances entails observation of general appearance, vital signs, and measurement of I&O.
- Oxygen can be administered by hood, mask, nasal cannula, prongs, or face tent.
- Tracheostomy suctioning involves premeasured insertion of the catheter, application of suction for 5 seconds when withdrawing the catheter, and supplemental oxygen before and after suctioning.
- Alternative forms of feeding include gavage feeding, gastrostomy feeding, and TPN.
- In the care of children with ostomies, nurses play an important role in family support and instruction in care of the stoma site.

CHAPTER

40

Respiratory Dysfunction

David Wilson

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify the factors leading to respiratory tract infection in the infant and young child.
- Contrast the effects of various respiratory infections observed in infants and children.
- Describe the postoperative nursing care of the child with an adenotonsillectomy.
- Outline a nursing care plan for a child with croup.
- Outline a nursing care plan for a child with acute otitis media.
- Demonstrate an understanding of the ways in which inhalation of noninfectious irritants produce pulmonary dysfunction.
- Describe the ways in which the various therapeutic measures relieve the symptoms of asthma.
- Outline a plan for teaching home care for the child with asthma.
- Describe the physiologic effects of cystic fibrosis on the gastrointestinal, endocrine, reproductive, and pulmonary systems.
- Outline a plan of care for the child with cystic fibrosis.
- List the major signs of respiratory distress in infants and children.
- Describe the nursing care for a child with respiratory failure.

RESPIRATORY INFECTION

General Aspects of Respiratory Infections

Infections of the respiratory tract are described according to the anatomic area of involvement. The *upper respiratory tract,* or *upper airway,* consists of the oronasopharynx, pharynx, larynx, and upper part of the trachea. The *lower respiratory tract* consists of the lower trachea, mainstem bronchi, segmental bronchi, subsegmental bronchioles, terminal bronchioles, and alveoli. In this discussion, the trachea is considered with lower tract disorders and infections of the epiglottis and larynx are categorized as croup syndromes. However, respiratory infections seldom fall into discrete anatomic areas. Infections often spread from one structure to another because of the contiguous nature of the mucous membrane lining the entire tract. Consequently, respiratory tract infections involve several areas rather than a single structure, although the effect on one area may predominate in any given illness.

Etiology and Characteristics

Respiratory infections account for the majority of acute illnesses in children. The etiology and course of these infections are influenced by the age of the child, the season, living conditions, and preexisting medical problems.

Infectious Agents. The respiratory tract is subject to a wide variety of infective organisms. Most infections are caused by viruses, particularly respiratory syncytial virus (RSV), nonpolio enteroviruses A, B, C, and D (formerly coxsackieviruses A and B), adenoviruses, parainfluenza viruses, and human meta-pneumoviruses. Other agents involved in primary or secondary invasion include group A β-hemolytic streptococci (GABHS), staphylococci, *Haemophilus influenzae, Chlamydia trachomatis, Mycoplasma* organisms, and pneumococci.

Age. Healthy full-term infants younger than 3 months are presumed to have a lower infection rate than older infants because of the protective function of maternal antibodies; however, infants may be susceptible to specific respiratory tract infections, namely pertussis, during this period. The infection rate increases from 3 to 6 months of age—the time between the disappearance of maternal antibodies and the infant's own antibody production. The viral infection rate remains high during the toddler and preschool years. By 5 years of age, viral respiratory tract infections are less frequent but the incidence of *Mycoplasma pneumoniae* and GABHS infections increases. The amount of lymphoid tissue increases throughout middle childhood, and repeated exposure to organisms confers increasing immunity as children grow older.

Some viral or bacterial agents produce a mild illness in older children but severe lower respiratory tract illness or croup in infants.

For example, pertussis causes a relatively harmless tracheobronchitis in childhood but is a serious disease in infancy.

Size. Anatomic differences influence the response to respiratory tract infections. The diameter of the airways is smaller in young children and subject to considerable narrowing from edematous mucous membranes and increased production of secretions. The distance between structures within the respiratory tract is also shorter in the young child, and organisms may move rapidly down the respiratory tract, causing more extensive involvement. The relatively short and open eustachian tube in infants and young children allows pathogens easy access to the middle ear.

Resistance. The ability to resist invading organisms depends on several factors. Deficiencies of the immune system place the child at risk for infection. Other conditions that decrease resistance are malnutrition, anemia, fatigue, and chilling of the body. Conditions that weaken defenses of the respiratory tract and predispose children to infection also include allergies (e.g., allergic rhinitis), preterm birth, bronchopulmonary dysplasia (BPD), asthma, history of RSV infection, cardiac anomalies that cause pulmonary congestion, and cystic fibrosis (CF). Day care attendance and exposure to secondhand smoke increase the likelihood of infection.

Seasonal Variations. The most common respiratory pathogens appear in epidemics during the winter and spring months. Mycoplasmal infections occur more often in autumn and early winter. Infection-related asthma occurs more frequently during cold weather, whereas winter and spring are typically the "RSV seasons."

Clinical Manifestations

Infants and young children, especially those between 6 months and 3 years of age, react more severely to acute respiratory tract infection than do older children. Young children display a number of generalized signs and symptoms and local manifestations (Box 40-1).

BOX 40-1 SIGNS AND SYMPTOMS ASSOCIATED WITH RESPIRATORY INFECTIONS IN INFANTS AND SMALL CHILDREN

Fever
- May be absent in newborn infants
- Greatest at ages 6 months to 3 years
- Temperature may reach 39.5° to 40.5° C (103° to 105° F) even with mild infections
- Often appears as first sign of infection
- May be listless and irritable or somewhat euphoric and more active than normal temporarily
- Tendency to develop high temperatures with infection in certain families
- May precipitate febrile seizures (see Chapter 45)
- Febrile seizures uncommon after 3 or 4 years of age

Meningismus
- Meningeal signs without infection of the meninges
- Occurs with abrupt onset of fever
- Accompanied by the following:
  - Headache
  - Pain and stiffness in the back and neck
  - Presence of Kernig and Brudzinski signs
- Subsides as the temperature decreases

Anorexia
- Common with most childhood illnesses
- Frequently the initial evidence of illness
- Persists to a greater or lesser degree throughout febrile stage of illness; often extends into convalescence

Vomiting
- Small children vomit readily with illness
- Clue to onset of infection
- May precede other signs by several hours
- Usually short-lived but may persist during the illness
- Frequent cause of dehydration if fluid intake is impaired

Diarrhea
- Usually mild, transient diarrhea but may become severe
- Often accompanies viral respiratory infections
- Frequent cause of dehydration

Abdominal Pain
- Common complaint
- Sometimes indistinguishable from pain of appendicitis
- Mesenteric lymphadenitis may be cause
- Muscle spasms from vomiting may be a factor, especially in nervous, tense child

Nasal Blockage
- Small nasal passages of infants easily blocked by mucosal swelling and exudation
- Can interfere with respiration and feeding in infants
- May contribute to the development of otitis media and sinusitis

Nasal Discharge
- Frequent occurrence
- May be thin and watery (rhinorrhea) or thick and purulent
- Depends on the type or stage of infection
- Associated with itching
- May irritate upper lip and skin surrounding the nose

Cough
- Common feature
- May be evident only during acute phase
- May persist several months after a disease

Respiratory Sounds
- Sounds associated with respiratory disease:
  - Cough
  - Hoarseness
  - Grunting
  - Stridor
  - Wheezing
- Auscultation:
  - Wheezing
  - Crackles
  - Absence of air movement

Sore Throat
- Frequent complaint of older children
- Young children (unable to describe symptoms) may not complain even when highly inflamed
- Child will often refuse to take oral fluids or solids

CARE MANAGEMENT

Assessment of the respiratory system follows the guidelines described in Chapter 29 (for assessment of the ears, nose, mouth and throat, chest, and lungs). The assessment should include respiratory rate, depth, and rhythm; heart rate; oxygenation; hydration status; body temperature; activity level; and level of comfort. Special attention should also be given to the components and observations listed in Box 40-2. A noninvasive pulse oximeter (oxygen saturation) measurement should be performed on *all* children as part of the routine physical assessment. The nursing process in the care of the child with acute respiratory tract infection is outlined in the Nursing Care Plan.

Ease Respiratory Efforts. Many acute respiratory tract infections are mild and cause few symptoms. Although children may feel uncomfortable and have a "stuffy" nose and some mucosal swelling, respiratory distress occurs infrequently. Interventions delivered at home are usually sufficient to relieve minor discomfort and ease respiratory efforts. However, in some cases, the infant or child may require close observation by health care professionals for adequate oxygenation and fluid and electrolyte status.

Warm or cool mist is a common therapeutic measure for symptomatic relief of respiratory discomfort. The moisture soothes inflamed membranes and is beneficial when there is hoarseness or laryngeal involvement. The use of steam vaporizers in the home is often discouraged because of the hazards related to their use and limited evidence to support their efficacy.

A time-honored method of producing steam is the shower. Running a shower of hot water into the empty bathtub or open shower stall with the bathroom door closed produces a quick source of steam. Keeping a child in this environment for approximately 10 to 15 minutes humidifies inspired air and can help relieve symptoms. A small child can be held on the lap of a parent or other adult. Older children can sit in the bathroom under the supervision of an adult.

Promote Rest. Children who have an acute febrile illness usually have limited activity. One of the cardinal signs that the child is feeling better is the increase in activity; this may, however, be temporary if a high fever returns after a few hours of increased activity. Children should be encouraged to rest or play quietly to avoid exacerbating symptoms.

Promote Comfort. Older children are usually able to manage nasal secretions with little difficulty. For very young infants, who normally breathe through their noses, an infant nasal aspirator or a bulb syringe is helpful in removing nasal secretions, especially before being put to bed to sleep and before feeding. This practice, preceded by instillation of saline nose drops as needed, may clear nasal passages and promote feeding. Saline nose drops can be prepared at home by dissolving 1 tsp of salt in 1 pint of warm water.

For older infants and children who can tolerate decongestants, vasoconstrictive nose drops may be administered 15 to 20 minutes before feeding and at bedtime. Two drops are instilled, and because this shrinks only the anterior mucous membranes, two more drops are instilled 5 to 10 minutes later. Phenylephrine 0.25% (for infants and children older than 6 months), ephedrine 1% (for children older than 6 years), or oxymetazoline 0.05% (for children older than 6 years) is sometimes prescribed. Older cooperative children often prefer nasal sprays. They are taught to compress the plastic container at the moment of inspiration while occluding the other nostril. Bottles of nose drops should be used for only one child and one illness because they are easily contaminated with bacteria and viruses. To avoid rebound congestion, nose drops or sprays should not be administered for more than 3 days. To prevent cross-contamination with nose drops, draw the nose spray solution into a clean tuberculin syringe. Inject the nose spray solution into the child's nostrils using the blunt syringe.

Hot or cold applications sometimes provide relief for children with painful cervical adenitis. An ice bag or heating pad applied

BOX 40-2 COMPONENTS FOR ASSESSING RESPIRATORY FUNCTION

Respirations

The pattern of respirations is observed for rate, depth, ease, and rhythm of breathing:

- Rate—Rapid *(tachypnea),* normal, or slow for the particular child
- Depth—Normal depth, too shallow *(hypopnea),* too deep *(hyperpnea);* usually estimated from the amplitude of thoracic and abdominal excursion
- Ease—Effortless, labored *(dyspnea),* difficult breathing except in upright position *(orthopnea);* associated with intercostal or substernal retractions (inspiratory "sinking in" of soft tissues in relation to the cartilaginous and bony thorax); flaring nares; head bobbing (head of sleeping child with suboccipital area supported on caregiver's forearm bobs forward in synchrony with each inspiration); grunting; or wheezing
- Labored breathing—Continuous, intermittent, becoming steadily worse, sudden onset, at rest or on exertion, associated with wheezing or grunting, associated with pain
- Rhythm—Variation in rate and depth of respirations

Other Observations

In addition to respirations, particular attention is addressed to the following:

- Evidence of infection—Check for elevated temperature; enlarged cervical lymph nodes; inflamed mucous membranes; and purulent discharges from the nose, ears, or lungs (sputum).
- Cough—Observe characteristics of cough (if present); under what circumstances cough is heard (e.g., night only, on arising); nature of cough (paroxysmal with or without wheeze; "croupy" or "brassy"); frequency of cough; associated with swallowing or other activity; character of cough (moist and dry); productivity.
- Wheeze—Note if expiratory or inspiratory, high-pitched or musical, prolonged, slowly progressive or sudden, associated with labored breathing.
- Cyanosis—Note distribution (peripheral, perioral, facial, trunk, and face), degree, duration, associated with activity or feeding (infant).
- Abdominal pain—May be a complaint in preschooler and school-age children; probably represents referred pain from chest; may be a complaint in children with pneumonia.
- Chest pain—May be a complaint of older children; note location and circumstances: localized or generalized, referred to base of neck or abdomen, dull or sharp, deep or superficial, associated with rapid, shallow respirations or grunting.
- Sputum—Older children may provide sputum sample by coughing, whereas young children may need use of bulb suction to provide a sample; note volume, color, viscosity, and odor.
- Bad breath—May be associated with some lung infections.
- Stridor—A high-pitched wheezing sound; may be present on inspiration, exhalation, or both and is a sign of upper airway edema or obstruction by mass or object.

NURSING CARE PLAN

The Child with Acute Respiratory Tract Infection

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
Ineffective Breathing Pattern related to inflammatory process **Child's Defining Characteristics *(Subjective and Objective Data)*** Use of accessory muscles to breathe Dyspnea Shortness of breath Nasal flaring Altered chest excursion Assumption of three-point position (tripod) Respiratory rate outside normal parameter for child's age (increased or decreased rate)	Child's respirations will be nonlabored.	Position child for maximum ventilatory efficiency and airway patency Position child to facilitate drainage of secretions Provide humidified oxygen as prescribed Monitor oxygenation status, including vital signs, for changes in condition Suction airway (nose, trachea) as necessary Administer prescribed antibiotics (if bacterial) Administer bronchodilator medications as prescribed Administer antiinflammatory medications as prescribed Assist with coughing	To allow increased chest expansion To maintain patent airway and prevent airway obstruction To improve oxygenation To determine need for additional interventions To remove secretions and maintain airway patency To treat infection source To promote bronchodilation and improve ventilation To decrease airway inflammation and inflammatory response To remove secretions and clear airway
Ineffective Airway Clearance related to inflammation, mechanical obstruction, increased secretions **Child's Defining Characteristics *(Subjective and Objective Data)*** Dyspnea Difficulty vocalizing Orthopnea Adventitious breath sounds (crackles, wheezing, rhonchi) Cough ineffective or absent Restlessness Changes in respiratory rate and rhythm	Child's airways will remain patent.	Position child to facilitate drainage of secretions Perform chest percussion and postural drainage only as prescribed Suction airway as necessary Provide humidified oxygen as prescribed Assist with coughing (as developmentally or age appropriate) Avoid throat examination if epiglottitis is suspected Assure child (as appropriate) all measures will be taken to ensure adequate airway is maintained Implement comfort measures such as allowing parental presence, parental holding, favorite blanket or stuffed animal at side; explain all procedures beforehand	To prevent airway obstruction To loosen and remove secretions To remove secretions To moisten secretions and prevent airway drying To remove secretions To prevent airway compromise To allay anxiety To reduce anxiety and decrease effects of medical therapy, including hospitalization if required
Risk for Injury related to presence (only as indicated) of infective organisms **Child's or Family's Defining Characteristics *(Subjective and Objective Data)*** Tissue hypoxia Abnormal blood profile People or health care provider (HAI [health care–associated infection]) Mode of transport Developmental age	Child will remain free from complications of infection.	Maintain aseptic environment using sterile suction equipment and technique Implement and practice Standard Precautions Implement Contact and Airborne Precautions as necessary Obtain (secretion, tissue, or blood) specimen as indicated and prescribed Encourage child and family contacts to practice frequent hand hygiene and avoid hand-to-eye and hand-to-mouth contact Teach child (as age appropriate) and family how to decrease spread of organisms through coughing and other secretions (e.g., by covering mouth when coughing; disposing of secretions to avoid cross-contamination) Administer antibiotic or antiviral medications as prescribed Administer fever reduction medication(s) as prescribed Monitor and assess for signs and symptoms of secondary complications: hypoxia, skin breakdown, poor nutrient and fluid intake, increased work of breathing, deteriorating cardiorespiratory status Encourage small amounts of oral clear liquids as condition allows	To prevent spread of infectious organisms in child and family To identify infective organism To prevent spread of infection To prevent spread of infection To treat infection source To promote comfort if fever is present To implement therapy for prevention of secondary complications To promote hydration

NURSING CARE PLAN

The Child with Acute Respiratory Tract Infection—cont'd

NURSING DIAGNOSIS	EXPECTED OUTCOME	NURSING INTERVENTIONS	RATIONALES
Interrupted Family Processes related to child's illness, hospitalization, and medical or therapeutic regimen	Family will demonstrate ability to cope with child's illness.	Encourage family to remain with child	To decrease effects of separation
		Promote family-centered care	To promote family integrity
		Explain procedures and therapeutic regimen to family	To provide accurate information regarding therapy and child's condition
Child's or Family's Defining Characteristics ***(Subjective and Objective Data)***		Keep family informed of child's status	To promote family sense of control and involvement in care
		Encourage family involvement in child's care	
		Provide support and referral for continued support as necessary	
Communication patterns			
Participation in decision making			
Availability for emotional support			
Expressions of conflict within family			
Patterns and rituals			

to the neck may decrease the discomfort, but safety precautions must be observed to prevent burns. The ice bag or heating device must be covered, and the heating pad should not be set at high settings.

Prevent Spread of Infection. Careful hand washing is important when caring for children with respiratory tract infections. Older children should use a tissue or their arm to cover their nose and mouth when they cough or sneeze, dispose of the tissues properly, and wash their hands. Remembering to cover the nose or mouth is often difficult for small children. Used tissues should be immediately thrown into the wastebasket and not allowed to accumulate in a pile. Children with respiratory tract infections should not share drinking cups, eating utensils, washcloths, or towels. Well individuals generally should not touch their eyes or nose with unwashed hands. Parents should try to remove affected children from contact with other children. Parents should also keep affected children out of school or day care settings to prevent the spread of infection. This may be a problem when living arrangements are crowded and the family has several children. An effort should be made to teach well children to stay away from ill children, to wash their hands frequently, and to avoid eating and drinking from the same utensils or cups.

Reduce Temperature. If the child has a significantly elevated body temperature, controlling the fever is important. Parents should know how to take a child's temperature and read a thermometer accurately. Nurses should not assume that all parents can read a thermometer and should provide education when needed.

If the health care practitioner prescribes acetaminophen or ibuprofen (for infants and children 6 months and older), parents will need instruction on how to administer it. Most parents can read the label and calculate the desired dosage, but parents of infants and toddlers require detailed instruction and dosing parameters. It is important to emphasize accuracy in determining both the amount of drug to be given and the time intervals for administration.

Cool liquids are encouraged to reduce the temperature and minimize the chances of dehydration (see Controlling Elevated Temperatures, Chapter 39).

! NURSING ALERT

Caution parents about the use of over-the-counter combination "cold" remedies, since these often include acetaminophen. Careful calculation of both the acetaminophen given separately and the acetaminophen in combination medications is necessary to avoid an overdose.

Promote Hydration. Dehydration is a potential complication when children have respiratory tract infections and are febrile or anorectic, especially when vomiting or diarrhea is present. Infants are especially prone to fluid and electrolyte deficits when they have a respiratory illness because a rapid respiratory rate that accompanies such illnesses precludes adequate oral fluid intake. In addition, the presence of fever increases the total body fluid turnover in infants. If the infant has nasal secretions, this further prevents adequate respiratory effort by blocking the narrow nasal passages when the infant reclines to bottle feed or breastfeed and ceases the compensatory mouth breathing effort, thus causing the child to limit intake of fluids. Adequate fluid intake is encouraged by offering small amounts of favorite fluids (clear liquids if vomiting) at frequent intervals. Oral rehydration solutions, such as Infalyte or Pedialyte, should be considered for infants, and water or a low-carbohydrate (≤5 g per 8 oz) flavored drink should be considered for older children. Fluids with caffeine (tea, coffee) should be avoided because these may act as diuretics and promote fluid loss. Sports drinks and energy drinks are not recommended for oral rehydration (American Academy of Pediatrics [AAP], 2011); some sports drinks may be diluted for older children. When encouraging oral fluids to prevent dehydration, sports drinks with "replacement electrolytes" offer no benefit over water and should be used cautiously in small children. Breastfeeding infants should continue to be breastfed because human milk confers some degree of protection from infection (see Chapter 23). Fluids should not be forced, and children should not be awakened to take fluids. Forcing fluids creates the same problem as urging unwanted food. Gentle persuasion with preferred beverages or sugar-free popsicles is usually more successful. Younger children may like to drink smaller amounts from a plastic medicine cup.

To assess their child's level of hydration (see Chapter 41), parents are advised to observe the frequency of voiding and to notify the nurse or health care practitioner if there is insufficient voiding. Counting the number of wet diapers in a 24-hour period is a satisfactory method to assess output in infants and toddlers. In the hospital, diapers are weighed to assess output, which should be at least 1 mL/kg/hr up to 30 kg in child's weight. Then it should be at least 30 mL per hour in patients weighing more than 30 kg. The practitioner should be notified if the urine output is low.

Provide Nutrition. Loss of appetite is characteristic of children with acute infections. In most cases, children can be permitted to determine their own need for food. Many children show no decrease in appetite, and others respond well to foods such as gelatin, soup, and puddings (see Feeding the Sick Child, Chapter 39). Urging foods on anorexic children may precipitate nausea and vomiting and cause an aversion to feeding that may extend into the convalescent period and beyond.

Young children with respiratory tract infections are irritable and difficult to comfort; therefore the family needs support, encouragement, and practical suggestions concerning comfort measures and administration of medication. In addition to antipyretics and nose drops, the child may require antibiotic therapy. Parents of children receiving oral antibiotics must understand the importance of regular administration and continuing the drug for the prescribed length of time, regardless of whether the child appears ill. Parents should be cautioned against giving their child any medications that are not approved by the health care practitioner and to avoid giving antibiotics left over from a previous illness or prescribed for another child. Administering unprescribed antibiotics can produce serious side effects and adverse reactions (see Chapter 39 for administration of medications and teaching parents). See also the Nursing Care Plan on p. 1198.

UPPER RESPIRATORY TRACT INFECTIONS

Nasopharyngitis

Acute nasopharyngitis, or the equivalent of the "common cold," is caused by the rhinovirus, RSV, adenoviruses, enteroviruses, influenza virus, and parainfluenza virus. Symptoms are more severe in infants and children than in adults. Fever is common in young children, and older children have low-grade fevers, which appear early in the course of the illness. Other clinical manifestations are listed in Box 40-3. Symptoms may last up to 10 days.

Therapeutic Management

Children with nasopharyngitis are managed at home. There is no specific treatment, and effective vaccines are not available. Antipyretics may be indicated for mild fever and discomfort (see Chapter 39 for management of fever). Rest is recommended. The provision of a humidified environment and increasing oral fluids may be beneficial to some children with a cold.

Cough suppressants containing dextromethorphan should be used with caution (cough is a protective way of clearing secretions) but may be prescribed for a dry, hacking cough, especially at night. However, some preparations contain 22% alcohol and can cause adverse effects such as confusion, hyperexcitability, dizziness, nausea, and sedation. Parents should monitor the child carefully for potential adverse effects. Recent concerns regarding serious side effects of cough and cold preparations in young children, particularly infants, and lack of convincing evidence that such medications are effective in reducing symptoms have prompted recommendations by health care experts to carefully evaluate the benefits and risks of recommending such preparations for children younger than 6 years (Bell and Tunkel, 2010; Ryan, Brewer, and Small, 2008; Vassilev, Kabadi, and Villa, 2010). Over-the-counter cold preparation such as pseudoephedrine and some antihistamines are not appropriate for the treatment of the common cold in infants and toddlers; these may cause serious side effects in such children and have been associated with death in infants (Rimsza and Newberry, 2008; Ryan, Brewer, and Small, 2008).

Antihistamines are largely ineffective in treatment of nasopharyngitis (Kinyon Munch, 2010). These drugs have a weak atropine-like effect that dries secretions, but they can cause drowsiness or, paradoxically, have a stimulatory effect on children. Second-generation antihistamines such as loratadine or cetirizine are nonsedating but also have not been shown to be effective in relieving the symptoms of the common cold in small children and are not recommended by the American College of Chest Physicians (Pratter, 2006). There is no support for the usefulness of expectorants, and antibiotics are usually not indicated because most infections are viral.

Supportive treatment with antipyretics, nasal saline irrigation, and adequate fluid hydration is still the safest and most often recommended therapy for infants and small children with the common cold (Kinyon Munch, 2010).

Prevention

Nasopharyngitis is so widespread in the general population that it is impossible to prevent. Children are more susceptible because they

BOX 40-3 CLINICAL MANIFESTATIONS OF NASOPHARYNGITIS AND PHARYNGITIS

Nasopharyngitis

Younger Child
- Fever
- Irritability, restlessness
- Sneezing
- Vomiting or diarrhea

Older Child
- Dryness and irritation of nose and throat
- Sneezing, chilling sensation
- Muscular aches
- Cough, sometimes

Physical Signs
- Edema and vasodilation of mucosa

Pharyngitis

Younger Child
- Fever
- General malaise
- Anorexia
- Moderate sore throat
- Headache

Older Child
- Fever (may reach 40° C [104° F])
- Headache
- Anorexia
- Dysphagia
- Abdominal pain
- Vomiting

Physical Signs

Younger Child
- Mild to moderate hyperemia

Older Child
- Mild to fiery red, edematous pharynx
- Hyperemia of tonsils and pharynx; may extend to soft palate and uvula
- Often abundant follicular exudate that spreads and coalesces to form pseudomembrane on tonsils
- Cervical glands enlarged and tender

have not yet developed resistance to many viruses. Young infants and those with decreased resistance and pulmonary illness are subject to serious complications, so attempts should be made to protect them from exposure.

CARE MANAGEMENT

A cold is often the parents' first introduction to an illness in their infant. Most discomfort of nasopharyngitis is related to the nasal obstruction, especially in small infants. Elevating the head of the bed or crib mattress assists with drainage of secretions. Suctioning and vaporization may also provide relief. Saline nose drops and gentle suction with a bulb syringe before feeding and sleep time may be useful.

Maintaining adequate fluid intake is essential. Although a child's appetite for solid foods is usually diminished for several days, it is important to offer appropriate fluids to prevent dehydration.

Because nasopharyngitis is spread from secretions, the best means for prevention is avoiding contact with affected persons. This goal is difficult to accomplish in family settings, classrooms, and day care centers. Family members with a cold should try to "keep it to themselves" by carefully disposing of tissues; not sharing towels, glasses, or eating utensils; covering the mouth and nose with tissues when coughing or sneezing; and washing the hands thoroughly after nose blowing or sneezing. The most frequent carriers of infection are the human hands, which deposit viruses on doorknobs, faucets, and other everyday objects. Children should be taught to wash their hands thoroughly and avoid touching their eyes, nose, and mouth.

Support and reassurance are important elements of care for families of young children with recurrent upper respiratory infections (URIs). Because URIs are frequent in children younger than 3 years, families may feel they are on an endless roller coaster of illness. They need reassurance that frequent colds are a normal part of childhood and that by 5 years of age, their children will have developed immunity to many viruses. When children spend time in day care centers, their infection rate is higher than if they are cared for in the home because of increased exposure. Parents should know the signs of respiratory complications and should notify a health care professional if complications occur or the child does not improve within 2 to 3 days (Box 40-4).

BOX 40-4 EARLY EVIDENCE OF RESPIRATORY COMPLICATIONS

Parents are instructed to notify the health care professional if any of the following are noted:

- Evidence of earache (see p. 1205)
- Respirations faster than 50 to 60 breaths/min
- Fever over 38.3° C (101° F)
- Listlessness
- Increasing irritability with or without fever
- Persistent cough for 2 days or more
- Wheezing
- Crying
- Refusal to eat
- Restlessness and poor sleep patterns

Acute Streptococcal Pharyngitis

Children who experience GABHS infection of the upper airway (strep throat) are at risk for rheumatic fever (RF), an inflammatory disease of the heart, joints, and central nervous system (CNS) (see Chapter 42), and acute glomerulonephritis (AGN), an acute kidney infection (see Chapter 44). Permanent damage can result from these sequelae, especially RF. GABHS may also cause skin manifestations, including impetigo and pyoderma.

Clinical Manifestations

Group A β-hemolytic streptococci infection is generally a relatively brief illness that varies in severity from subclinical (no symptoms) to severe toxicity. The onset is often abrupt and characterized by pharyngitis, headache, fever, and abdominal pain. The tonsils and pharynx may be inflamed and covered with exudate (Fig. 40-1), which usually appears by the second day of illness. However, streptococcal infections should be suspected in children older than 2 years who have pharyngitis without exudate or nasal symptoms. The tongue may appear edematous and red (strawberry tongue), and the child may have a fine sandpaper rash on the trunk, axillae, elbows, and groin seen in scarlet fever (caused by a strain of group A streptococcus). The uvula is edematous and red. Anterior cervical lymphadenopathy (in ≈30% to 50% of cases) usually occurs early, and the nodes are often tender. Pain can be relatively mild to severe enough to make swallowing difficult. Clinical manifestations usually subside in 3 to 5 days unless complicated by sinusitis or parapharyngeal, peritonsillar, or retropharyngeal abscess. Nonsuppurative complications may appear after the onset of GABHS—AGN in about 10 days and RF in an average of 18 days.

Children who are GABHS carriers may have a positive throat culture but often experience a coincidental viral illness. Although antibiotic administration is not indicated for most GABHS carriers, some conditions require antibiotic therapy; these are published in the AAP's *Red Book* (American Academy of Pediatrics [AAP] Committee on Infectious Diseases, 2012).

Diagnostic Evaluation

Although 80% to 90% of all cases of acute pharyngitis are viral, a throat culture or rapid streptococcal identification test should be performed to rule out GABHS. Most streptococcal infections are short-term illnesses, and antibody responses (e.g., antistreptolysin-O titer) appear later than symptoms and are useful only for retrospective diagnosis.

Rapid identification of GABHS with diagnostic test kits (rapid antigen detection test) is possible in the office or clinic setting. Because of the high specificity of these rapid tests, a positive test

FIG 40-1 Tonsillitis and pharyngitis. (Courtesy Dr. Edward L. Applebaum, Head, Department of Otolaryngology, University of Illinois Medical Center, Chicago.)

result generally does not require throat culture confirmation. However, the sensitivities of these kits vary considerably and a confirmatory throat culture is recommended in patients who have a negative test result (AAP Committee on Infectious Diseases, 2012).

Therapeutic Management

If streptococcal sore throat infection is present, oral penicillin is prescribed in a dose sufficient to control the acute local manifestations and to maintain an adequate level for at least 10 days to eliminate any organisms that might remain to initiate RF symptoms. Penicillin does not prevent the development of AGN in susceptible children; however, it may prevent the spread of a nephrogenic strain of GABHS to others in the family. Penicillin usually produces a prompt response within 24 hours. Patients who have a history of RF or who remain symptomatic after a full course of antibiotics may require a follow-up throat swab.

Intramuscular (IM) benzathine penicillin G is an appropriate therapy, but it is painful and is not the first choice for children. Oral erythromycin is indicated for children who are allergic to penicillin. Other antibiotics used to treat GABHS are azithromycin, clarithromycin, oral cephalosporins, amoxicillin, and amoxicillin with clavulanic acid (AAP Committee on Infectious Diseases, 2012; Wessels, 2011).

CARE MANAGEMENT

The nurse often obtains a throat swab for culture or rapid antigen testing and instructs the parents about administering oral antibiotics and analgesics as prescribed. Cold or warm compresses to the neck may provide relief. In children who can cooperate, warm saline gargles may offer relief of throat discomfort. Acetaminophen and ibuprofen may be effective in decreasing the throat pain; liquid preparations or chewable forms may be preferable because of the pain associated with swallowing. Pain may interfere with oral intake, and children should not be forced to eat, but fluid intake is essential. Cool liquids or ice chips may be more acceptable than solids.

Special emphasis is placed on correct administration of oral medication and completion of the course of antibiotic therapy (see Administration of Medication, and Compliance, Chapter 39). If an injection is required, it must be administered deep into a large muscle mass (e.g., vastus lateralis or ventrogluteal muscle). To prevent pain, application of a topical anesthetic cream such as EMLA (an eutectic mixture of lidocaine and prilocaine) over the injection site 2½ hours before the injection or LMX4 (4% lidocaine) over the site 30 minutes before the injection is helpful (see Administration of Medication: Intramuscular Administration, Chapter 39). The injection site may be tender for 1 to 2 days.

Children are considered infectious to others at the onset of symptoms and up to 24 hours after initiation of antibiotic therapy, but they should not return to school or day care until they have been taking antibiotics for a full 24-hour period. Nurses should remind the children to discard their toothbrushes and replace them with new ones after they have been taking antibiotics for 24 hours. Orthodontic appliances should be washed thoroughly because they may harbor the organisms. Parents are cautioned to prevent other household members, especially if immunocompromised, from having close contact with the sick child and avoid sharing drinking or eating items.

If the child continues to have a high fever that does not respond to antipyretics, has an extremely sore throat, refuses liquids, and appears toxic 24 to 48 hours after starting antibiotics, further evaluation by the health care practitioner is recommended.

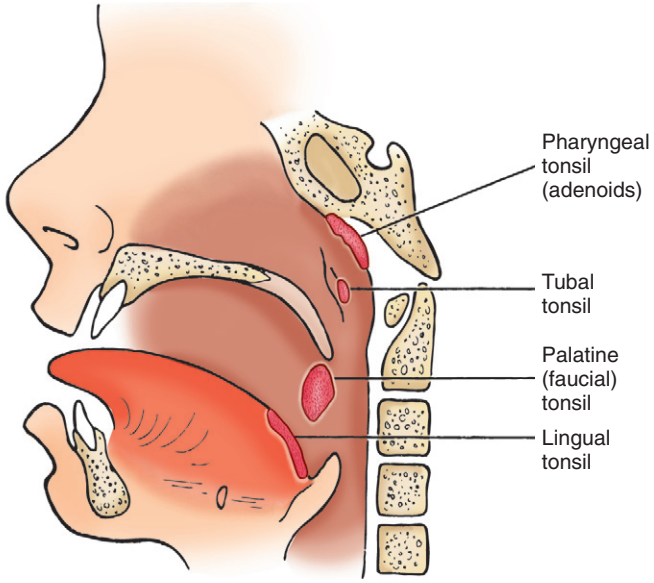

FIG 40-2 Location of various tonsillar masses.

Tonsillitis

The tonsils are masses of lymphoid tissue located in the pharyngeal cavity. They filter and protect the respiratory and alimentary tracts from invasion by pathogenic organisms and play a role in antibody formation. Although tonsil size varies, children generally have much larger tonsils than do adolescents or adults. This difference is thought to be a protective mechanism because young children are especially susceptible to URIs.

Pathophysiology

Several pairs of tonsils are part of a mass of lymphoid tissue encircling the nasal and oral pharynx, known as the Waldeyer tonsillar ring (Fig. 40-2). The palatine, or faucial, tonsils are located on either side of the oropharynx behind and below the pillars of the fauces (opening from the mouth). A surface of the palatine tonsils is usually visible during oral examination. The palatine tonsils are those removed during tonsillectomy. The pharyngeal tonsils, also known as the adenoids, are located above the palatine tonsils on the posterior wall of the nasopharynx. Their proximity to the nares and eustachian tubes causes difficulties in instances of inflammation. The lingual tonsils are located at the base of the tongue. The tubal tonsils, found near the posterior nasopharyngeal opening of the eustachian tubes, are not part of the Waldeyer tonsillar ring.

Etiology

Tonsillitis often occurs with pharyngitis. Because of the abundant lymphoid tissue and the frequency of URIs, tonsillitis is a common cause of illness in young children. The causative agent may be viral or bacterial.

Clinical Manifestations

The manifestations of tonsillitis are caused by inflammation. As the palatine tonsils enlarge from edema, they may meet in the midline (kissing tonsils), obstructing the passage of air or food. The child has difficulty swallowing and breathing. When enlargement of the adenoids occurs, the space behind the posterior nares becomes blocked, making it difficult or impossible for air to pass from the nose to the throat. As a result, the child breathes through the mouth.

Therapeutic Management

Because tonsillitis is self-limiting, treatment of viral pharyngitis is symptomatic. Throat cultures positive for GABHS infection warrant antibiotic treatment. It is important to differentiate between viral and streptococcal infection in febrile exudative tonsillitis. Because most infections are of viral origin, early rapid tests can eliminate unnecessary antibiotic administration.

Tonsillectomy is the surgical removal of the palatine tonsils. Absolute indications for a tonsillectomy are recurrent peritonsillar abscess, airway obstruction, tonsillitis resulting in febrile seizures, and tonsils requiring tissue pathology (American Academy of Otolaryngology—Head and Neck Surgery, 2011). Relative indications include three or more tonsil infections per year, persistent foul taste or breath caused by chronic tonsillitis, unilateral tonsil hypertrophy presumed to be malignant, and chronic tonsillitis in a streptococcus carrier who fails to respond to antibiotics (American Academy of Otolaryngology—Head and Neck Surgery, 2011).

Adenoidectomy (the surgical removal of the adenoids) is recommended for children who have hypertrophied adenoids that obstruct nasal breathing; additional indications for adenoidectomy include recurrent adenoiditis and sinusitis, chronic otitis media (OM) with effusion (especially if associated with hearing loss), airway obstruction and subsequent sleep-disordered breathing, persistent mouth-breathing, nasal speech, and recurrent nasopharyngitis (Benninger and Walner, 2007a). For some children, the effectiveness of tonsillectomy or adenoidectomy is modest and may not justify the risk of surgery. In practice, many physicians rely on individualized decision making and do not subscribe to an absolute set of eligibility criteria for these surgical procedures. Contraindications to either tonsillectomy or adenoidectomy are (1) cleft palate because the tonsils help minimize escape of air during speech; (2) acute infections at the time of surgery because locally inflamed tissues increase the risk for bleeding; (3) uncontrolled systemic diseases or blood dyscrasias; and (4) poor anesthetic risk.

CARE MANAGEMENT

Nursing care of tonsillitis involves providing comfort and minimizing activities or interventions that precipitate bleeding. Patients with sleep-disordered breathing require close monitoring of airway and breathing postoperatively. A soft to liquid diet is preferred. A cool-mist vaporizer keeps the mucous membranes moist during periods of mouth breathing. Warm salt-water gargles, throat lozenges, and analgesic–antipyretic drugs such as acetaminophen are used to promote comfort. Opioids are often needed to reduce pain so the child can drink. Combination non-opioid and opioid elixirs such as acetaminophen with codeine or with hydrocodone (Lortab) relieve pain and should be given routinely every 4 hours.

If surgery is required, the child requires the same psychologic preparation and physical care as for any other surgical procedure. Most tonsillectomy and adenoidectomy (T&A) surgeries now take place in outpatient settings; however, the priorities of preoperative and postoperative care remain the same. The following discussion focuses on postoperative nursing care for tonsillectomy and adenoidectomy, although both procedures may not be performed.

Until fully awake, the child is placed on his or her abdomen or side to facilitate drainage of secretions. Routine suctioning is avoided, but when performed, it is done carefully to avoid trauma to the oropharynx. When alert, the child may prefer sitting up. The child is discouraged from coughing frequently, clearing the throat, blowing the nose, and any other activity that may aggravate the operative site.

Some secretions are common, particularly dried blood from surgery. All secretions and vomitus are inspected for evidence of fresh bleeding (some blood-tinged mucus is expected). Dark brown (old) blood is usually present in the emesis, in the nose, and between the teeth. If parents do not expect this, they often become frightened at a time when they need to be calm and reassuring.

The throat is sore after surgery. An ice collar may provide relief, but many children find it bothersome and refuse to use it. Most children experience moderate pain after a T&A and need pain medication regularly for at least the first few days. Analgesics may be given rectally or intravenously to avoid the oral route. Because the pain is continuous, analgesics should be administered at regular intervals, even at night (see Pain Management, Chapter 30). An antiemetic such as ondansetron (Zofran) may be administered postoperatively if nausea or vomiting is present.

Food and fluids are restricted until the child is fully alert and there are no signs of hemorrhage. Cool water, crushed ice, flavored ice pops, or diluted fruit juice may be given, but fluids with a red or brown color are avoided to distinguish fresh or old blood in emesis from the ingested liquid. Citrus juice may cause discomfort and is usually poorly tolerated. Soft foods, particularly gelatin, cooked fruits, sherbet, soup, and mashed potatoes, are started on the first or second postoperative day or as the child tolerates feeding. The pain from surgery often inhibits fluid intake, reinforcing the need for adequate pain control. Milk, ice cream, and pudding are usually not offered because milk products coat the mouth and throat and may cause the child to clear the throat, which can initiate bleeding.

Postoperative hemorrhage is uncommon but can occur in up to 5% of patients up to 14 days after surgery. The nurse observes the throat directly for evidence of bleeding—using a good source of light and, if necessary, carefully inserting a tongue depressor. Other signs of hemorrhage are tachycardia, pallor, frequent clearing of the throat or swallowing by a younger child, and vomiting of bright red blood. Restlessness, an indication of hemorrhage, may be difficult to differentiate from general discomfort after surgery. Decreasing blood pressure is a late sign of shock.

Surgery may be required to ligate a bleeding vessel. Airway obstruction may also occur as a result of edema or accumulated secretions and is indicated by signs of respiratory distress, such as stridor, drooling, restlessness, agitation, increasing respiratory rate, and progressive cyanosis. Suction equipment and oxygen should be available after tonsillectomy.

! NURSING ALERT

The most obvious early sign of bleeding is the child's continuous swallowing of the trickling blood. While the child is sleeping, note the frequency of swallowing. If continuous bleeding is suspected, notify the surgeon immediately.

Discharge instructions include (1) avoiding irritating and highly seasoned foods, (2) avoiding gargles or vigorous toothbrushing, (3) avoiding coughing or clearing of the throat or putting objects in the mouth (e.g., a straw), (4) using analgesics or an ice collar for pain, and (5) limiting activity to decrease the potential for bleeding. Chewing gum may prevent throat and ear pain in older children. Objectionable mouth odor and slight ear pain with a low-grade fever are common for 5 to 10 days postoperatively. However, persistent severe earache, fever, or cough requires medical evaluation. Most children are ready to resume normal activity within 1 to

2 weeks after the operation. The child's voice may sound different postoperatively, especially if the tonsils were large.

Children who have received codeine after tonsillectomy or adenoidectomy or who are prescribed codeine should be observed closely for adverse effects (disorientation, confusion, unusual sleepiness, difficult to awaken, labored breathing) (FDA, 2013).

Influenza

Influenza, or the "flu," is caused by three orthomyxoviruses, which are antigenically distinct: types A and B, which cause epidemic disease; and type C, which is unimportant from an epidemiologic standpoint. Influenza is spread from one individual to another by direct contact (large-droplet infection) or by articles recently contaminated by nasopharyngeal secretions. There is no predilection for a specific age-group, but attack rates are highest in young children who have had no previous contact with a strain. Influenza is frequently most severe in infants. During epidemics, infection among school-age children is believed to be a major source of transmission in a community. The disease is more common during the winter months and has a 1- to 3-day incubation period. Affected persons are most infectious for 24 hours before and after the onset of symptoms. The virus has a peculiar affinity for epithelial cells of the respiratory tract mucosa, where it destroys ciliated epithelium with metaplastic hyperplasia of the tracheal and bronchial epithelium with associated edema. The alveoli may also become distended with a hyaline-like material. The viruses can be isolated from nasopharyngeal secretions early after the onset of infection, and serologic tests identify the type by complement fixation or the subgroups by hemagglutination inhibition.

H1N1 (swine flu) is a subtype of influenza type A. In 2009, a pandemic of H1N1 caused significant morbidity and mortality, particularly in Mexico and the United States; it was declared at an end in August 2010. A *pandemic* is defined by the World Health Organization (WHO) (2011) as the spread of a new disease to which the population has little or no immunity and that spreads rapidly from human to human. The signs and symptoms of H1N1 are the same as those mentioned below for influenza. H1N1 vaccine was combined with the seasonal influenza vaccine in the 2012 to 2013 season.

Clinical Manifestations

The manifestations of influenza may be subclinical, mild, moderate, or severe. Most patients have a dry throat and nasal mucosa, a dry cough, and a tendency toward hoarseness. A flushed face, photophobia, myalgia, hyperesthesia, and sometimes exhaustion and lack of energy accompany a sudden onset of fever and chills. Subglottal croup is common, especially in infants. The symptoms of influenza last for 4 to 5 days. Complications include severe viral pneumonia (often hemorrhagic); encephalitis; and secondary bacterial infections such as OM, sinusitis, or pneumonia.

Therapeutic Management

Uncomplicated influenza in children usually requires only symptomatic treatment, including acetaminophen or ibuprofen for fever and sufficient fluids to maintain hydration. Amantadine hydrochloride (Symmetrel) has been effective in reducing symptoms associated with type A disease if administered within 24 to 48 hours after their onset; the symptoms associated with influenza are reportedly shortened by 24 hours, but the drug does not "cure" the disease. It is ineffective against type B or C influenza or other viral diseases. It should not be given to children younger than 1 year but is recommended for unvaccinated high risk children.

Rimantadine has been approved for the treatment of flu symptoms in children and adults, but it is effective only for type A virus; this drug is taken orally in tablet or syrup twice daily for 7 days. It cannot be used for children younger than 1 year.

Zanamivir can be used for treatment of influenza in patients 7 years of age and older and for prophylaxis of influenza in patients 5 years of age and older. Both medications must also be started within 48 hours of symptom onset. Zanamivir is an inhaled medication effective for type A and type B influenza. The drug is taken twice daily for 5 days and is administered by a specially designed oral inhaler (Diskhaler).

A fourth drug, oseltamivir (Tamiflu), is a neuraminidase inhibitor that may be administered orally for 5 days to any child—from newborns to adolescents—and to adults to decrease the flu symptoms; as with other antiviral drugs, this drug must be taken within 2 days of the onset of symptoms. It is reported to be effective for types A and B influenza (AAP Committee on Infectious Diseases, 2012). Bronchospasm and a decline in lung function can occur when zanamivir is used in patients with underlying airway disease such as asthma or chronic obstructive pulmonary disease (COPD). At the time of this writing, oseltamivir and zanamivir are the only antiviral medications recommended for treatment during the 2012 to 2013 flu season because of widespread resistance to amantidine and rimantadine (AAP Committee on Infectious Diseases, 2012).

Prevention

The influenza vaccine is now recommended annually for children 6 months to 18 years of age. Influenza vaccine (inactivated influenza vaccine [IIV]) may be given to healthy children 6 months old and older. The inactivated influenza viral (IIV) vaccines are safe and effective provided the antigens in the vaccine correlate with the circulating influenza viruses (see Immunizations, Chapter 31) but are contraindicated in patients who developed Guillain-Barré syndrome within 6 weeks of receiving the vaccine in the past. The live-attenuated influenza vaccine (LAIV) is a nasal spray flu vaccine approved by the U.S. Food and Drug Administration (FDA) that is licensed for administration in persons ages 2 to 49 years. However, this preparation contains a live virus and should not be used in individuals who are immunocompromised, have reactive airway disease, are receiving immunosuppressive therapy, have a febrile illness, are receiving aspirin therapy, have a chronic respiratory condition, have received a live vaccine in the previous 28 days, are or could be pregnant, or have a history of Guillain-Barré syndrome. Patients who have had anaphylactic reactions to egg protein should receive a risk assessment evaluation by a physician with expertise in the management of allergic conditions (Centers for Disease Control and Prevention, [CDC], 2012). The Centers for Disease Control and Prevention (CDC) (2012) recommends that persons who have only experienced hives after an influenza vaccine receive the IIV. Note that children ages 6 months through 8 years now require 2 doses of influenza vaccine when it is their first season of receiving an influenza vaccine, to optimize immune response (CDC, 2012).

CARE MANAGEMENT

Nursing care for influenza is the same as for any child with a URI, including implementing measures to relieve symptoms. The greatest danger to affected children is development of a secondary infection. Prolonged fever or the appearance of fever during early convalescence is a sign of secondary bacterial infection and should be reported to the health care practitioner for antibiotic therapy.

BOX 40-5 STANDARD TERMINOLOGY FOR OTITIS MEDIA

Otitis media (OM)—An inflammation of the middle ear without reference to etiology or pathogenesis

Acute otitis media (AOM)—An inflammation of the middle ear with a rapid onset of the signs and symptoms of acute infection (i.e., fever and otalgia [ear pain])

Otitis media with effusion (OME)—Inflammation and fluid in the middle ear without symptoms of acute infection

Middle ear effusion (MEE)—Fluid in the middle ear without reference to etiology, pathogenesis, pathology, or duration

Children with influenza (or other similar viruses) should not receive aspirin because of its possible link with Reye syndrome.

Otitis Media

Otitis media is one of the most prevalent diseases of early childhood. Its incidence is highest in the winter months. Many cases of bacterial OM are preceded by a viral respiratory infection. The two viruses most likely to precipitate OM are RSV and influenza. Most episodes of acute otitis media (AOM) occur in the first 24 months of life, but the incidence decreases with age except for a small increase at age 5 or 6 years when children enter school. OM occurs infrequently in children older than 7 years. Preschool-age boys are affected more frequently than preschool-age girls. Children who have siblings or parents with a history of chronic OM have a higher incidence of OM. Children living in households with many members (especially smokers) are more likely to have OM than those living with fewer persons. Passive smoking increases the risk for persistent middle ear effusion by enhancing attachment of the pathogens that cause otitis to the respiratory epithelium in the middle ear space, by prolonging the inflammatory response, and by impeding drainage through the eustachian tube (AAP, 2004a). Family socioeconomic status and extent of exposure to other children are the two most important identifiable risk factors for the occurrence of OM (AAP, 2004a).

OM has been defined in a variety of ways. The standard terminology used to define OM is outlined in Box 40-5, and AOM treatment guidelines have been published (Lieberthal, Carroll, and Chonmaitree, 2013).

Etiology

Streptococcus pneumoniae, H influenzae, and *Moraxella catarrhalis* are the three most common bacteria causing AOM. The etiology of noninfectious OM is unknown, but OM may occur because of blocked eustachian tubes, which results in negative ear pressure. Fluid is pulled from the mucosal lining, which accumulates and becomes colonized by infectious organisms. Predisposing factors include URIs, allergies, Down syndrome, cleft palate, day care attendance, exposure to secondhand smoke, and bottle propping during feeding. Breastfed infants have a lower incidence of OM than formula-fed infants. Breastfeeding may protect infants against respiratory viruses and allergy because it contains secretory immunoglobulin A, which limits the exposure of the eustachian tube and middle ear mucosa to microbial pathogens and foreign proteins. Exclusive breastfeeding for at least 4 to 6 months shows a protective effect for prevention of OM and recurrent AOM (Lieberthal, Carroll, and Chonmaitree, 2013). Reflux of milk up the eustachian tubes is less likely in breastfed infants because of the semivertical positioning during breastfeeding compared with bottle feeding.

BOX 40-6 CLINICAL MANIFESTATIONS OF OTITIS MEDIA

Acute Otitis Media

- Follows an upper respiratory infection
- Otalgia (ear pain)
- Fever
- Purulent discharge (otorrhea) may or may not be present

Infant or Very Young Child

- Crying
- Fussy, restless, irritable
- Tendency to rub, hold, or pull affected ear
- Rolls head from side to side
- Difficulty comforting child
- Refuses to nurse or take bottle
- Loss of appetite

Older Child

- Crying or verbalizing feelings of discomfort
- Irritability
- Lethargy
- Loss of appetite

Chronic Otitis Media

- Hearing loss
- Difficulty communicating
- Possible feeling of fullness, tinnitus, or vertigo

Pathophysiology

Otitis media is primarily a result of malfunctioning eustachian tubes. Eustachian tubes have three functions relative to the middle ear: (1) protection of the middle ear from nasopharyngeal secretions; (2) drainage of secretions produced in the middle ear into the nasopharynx; and (3) ventilation of the middle ear to equalize air pressure within the middle ear and atmospheric pressure in the external ear canal and to replenish oxygen that has been absorbed.

Mechanical or functional obstruction of the eustachian tube causes accumulation of secretions in the middle ear. Intrinsic obstruction can be caused by infection or allergy; extrinsic obstruction is usually a result of enlarged adenoids or nasopharyngeal tumors. When the passage is not totally obstructed, contamination of the middle ear can take place by reflux, aspiration, or insufflation during crying, sneezing, nose blowing, and swallowing when the nose is obstructed.

Diagnostic Evaluation

Careful assessment of tympanic membrane mobility with a pneumatic otoscope is essential to differentiate AOM from OM with effusion (OME) (Lieberthal, Carroll, and Chonmaitree, 2013). A diagnosis of AOM is made if visual inspection of the tympanic membrane reveals a purulent discolored effusion and a bulging or full, opacified, or reddened immobile membrane, as well as an acute onset of ear pain for less than 48 hours (Lieberthal, Carroll, and Chonmaitree, 2013). An immobile tympanic membrane or an orange, discolored membrane indicates OME. Clinical symptoms of otitis are also helpful in making the diagnosis (Box 40-6). In AOM, symptoms such as acute onset of ear pain, fever, and a bulging yellow or red tympanic membrane are usually present. In OME, these symptoms may be absent and other nonspecific symptoms such as rhinitis, cough, or diarrhea are often present. OME may precede

AOM or predispose to its development, but OME does not represent an acute infectious process that requires antibiotic therapy (Lieberthal, Carroll, and Chonmaitree, 2013).

Therapeutic Management

Treatment for AOM is one of the most common reasons for antibiotic use in the ambulatory setting. Recently, however, concerns about drug-resistant *S. pneumoniae* and other drug resistances have led infectious disease authorities to recommend careful and judicious use of antibiotics for the treatment of this illness. Current recommendations regarding antibiotic administration to children with AOM are as follows (Lieberthal, Carroll, Chonmaitree, et al., 2013):

- Prescribe antibiotics for children 6 months of age and older who have severe signs or symptoms of AOM (moderate or severe otalgia for at least 48 hours or temperature 102.2° F [39° C]).
- Prescribe antibiotics for bilateral AOM in children younger than 24 months of age who do not have severe signs or symptoms (moderate or severe otalgia for at least 48 hours or temperature 102.2° F [39° C])
- Either prescribe antibiotics *or* offer observation with close follow-up (based on joint decision making with parent or caregiver) for unilateral AOM in children 6 months to 23 months of age who do not have severe signs or symptoms (moderate or severe otalgia for at least 48 hours or temperature 102.2° F [39° C]); if child does not improve within 48 to 72 hours, begin antibiotic therapy
- Either prescribe antibiotics *or* offer observation with close follow-up (based on joint decision making with parent or caregiver) for unilateral or bilateral AOM in children 24 months of age or older who do not have severe signs and symptoms (moderate or severe otalgia for at least 48 hours or temperature 102.2° F [39° C])

The latest AAP recommendations also place emphasis on the assessment and management of pain in children with AOM. For fever or discomfort associated with OM, analgesic-antipyretic drugs such as acetaminophen or ibuprofen may be given. The health care practitioner may prescribe topical pain relief drops such as benzocaine or lidocaine. A narcotic analgesic with codeine may be required for children with severe pain; however, side effects are common and the child should be closely monitored for GI upset, constipation, respiratory depression, and altered mental status (Lieberthal, Carroll, Chonmaitree, et al., 2013).

When antibiotics are warranted, oral amoxicillin in high doses (80-90 mg/kg/day divided twice daily) is the treatment of choice for initial episodes of AOM in children who have not received amoxicillin within the past month (Lieberthal, Carroll, and Chonmaitree, 2013). The recommendation for the duration of antibiotic therapy in severe AOM is 10 days. A 5- to 7-day course may be sufficient in children 6 years of age and older with uncomplicated AOM or a moderate or mild infection, whereas children 2 to 5 years of age with mild or moderate AOM may benefit from a 7-day course of antibiotics (Lieberthal, Carroll, Chonmaitree, et al., 2013).

Second-line antibiotics used to treat OM include amoxicillin-clavulanate; azithromycin; and cephalosporins such as cefdinir, cefuroxime, and cefpodoxime. Alternative dosing schedules and conditions are discussed in the 2013 AAP clinical practice guidelines. IM ceftriaxone is used if the causative organism is a highly resistant pneumococcus or if the parents are noncompliant with the therapy. An important consideration with the use of single-dose IM injections is the pain involved in this therapy. One strategy to minimize pain at the injection site is to reconstitute the cephalosporin with 1% lidocaine. A topical analgesic cream such as EMLA or LMX4 can also be applied to the site beforehand to reduce pain. The use of steroids, decongestants, and antihistamines to treat AOM is not recommended.

Myringotomy, a surgical incision of the eardrum, may be necessary to alleviate the severe pain of AOM. A myringotomy is also performed to provide drainage of infected middle ear fluid in the presence of complications (mastoiditis, labyrinthitis, or facial paralysis) or to allow purulent middle ear fluid to drain into the ear canal for culture. A minimally invasive laser-assisted myringotomy procedure may be performed in outpatient settings. These procedures should be performed only by ear, nose, and throat (ENT) specialists.

Tympanostomy tube placement and adenoidectomy are surgical procedures that may be done to treat recurrent chronic AOM (defined as three bouts in 6 months, six in 12 months, or six by 6 years of age). Tympanostomy tubes are pressure-equalizer (PE) tubes or grommets that facilitate continued drainage of fluid and allow ventilation of the middle ear. They are inserted to treat severe eustachian tube dysfunction, OM with effusion, or complications of OM (mastoiditis, facial nerve paralysis, brain abscess, labyrinthitis). Adenoidectomy is not recommended for treatment of AOM and is performed only in children with recurrent AOM or chronic OME with postnasal obstruction, adenoiditis, or chronic sinusitis.

In some children, residual middle ear effusions remain after episodes of AOM. Some children have fluid that persists in the middle ear for weeks or months. Antibiotics are not required for initial treatment of OME but may be indicated for children with persistent effusion for more than 3 months (AAP, 2004a). Placement of tympanostomy tubes is recommended after a total of 4 to 6 months of bilateral effusion with a bilateral hearing deficit (AAP, 2004b). This therapy allows for mechanical drainage of the fluid, which promotes healing of the membrane and prevents scar formation and loss of elasticity. Myringotomy with or without insertion of PE tubes should not be performed for initial management of OME but may be recommended for children who have recurrent episodes of OME with a long cumulative duration (AAP, 2004b).

Otitis media with effusion is frequently associated with mild to moderate impairment of hearing; therefore a hearing test should also be performed if OME persists for 3 months or more or if there is evidence of language or learning delays. Follow-up examinations of children with chronic OME should be maintained on a 3- to 6-month basis until the OME is resolved, a significant hearing loss is identified, or structural defect of the tympanic membrane or middle ear is identified (AAP, 2004a). Children with hearing loss should be referred to an otolaryngologist and should receive a speech and language evaluation as necessary.

Prevention

Routine immunization with the pneumococcal conjugate vaccine PCV7 (Prevnar 7) has reduced the incidence of AOM in many infants and children (Rodgers and Klugman, 2011). In 2010, the FDA approved a new conjugate vaccine, Prevnar 13, which replaces Prevnar 7. The vaccine is administered as a four-dose series beginning at 2 months of age; infants and children who have started the series with Prevnar 7 may complete the series with Prevnar 13 (CDC, 2010). The latest AAP clinical guidelines also recommend an annual influenza vaccination as a prevention for AOM (Lieberthal, Carroll, Chonmaitree, et al., 2013).

Parents are encouraged to reduce risk factors for AOM by breastfeeding infants for at least the first 6 months of life, avoid propping

the formula bottle, decrease or discontinue pacifier use after 6 months, and prevent exposure to tobacco smoke (Lieberthal, Carroll, Chonmaitree, et al., 2013; AAP, 2004a). Xylitol or birch sugar, either in chewing gum or lozenge form, may be beneficial in preventing recurrent AOM in children over 2 years of age when used 3 to 5 times a day (Lieberthal, Carroll, Chonmaitree, et al., 2013).

CARE MANAGEMENT

Nursing objectives for children with AOM include (1) relieving pain, (2) facilitating drainage when possible, (3) preventing complications or recurrence, (4) educating the family in care of the child, and (5) providing emotional support to the child and family.

Analgesic drugs such as acetaminophen (all ages) and ibuprofen (6 months of age and older) are used to treat mild pain. For more severe pain, the AAP (Lieberthal, Carroll, Chonmaitree, et al., 2013) guidelines recommend a stronger analgesic such as codeine.

If the ear is draining, the external canal may be cleaned with sterile cotton swabs or pledgets coupled with topical antibiotic treatment. If ear wicks or lightly rolled sterile gauze packs are placed in the ear after surgical treatment, they should be loose enough to allow accumulated drainage to flow out of the ear; otherwise, infection may be transferred to the mastoid process. The wicks need to stay dry during shampoos or baths. Occasionally, drainage is so profuse that the auricle and the skin surrounding the ear become excoriated from the exudate. This is usually prevented by frequent cleansing and application of various moisture barriers (e.g., Proshield Plus), zinc oxide–based products, or petrolatum jelly (e.g., Vaseline).

Tympanostomy tubes may allow water to enter the middle ear, but recommendations for earplugs are inconsistent. Research evidence indicates that swimming without earplugs poses a slight increased risk for infection (Goldstein, Mandel, Kurs-Lasky, et al., 2005). However, lake and river water are potentially contaminated and wearing earplugs while swimming in a lake prevents total flooding of the external canal. Bathwater and shampoo water should be kept out of the ear, if possible, because soap reduces the surface tension of water and facilitates entry through the tube. Parents should be aware of the appearance of a grommet (usually a tiny, white, plastic spool-shaped tube) so that they can recognize it if it falls out. They are reassured that this is normal and requires no immediate intervention, although they should notify the health care practitioner.

Prevention of recurrence requires adequate education regarding antibiotic therapy. The symptoms of pain and fever usually subside within 24 to 48 hours, but nurses must emphasize that all of the prescribed medication should be taken. Parents should be aware that potential complications of OM, such as hearing loss, can be prevented with adequate treatment and follow-up care.

Parents also need anticipatory guidance regarding methods to reduce the risks of OM, especially in children younger than 2 years. Reducing the chances of OM is possible with simple measures, such as sitting or holding an infant upright for feedings, maintaining routine childhood immunizations, and exclusively breastfeeding until at least 6 months of age. Propping bottles is discouraged to avoid pooling of milk while the child is in the supine position and to encourage human contact during feeding. Eliminating tobacco smoke and known allergens is also recommended. Early detection of middle ear effusion is essential to prevent complications. Infants and preschool children should be screened for effusion, and all schoolchildren, especially those with learning disabilities, should be tested for hearing deficits related to a middle ear effusion.

BOX 40-7 CLINICAL MANIFESTATIONS OF INFECTIOUS MONONUCLEOSIS

Early Signs
- Headache
- Malaise
- Fatigue
- Chills
- Low-grade fever
- Loss of appetite
- Puffy eyes

Acute Disease

Cardinal Features
- Fever
- Sore throat
- Cervical adenopathy

Common Features
- Splenomegaly (may persist for several months)
- Palatine petechiae
- Macular eruption (especially on trunk)
- Exudative pharyngitis or tonsillitis

Infectious Mononucleosis

Infectious mononucleosis is an acute, self-limiting infectious disease that is common among adolescents. Symptoms include fever, exudative pharyngitis, lymphadenopathy, hepatosplenomegaly, and an increase in atypical lymphocytes. The course is usually mild but occasionally can be severe or, rarely, accompanied by serious complications.

Etiology and Pathophysiology

The herpes-like Epstein-Barr virus (EBV) is the principal cause of infectious mononucleosis. It appears in both sporadic and epidemic forms, but the sporadic cases are more common. The mechanism of spread has not been proven, but it is believed to be transmitted in saliva by direct intimate contact, although it survives in saliva for many hours outside of the body. The incubation period after exposure is approximately 30 to 50 days (AAP Committee on Infectious Diseases, 2012).

Diagnostic Tests

The onset of symptoms may be acute or insidious and may appear anywhere from 10 days to 6 weeks after exposure. The presenting symptoms vary greatly in type, severity, and duration (Box 40-7). The clinical manifestations of infectious mononucleosis are usually less severe (often subclinical or unapparent) and the convalescent phase is shorter in younger children than in older children and young adults. Heterophil antibody tests (Paul-Bunnell or Monospot) determine the extent to which the patient's serum will agglutinate sheep red blood cells; the response in these tests is primarily to immunoglobulin M, which is present in the first 2 weeks of the illness in adolescents. The spot test (Monospot) is a slide test of venous blood that has high specificity. It is rapid, sensitive, inexpensive, and easy to perform and has the advantage over the Paul-Bunnell test in that it can detect significant agglutinins at lower levels, thus allowing earlier diagnosis. Blood is usually obtained for the test by finger puncture or venous sampling and is placed on special paper. If the blood agglutinates, forming fragments or clumps, the test result is positive for the infection.

Therapeutic Management

No specific treatment exists for infectious mononucleosis. A mild analgesic is often sufficient to relieve the headache, fever, and malaise. Rest is encouraged for fatigue but is not imposed for any specific period. Affected persons are instructed to regulate activities

according to their own tolerance unless complicating factors are present. Contact sports are discouraged in the presence of splenomegaly.

Antibiotics are contraindicated unless β-hemolytic streptococci are present (amoxicillin or ampicillin can cause a rash in patients with EBV infection). If sore throat is severe, effective therapies include gargles; hot drinks; anesthetic troches; or analgesics, including opioids. Corticosteroids have been used to treat respiratory distress from significant tonsillar inflammation, myocarditis, hemolytic anemia, thrombocytopenia, and neurologic complications; however, routine use of steroids is not recommended (AAP Committee on Infectious Diseases, 2012).

Prognosis. The course of this disease is usually self-limiting and uncomplicated. Acute symptoms often disappear within 7 to 10 days, and persistent fatigue subsides within 2 to 4 weeks. Some adolescents may need to restrict their activities for 2 to 3 months, but the disease rarely extends for longer periods. The adolescent is encouraged to maintain limited exercise to prevent deconditioning.

CARE MANAGEMENT

Nursing responsibilities for infectious mononucleosis are directed toward providing comfort measures to relieve symptoms and helping affected adolescents and their families determine appropriate activities for the stage of the disease. The adolescent is advised to limit exposure to persons outside the family, especially during the acute phase of illness. It may be more comfortable to limit intake to liquids during the acute phase; milkshakes are a good alternative to solid foods on a temporary basis. Throat pain may be severe enough to require an analgesic such as acetaminophen, ibuprofen, or even codeine. Careful nursing assessment of swallowing ability is essential to detect serious airway edema and airway compromise.

! NURSING ALERT

Advise the family to seek medical evaluation of the child or adolescent if:

- Breathing becomes difficult.
- Severe abdominal pain develops.
- Sore throat pain is so severe that the child is unable drink liquids.
- Respiratory stridor is observed.

CROUP SYNDROMES

Croup is a general term applied to a symptom complex characterized by hoarseness, a resonant cough described as "barking" or "brassy" (croupy), varying degrees of inspiratory stridor, and varying degrees of respiratory distress resulting from swelling or obstruction in the region of the larynx. Acute infections of the larynx are important in infants and small children because of their increased incidence in these age-groups and because the small diameter of the airway in infants and children places them at risk for significant narrowing with inflammation.

Croup syndromes can affect the larynx, trachea, and bronchi. However, laryngeal involvement often dominates the clinical picture because of the severe effects on the voice and breathing. Croup syndromes are described according to the primary anatomic area affected (i.e., epiglottitis [or supraglottitis], laryngitis, laryngotracheobronchitis [LTB], and tracheitis). In general, LTB occurs in very young children and epiglottitis is more common in older children. A comparison of croup syndromes is provided in Table 40-1.

With widespread immunization programs aimed at preventing *H. influenzae* type b, the cause of most cases of croup in the United States is attributed to viruses, namely parainfluenza virus, human metapneumovirus, influenza types A and B, adenovirus, and measles.

TABLE 40-1 COMPARISON OF CROUP SYNDROMES

	ACUTE EPIGLOTTITIS	ACUTE LARYNGOTRACHEOBRONCHITIS (LTB)	ACUTE SPASMODIC LARYNGITIS	ACUTE TRACHEITIS
Age-group affected	2-5 years but varies	Infant or child younger than 5 years	1-3 years	1 month–6 years (mean 5 to 7 years)
Etiologic agent	Bacterial	Viral	Viral with allergic component	Viral or bacterial with allergic component
Onset	Rapidly progressive	Slowly progressive	Sudden; at night	Moderately progressive
Major symptoms	Dysphagia Stridor aggravated when supine Drooling High fever Toxic appearance Rapid pulse and respirations	URI Stridor Brassy cough Hoarseness Dyspnea Restlessness Irritability Low-grade fever Nontoxic appearance	URI Croupy cough Stridor Hoarseness Dyspnea Restlessness Symptoms awakening child but disappearing during day Tendency to recur	URI Croupy cough Purulent secretions High fever No response to LTB therapy
Treatment	Airway protection Corticosteroids Fluids Antibiotics Reassurance	Racemic epinephrine Corticosteroids Fluids Reassurance	Cool mist Reassurance	Antibiotics Fluids

URI, Upper respiratory infection.

Acute Epiglottitis

A presumptive diagnosis of acute epiglottitis, or acute supraglottitis, is a medical emergency. It is a serious obstructive inflammatory process that occurs predominantly in children ages 2 to 5 years but can occur from infancy to adulthood. The obstruction is supraglottic as opposed to the subglottic obstruction of laryngitis. The responsible organism is usually *H. influenzae*. LTB and epiglottitis do not occur together.

Clinical Manifestations

The onset of **epiglottitis** is abrupt, and it can rapidly progress to severe respiratory distress. The child usually goes to bed asymptomatic to awaken later, complaining of sore throat and pain on swallowing. The child has a fever; appears sicker than clinical findings suggest; and insists on sitting upright and leaning forward with the chin thrust out, mouth open, and tongue protruding **(tripod position).** Drooling of saliva is common because of the difficulty or pain on swallowing and excessive secretions.

! NURSING ALERT

Three clinical observations that are predictive of epiglottitis are absence of spontaneous cough, presence of drooling, and agitation.

The child is irritable; extremely restless; and has an anxious, apprehensive, and frightened expression. The voice is thick and muffled, with a froglike croaking sound on inspiration, but the child is not hoarse. Suprasternal and substernal retractions may be evident. The child seldom struggles to breathe, and slow, quiet breathing provides better air exchange. The throat is red and inflamed, and a distinctive large, cherry red, edematous epiglottis is visible on careful throat inspection.

! NURSING ALERT

Throat inspection should be attempted only when immediate endotracheal intubation can be performed if needed.

Therapeutic Management

The course of epiglottitis may be fulminant, with respiratory obstruction appearing suddenly. Progressive obstruction leads to hypoxia, hypercapnia, and acidosis followed by decreased muscular tone; reduced level of consciousness; and, when obstruction becomes more or less complete, a rather sudden death.

The child who is suspected of having epiglottitis should be examined in a setting where emergency airway equipment is readily available. Examination of the throat with a tongue depressor is contraindicated until experienced personnel and equipment are available to proceed with immediate intubation or tracheostomy in the event that the examination precipitates further or complete obstruction.

Nasotracheal intubation or tracheostomy is usually considered for the child with epiglottitis with severe respiratory distress. It is recommended that the intubation or tracheostomy and any invasive procedure, such as starting an intravenous (IV) infusion, be performed in an area where emergency airway maintenance can be easily and quickly accomplished. Humidified oxygen is administered as necessary either via mask in older children or flow-by in younger children to avoid further agitation. Whether or not there is an artificial airway, the child requires intensive observation by experienced personnel. The epiglottal swelling usually decreases after 24 hours of antibiotic therapy (ceftriaxone sodium or alternate cephalosporin), and the epiglottis is near normal by the third day. Intubated children are generally extubated at this time. The use of corticosteroids for reducing edema may be beneficial during the early treatment phase.

Children with suspected bacterial epiglottitis are given antibiotics intravenously followed by oral administration to complete a 7- to 10-day course. Family contacts with children younger than 4 years and any contacts younger than 4 years are treated with rifampin for 4 days (AAP Committee on Infectious Diseases, 2012).

CARE MANAGEMENT

Epiglottitis is a serious and frightening disease for the child and family. It is important to act quickly but calmly and to provide support without increasing anxiety. The child is allowed to remain in the position that provides the most comfort and security, and the parents are reassured that everything possible is being done to obtain relief for their child.

! NURSING ALERT

When epiglottitis is suspected, the nurse should not attempt to visualize the epiglottis directly with a tongue depressor or take a throat culture but should refer the child for medical evaluation immediately (see Critical Thinking Case Study).

Acute care of the child is the same as that described later for the child with LTB. Continuous monitoring of respiratory status, including pulse oximetry (and blood gases if the patient is intubated), is an important part of nursing observations, and the IV infusion is maintained as described in Chapter 39.

Acute Laryngotracheobronchitis

Laryngotracheobronchitis is the most common croup syndrome. It affects primarily children younger than 5 years, and the causative organisms are viral agents, particularly the parainfluenza virus types 2 and 3, human metapneumovirus, RSV, influenza A, and influenza B. Other causative agents include *M. pneumoniae,* pneumococcus, and staphylococcus. The disease is usually preceded by a

CRITICAL THINKING CASE STUDY

Croup Syndrome

Kim, a 4-year-old, is admitted to the emergency department with a sore throat, pain on swallowing, drooling, and a fever of 39° C (102.2° F). She looks ill, is agitated, and prefers to sit up leaning on her arms. What nursing interventions should the nurse implement in this situation?

1. Evidence—Is there sufficient evidence to draw any conclusions about Kim's condition at this time?
2. Assumptions—Describe some underlying assumptions about each of the following:
   a. Epiglottitis in children
   b. Symptoms of epiglottitis
   c. Precautions to be taken when a child has suspected epiglottitis
   d. Immediate nursing interventions when caring for a child with epiglottitis
3. What priorities for nursing care can be drawn at this time?
4. Does the evidence objectively support your argument (conclusion)?

URI, which gradually descends to adjacent structures. It is characterized by a gradual onset of low-grade fever, and the parents often report that the child went to bed and later awoke with a barky, brassy cough. Inflammation of the mucosa lining the larynx and trachea causes a narrowing of the airway. When the airway is significantly narrowed, the child inspires air past the obstruction and into the lungs, producing the characteristic inspiratory stridor and suprasternal retractions. Other classic manifestations include cough and hoarseness. Respiratory distress in infants and toddlers may be manifested by nasal flaring, intercostal retractions, tachypnea, and continuous stridor. The typical child with LTB develops the classic barking or seal-like cough and acute stridor after several days of rhinitis. When the child is unable to inhale a sufficient volume of air, symptoms of hypoxia become evident. Obstruction that is severe enough to prevent adequate ventilation and exhalation of carbon dioxide can cause respiratory acidosis and eventually respiratory failure.

Therapeutic Management

The major objective in medical management is maintaining the airway and providing adequate respiratory exchange. Children with mild croup (no stridor at rest) can be managed at home. Parents are taught the signs of respiratory distress and instructed to summon professional help early if needed. Children with labored respirations and stridor or other respiratory symptoms should receive medical attention.

The application of humidity with cool mist provides relief for most children. A cool-air vaporizer can be used at home. In the hospital, a nebulized mist for older infants and toddlers may be used to provide increased humidity and supplemental oxygen. However, controversy surrounds the use of mist therapy to treat croup. Studies have failed to demonstrate any significant improvement in subglottic edema with mist therapy (Moore and Little, 2007). A ride in the car with the windows down may help relieve symptoms.

Nebulized epinephrine (racemic epinephrine) is often used in children with severe disease, stridor at rest, retractions, or difficulty breathing. The α-adrenergic effects cause mucosal vasoconstriction and subsequently decrease subglottic edema. The onset of action is rapid, and the peak effect is observed in 2 hours. Children may be discharged home following racemic epinephrine after a 2- to 3-hour period of observation for return of acute symptoms.

Oral steroids (dexamethasone) have proven effective in the treatment of croup (often as a single dose) and are considered standard treatment for this condition (Zoorob, Sidani, and Murray, 2011); IM dexamethasone may be given to children who are unable to tolerate oral dosing. Nebulized budesonide may be administered in conjunction with IM dexamethasone.

In severe cases of LTB, the administration of heliox may be used to reduce the work of breathing and relieve airway obstruction. It reduces airway turbulence but is not recommended as a standard treatment of croup.

CARE MANAGEMENT

The most important nursing function in the care of children with LTB is continuous, vigilant observation and accurate assessment of respiratory status. Pulse oximetry is commonly used for monitoring oxygenation status. Changes in therapy are frequently based on the nurses' observations and assessments, the child's response to therapy, and tolerance of procedures. The trend away from early intubation of children with LTB emphasizes the importance of nursing observations and the ability to recognize impending respiratory failure so that intubation can be implemented without delay.

! NURSING ALERT

Early signs of impending airway obstruction include increased pulse and respiratory rate; substernal, suprasternal, and intercostal retractions; flaring nares; and increased restlessness.

Infants or small children find that being treated with cool mist, coughing, having laryngeal spasms, and needing IV therapy are additional sources of distress. In many acute care facilities, the infant is allowed to be held by the parent; if cool mist is used in the treatment, it can be administered through a tube held in front of the patient while the child is held on the parent's lap.

Children with mild croup are allowed to drink the beverages they like as long as their respiratory status is stable, and parents are encouraged to try whatever comforting measures work best (e.g., holding their child, rocking, singing). If the child is unable to take oral fluids, IV fluids may be required, and steroids may need to be given intravenously.

The rapid progression of croup, the alarming sound of the cough and stridor, and the child's apprehensive behavior and ill appearance combine to create a frightening experience for the parents and family. The family should be allowed to remain with their child as much as possible.

Parents need frequent reassurance provided in a calm, quiet manner and education regarding what they can do to make their child more comfortable. Home care includes monitoring for worsening symptoms, continued humidity, adequate hydration, and nourishment.

Acute Spasmodic Laryngitis

Acute spasmodic laryngitis (spasmodic croup) is distinct from laryngitis and LTB and is characterized by recurrent paroxysmal attacks of laryngeal obstruction that occur chiefly at night. Signs of inflammation are absent or mild, and it is followed by an uneventful recovery. The child feels well the next day. Some children appear to be predisposed to the condition; allergies or hypersensitivities may be implicated in some cases. Management is the same as for infectious croup.

Bacterial Tracheitis

Bacterial tracheitis, an infection of the mucosa of the upper trachea, is a distinct entity with features of both croup and epiglottitis. The disease occurs typically at a mean age between 5 and 7 years and may cause severe airway obstruction (Roosevelt, 2011). It is believed to be a complication of LTB, and although *Staphylococcus aureus* is the most frequent organism responsible, *M. catarrhalis, S. pneumonia,* and *H. influenzae* have also been implicated.

Many of the manifestations of bacterial tracheitis are similar to those of LTB but are unresponsive to LTB therapy. The child has a history of previous URI with croupy cough, stridor unaffected by position, toxicity, absence of drooling, absence of dysphagia, and high fever. Thick, purulent tracheal secretions are common, and respiratory difficulties are secondary to these copious secretions and mucosal edema at the level of the cricoid cartilage. The child's white cell count will be elevated. Children with this condition may develop a life-threatening upper airway obstruction, respiratory failure, acute respiratory distress syndrome (ARDS), and multiple organ dysfunction (Hopkins, Lahiri, Salerno, et al., 2006).

THERAPEUTIC MANAGEMENT AND CARE MANAGEMENT

Bacterial tracheitis requires vigorous management with oxygen therapy, antipyretics, and antibiotics. Many younger children require endotracheal intubation and mechanical ventilation; patients are closely monitored for impending respiratory failure if not intubated. Early recognition to prevent life-threatening airway obstruction is essential.

INFECTIONS OF THE LOWER AIRWAYS

The reactive portion of the lower respiratory tract includes the bronchi and bronchioles in children. Cartilaginous support of the large airways is not fully developed until adolescence. Consequently, the smooth muscle in these structures represents a major factor in the constriction of the airway, particularly in the bronchioles—the portion that extends from the bronchi to the alveoli. Table 40-2 compares some of the major features of bronchial and bronchiolar infections.

Bronchitis

Bronchitis (sometimes referred to as tracheobronchitis) is an inflammation of the large airways (trachea and bronchi), which is frequently associated with URIs. Viral agents are the primary cause of the disease, although *M. pneumoniae* is a common cause in children older than 6 years. A dry, hacking, nonproductive cough that worsens at night and becomes productive in 2 to 3 days characterizes this condition.

Bronchitis is a mild, self-limiting disease that requires only symptomatic treatment, including analgesics, antipyretics, and humidity. Cough suppressants may be useful to allow rest but can interfere with clearance of secretions. Most patients recover uneventfully in 5 to 10 days. It can be associated with other underlying conditions such as CF and bronchiectasis and can become chronic in nature (cough >3 months). Adolescents with bronchitis should be screened for tobacco or marijuana use.

Respiratory Syncytial Virus and Bronchiolitis

Bronchiolitis is a common, acute viral infection with maximum effect at the bronchiolar level. The infection occurs primarily in winter and early spring. By age 3 years, most children have been infected at least once. RSV infection is the most frequent cause of hospitalization in children younger than 1 year. In addition, severe RSV infections in the first year of life represent a significant risk factor for the development of asthma up to age 13 years (Chávez-Bueno, Mejías, Jafri, et al., 2005). However, a strong causal relationship between RSV and the subsequent development of asthma has not been conclusively demonstrated (Wu and Hartert, 2011). Significant RSV infection may also occur in children older than 1 year who have a chronic or serious disabling illness. Although most cases of bronchiolitis are caused by RSV, adenoviruses and parainfluenza viruses are also implicated; recently, human metapneumovirus and human bocavirus have also been associated with bronchiolitis in children. It can also rarely be caused by *M. pneumoniae.* Occasionally, infants with RSV may have a concurrent viral or bacterial infection (e.g., otitis media, pertussis) (Watts and Goodman, 2011).

TABLE 40-2 COMPARISON OF CONDITIONS AFFECTING THE BRONCHI

	ASTHMA*	BRONCHITIS	BRONCHIOLITIS
Description	Exaggerated response of bronchi to a trigger such as URI, animal dander, cold air, exercise Bronchospasm, exudation, and edema of bronchi, airway obstruction Inflammatory response	Usually occurs in association with URI Seldom an isolated entity	Most common infectious disease of lower airways Maximum obstructive impact at bronchiolar level
Age-group affected	Infancy to adolescence	First 4 years of life	Usually children 2 to 12 mo of age; rare after age 2 yr
Etiologic agents	Most often viruses such as RSV in infants but may be any of a variety of URI pathogens	Usually viral Other agents (e.g., bacteria, fungi, allergic disorders, airborne irritants) can trigger symptoms	Peak incidence, ≈age 6 mo Viruses, predominantly RSV; also adenoviruses, parainfluenza viruses, human metapneumovirus, and *Mycoplasma pneumoniae*
Predominant characteristics	Wheezing, cough	Persistent dry, hacking cough (worse at night) becoming productive in 2-3 days	Labored respirations, poor feeding, cough, tachypnea, retractions, nasal flaring, emphysema, increased nasal mucus, wheezing, may have fever
Treatment	Inhaled corticosteroids, bronchodilators, leukotriene modifiers, allergen and "triggers" control, long-term antiinflammatory medications	Cough suppressants if needed	Supplemental oxygen if saturations ≤90%; bronchodilators (optional) Suctioning nasopharynx Ensure adequate fluid intake Maintain adequate oxygenation

RSV, Respiratory syncytial virus; *URI,* upper respiratory infection.
*See Asthma, p. 1223.

Respiratory syncytial virus is transmitted from exposure to contaminated secretions. RSV can live on fomites for several hours and on hands for 30 minutes (AAP Committee on Infectious Diseases, 2012). The incubation period is 2 to 8 days.

Pathophysiology

Respiratory syncytial virus affects the epithelial cells of the respiratory tract. The ciliated cells swell, protrude into the lumen, and lose their cilia. RSV produces a fusion of cell membranes, forming a giant cell. The bronchiolar mucosa swells, and lumina are subsequently filled with mucus and exudate. The walls of the bronchi and bronchioles are infiltrated with inflammatory cells, and peribronchiolar interstitial pneumonitis is usually present. The varying degrees of intraluminal obstruction lead to hyperinflation, obstructive emphysema resulting from partial obstruction, and patchy areas of atelectasis. Dilation of bronchial passages on inspiration allows sufficient space for intake of air, but narrowing of the passages on expiration prevents air from leaving the lungs. Thus air is trapped distal to the obstruction and causes progressive overinflation (emphysema).

Clinical Manifestations

The illness usually begins with a URI after an incubation of about 5 to 8 days. Symptoms such as rhinorrhea and low-grade fever often appear first. OM and conjunctivitis may also be present. In time, a cough may develop. If the disease progresses, it becomes a lower respiratory tract infection and manifests typical symptoms (Box 40-8). Infants may have several days of URI symptoms or no symptoms except slight lethargy, poor feeding, or irritability.

When the lower airway is involved, classic manifestations include signs of altered air exchange, such as wheezing, retractions, crackles, dyspnea, tachypnea, and diminished breath sounds. Apnea may be the first recognized indicator of RSV infection in very young infants (younger than 1 month). Risk factors for the development of RSV infection include male gender, birth within 6 months of the start of RSV season, multiple birth, non-breastfed infants, young mothers and young mothers who smoke during pregnancy or thereafter, family history of atopy, low socioeconomic status and education, and living in crowded conditions; older family members may transmit the infection although they remain primarily asymptomatic or may only have a cold (Watts and Goodman, 2011). Preterm birth, chronic lung disease, congenital heart disease, neuromuscular disease, and immunodeficiency place children at higher risk for the development of severe RSV infection (AAP, 2006; Checchia, 2008).

BOX 40-8 SIGNS AND SYMPTOMS OF RESPIRATORY SYNCYTIAL VIRUS

Initial
- Rhinorrhea
- Pharyngitis
- Coughing/sneezing
- Wheezing
- Possible ear or eye drainage
- Intermittent fever

With Progression of Illness
- Increased coughing and wheezing
- Tachypnea and retractions
- Cyanosis

Severe Illness
- Tachypnea greater than 70 breaths/min
- Listlessness
- Apneic spells
- Poor air exchange; decreased breath sounds

Diagnostic Evaluation

Identification has been simplified by the development of tests done on nasopharyngeal secretions, using either a rapid immunofluorescent antibody–direct fluorescent antibody (DFA) staining or an enzyme-linked immunosorbent assay (ELISA) for RSV antigen detection (see Respiratory Secretion and Throat Specimens, Chapter 39). Hyperinflation of the lungs is generally seen on the chest radiograph.

Therapeutic Management

Children with bronchiolitis are treated symptomatically with humidified oxygen, adequate fluid intake, airway maintenance, and medications. Most children with bronchiolitis can be managed at home. Hospitalization is usually recommended for children with respiratory distress and those who cannot maintain adequate hydration. Other reasons for hospitalization include complicating conditions, such as underlying lung or heart disease or associated debilitated states, or a home environment where adequate management is questionable. An infant who is tachypneic or apneic, has marked retractions, appears listless, has a history of poor fluid intake, or is dehydrated should be closely observed for respiratory failure.

Humidified oxygen is administered in concentrations sufficient to maintain adequate oxygenation (Spo_2) at or above 90% as measured by pulse oximetry. Humidified mist may be administered. Routine chest percussion and postural drainage (formerly CPT) are not recommended (Roque Figuls, Gine-Garriga, Granados Rugeles, et al., 2012); infants with abundant nasal secretions benefit from periodic suctioning. Fluids by mouth may be contraindicated because of tachypnea, weakness, and fatigue; therefore IV fluids may be used until the acute stage of the disease has passed. Nasogastric fluids may be required if the infant is unable to tolerate oral fluids and a peripheral IV is difficult to establish.

Clinical assessments, noninvasive oxygen monitoring, and blood gas values may guide therapy. Medical therapy for bronchiolitis is primarily supportive and aimed at decreasing airway hyperresonance and inflammation and promoting adequate fluid intake. Bronchodilators may provide short-term benefits, yet overall significant improvement in the child's condition is not always appreciable. A single dose of bronchodilator therapy is often prescribed to assess for a clinical response. If it improves symptoms, it may be prescribed on an ongoing basis. If no response is evident, no further doses are given. Racemic epinephrine has been shown to produce modest improvement in ventilation status. Nebulized hypertonic saline (3%) treatments may decrease hospital length of stay and improve mucociliary clearance (Wright and Piedimonte, 2011).

Corticosteroids (inhaled or systemic) and antihistamines have not been shown to be effective in controlled studies and are not recommended for routine use. Antibiotics are not part of the treatment of RSV infection unless there is a coexisting bacterial infection such as OM (AAP, 2006). Additional recommendations in the AAP (2006) practice guideline are to encourage breastfeeding; avoid passive tobacco smoke exposure; and promote preventive measures, including hand washing.

Ribavirin, an antiviral agent (synthetic nucleoside analog), is the only specific therapy approved for hospitalized children; however, use of this drug is controversial because of concerns about the high cost, aerosol route of administration, potential toxic effects among exposed health care personnel (teratogenicity), and conflicting results of efficacy trials (AAP, 2006; Chávez-Bueno, Mejías, Jafri, et al., 2005; Ventre and Randolph, 2007).

Prevention of Respiratory Syncytial Virus Infection

The only product available in the United States for prevention of RSV infection is palivizumab (Synagis), a monoclonal antibody, which is given monthly in an IM injection to prevent hospitalization associated with RSV. According to the American Academy of Pediatrics (AAP) (Meissner and Bocchini, 2009), candidates for palivizumab include infants born before 32 weeks' gestation, infants with chronic lung disease, infants born at 32 to less than 35 weeks' gestation who attend day care or have a sibling younger than 5 years, children younger than 2 years with hemodynamically significant congenital heart disease, and children with severe immunodeficiencies (e.g., severe combined immunodeficiency or acquired immunodeficiency syndrome [AIDS]). Prophylaxis for RSV should be initiated at the onset of the RSV season and terminated at the end of the season (November to March or April). Additional age and condition recommendations are outlined in the AAP practice guideline (2006).

MEDICATION ALERT

The lyophilized powder form of palivizumab should be administered within 6 hours of being reconstituted with sterile water because it is preservative free. A new liquid form of the drug may be available for future use.

CARE MANAGEMENT

Children admitted to the hospital with suspected RSV infection are usually assigned separate rooms or grouped with other RSV-infected children. Contact and Standard Precautions are used, including hand washing, not touching the nasal mucosa or conjunctiva, and using gloves and gowns when entering the patient's room. The 2007 CDC isolation guidelines emphasize that, although RSV may be transmitted via the droplet route, direct contact with infected respiratory secretions is the most common method of transmission; the CDC recommends Standard and Contact Precautions with RSV (Siegel, Rhinehart, Jackson, et al., 2007). The AAP Committee on Infectious Diseases (2012) also recommends these precautions but suggests that Droplet Precautions be used if persons are closer than 3 feet; Droplet Precautions are not recommended by the AAP in the routine care of persons with RSV. Other isolation procedures of potential benefit are those aimed at limiting the number of hospital personnel, visitors, and uninfected children in contact with the child. Another measure is to make patient assignments so that nurses assigned to children with RSV infection are not caring for other patients who are considered high risk.

Infants with RSV infection often have copious nasal secretions, making breathing and breastfeeding or bottle feeding difficult. This engenders concerns that the child will lose weight or stop breastfeeding altogether. Encourage breastfeeding mothers to continue feeding the infant or, if feedings are contraindicated because of the acuity of the illness, mothers should pump their milk and store it appropriately for later use (see Chapter 24). Parents are taught how to instill normal saline drops into the nares and suction the mucus with a bulb syringe or portable suction machine before feedings and before bedtime so the child may eat and rest better; unfortunately, no medications appropriate for infants can help with these symptoms. To address the issue of decreased fluid intake, parents may offer small amounts of fluids frequently to maintain adequate hydration. Infants may cough or vomit as the secretions settle in the stomach and make them prone to emesis of such secretions.

Additional nursing care is aimed at monitoring oxygenation with pulse oximetry, ensuring any bronchodilator therapy is optimized by using a small mask for delivery, and providing information for the parent and family regarding the infant's status. For the most part, infants recover quickly from the disease and resume normal daily activities, including fluid intake. Such infants are at risk for further episodes of wheezing that may or may not involve another RSV infection; parents, however, may be concerned that the infant has another serious case of RSV infection.

Pneumonias

Pneumonia, inflammation of the pulmonary parenchyma, is common in childhood but occurs more frequently in early childhood. Clinically, pneumonia may occur either as a primary disease or as a complication of another illness. The causative agent is either inhaled into the lungs directly or comes from the bloodstream.

The most useful classification of pneumonia is based on the etiologic agent (e.g., viral, bacterial, mycoplasmal, or aspiration of foreign substances) (see Aspiration Pneumonia, p. 1220). Many organisms can cause pneumonia, and these vary according to the child's age (Ranganathan and Sonnappa, 2009):

- **Neonates—**Group B streptococci, gram-negative enteric bacteria, cytomegalovirus, *Ureaplasma urealyticum, Listeria monocytogenes, C. trachomatis*
- **Infants—**RSV, parainfluenza virus, influenza virus, adenovirus, metapneumovirus, *S. pneumoniae, H. influenzae, M. pneumoniae, Mycobacterium tuberculosis*
- **Preschool-age children—**RSV, parainfluenza virus, influenza virus, adenovirus, metapneumovirus, *S. pneumoniae, H. influenzae, M. pneumoniae, M. tuberculosis*
- **School-age children—***M. pneumoniae, Chlamydophila pneumoniae, M. tuberculosis,* respiratory viruses

Histomycosis, coccidioidomycosis, and other fungi also cause pneumonia. **Pneumonitis** is a localized acute inflammation of the lung without the toxemia associated with lobar pneumonia.

The clinical manifestations of pneumonia vary depending on the etiologic agent, the child's age, the child's systemic reaction to the infection, the extent of the lesions, and the degree of bronchial and bronchiolar obstruction. The causative agent is identified from the clinical history, the child's age, the general health history, the physical examination, radiography, and the laboratory examination.

Viral Pneumonia

Viral pneumonias, which occur more frequently than bacterial pneumonias, are seen in children of all ages and are often associated with viral URIs. Viruses that cause pneumonia include RSV in infants and parainfluenza, influenza, human bocavirus (HBoV), human metapneumovirus, enterovirus, and adenovirus in older children. Differentiation among viruses is usually made by clinical features such as the child's age, medical history, season of the year, and radiographic and laboratory examination (Box 40-9).

Viral infections of the respiratory tract render the affected child more susceptible to secondary bacterial infection, especially when there is denuded bronchial mucosa. Treatment is symptomatic and includes measures to promote oxygenation and comfort, such as oxygen administration with cool mist, antipyretics for fever management, monitoring fluid intake, and family support. Antimicrobial therapy is usually reserved for children in whom a bacterial infection is demonstrated by appropriate cultures.

Primary Atypical Pneumonia

Atypical pneumonia refers to pneumonia that is caused by pathogens other than the traditionally most common and readily cultured bacteria (e.g., *S. pneumoniae*). In the category of atypical

BOX 40-9 GENERAL SIGNS OF PNEUMONIA

- Fever—Usually quite high (≥39.5° C [103° F])
- Respiratory
  - Cough—Nonproductive to productive with whitish sputum
  - Tachypnea
  - Breath sounds—Rhonchi or fine crackles
  - Dullness with percussion
  - Chest pain; abdominal pain with lower lobe involvement
  - Retractions
  - Nasal flaring
  - Pallor to cyanosis (depends on severity)
- Chest x-ray film—Diffuse or patchy infiltration with peribronchial distribution
- Behavior—Irritable, restless, lethargic
- Gastrointestinal—Anorexia, vomiting, diarrhea, abdominal pain

BOX 40-10 PNEUMOTHORAX

Pneumothorax occurs when there is an accumulation of air in the pleural space; this air increases intrapleural pressure, making it more difficult to expand the affected lung and thus the clinical manifestations of dyspnea, chest pain and often back pain, labored respirations, tachycardia, and decreased oxygen saturation. In neonates and infants on mechanical ventilation, the first clinical signs of a pneumothorax are oxygen desaturation and hypotension. The three major types of pneumothorax are tension, spontaneous, and traumatic. The definitive diagnosis of pneumothorax is a chest radiograph. The emergent treatment involves needle aspiration of the air within the pleural space; subsequently a chest tube to closed drainage is usually inserted to prevent the reaccumulation of air. *Pleural effusion* occurs when there is an excessive accumulation of fluid in the pleural space. The diagnosis is made by chest radiography, and the treatment involves evacuation of the fluid by needle aspiration followed by insertion of a chest tube to closed drainage.

pneumonias, *M. pneumoniae* and *C. pneumonia* are the most common causes of community-acquired pneumonia in children 5 years of age or older (Sandora and Sectish, 2011). It occurs in the fall and winter months and is more prevalent in crowded living conditions. Most affected persons recover from acute illness at home in 7 to 10 days with symptomatic treatment followed by 1 week of convalescence. The incubation period is 2 to 3 weeks, but the cough may last several weeks.

Chlamydial pneumonia, caused by *C. trachomatis,* can occur in infants and generally appears between 3 and 19 weeks of age. The infant contracts this from the infected genital tract of the mother at birth.

Erythromycin (for those younger than 9 years), azithromycin, and clarithromycin are the primary agents used for treating atypical pneumonia.

Bacterial Pneumonia

S. pneumoniae is the most common bacterial pathogen responsible for community-acquired pneumonia in both children and adults (Rafei and Lichenstein, 2006). Other bacteria that cause pneumonia in children are pneumococcus, group A streptococcus, *S. aureus, M. catarrhalis,* and *C. pneumoniae.*

Beyond the neonatal period, bacterial pneumonias display distinct clinical patterns that facilitate their differentiation from other forms of pneumonia. The onset of illness is abrupt and generally follows a viral infection that disturbs the natural defense mechanisms of the upper respiratory tract.

The child with bacterial pneumonia usually appears ill. Symptoms include fever, malaise, rapid and shallow respirations, cough, and chest pain. The pain of pneumonia may be referred to the abdomen in young children and confused with appendicitis. Chills and meningeal symptoms (meningism) without meningitis are common.

Most older children with pneumonia can be treated at home if the condition is recognized and treatment is initiated early. Antibiotic therapy, rest, liberal oral intake of fluid, and administration of an antipyretic for fever are the principal therapeutic measures. Chest percussion and postural drainage may be indicated; however, this is controversial. Follow-up examination is recommended for small infants and toddlers. Hospitalization is indicated when pleural effusion or empyema accompanies the disease, when respiratory distress occurs, in situations in which compliance with therapy is estimated to be poor, in infants younger than 1 month, and when there are chronic illnesses such as congenital heart disease or BPD (Rafei and Lichenstein, 2006). IV fluids may be necessary to ensure adequate hydration, and oxygen is required if the child is in respiratory distress; some children may require initial therapy with parenteral antibiotics because of the severity of illness.

Complications. At present, the classic features and clinical course of pneumonia are seen infrequently because of early and vigorous antibiotic and supportive therapy. However, some children, especially infants, with staphylococcal or GABHS pneumonia develop empyema, pyopneumothorax, or tension pneumothorax. AOM and pleural effusion are common in children with pneumococcal pneumonia (Box 40-10) (see Evidence-Based Practice box).

Continuous closed chest drainage may be instituted when purulent fluid is aspirated. If a large amount of purulent drainage is obtained, an appropriate antibiotic may be instilled into the chest cavity, and chest drainage is discontinued for approximately 1 hour after the instillation. Closed drainage via a chest tube is continued until drainage fluid is minimal, which rarely requires more than 5 to 7 days. Sometimes repeated pleural taps are sufficient to remove fluid; however, if the purulent drainage accumulates rapidly and is highly viscous, continuous drainage is preferred. Thoracotomy with open debridement of the infected lung tissue may be required; if empyema and pneumothorax tend to recur, a partial thoracoscopic lobectomy may be performed. Alternatively, video-assisted thoracoscopy (VATS) and intrapleural fibrinolytic therapy may preclude the use of open debridement and thoracotomy (Sandora and Sectish, 2011).

Prevention

In February 2010, a 13-valent pneumococcal conjugate vaccine (PCV13) was approved for use in children ages 6 weeks to 71 months to protect against 13 pneumococcal serotypes. The Advisory Committee on Immunization Practices (ACIP) recommends routine vaccination with PCV13 of all children ages 2 to 59 months, children ages 60 to 71 months with underlying medical conditions that increase their risk for pneumococcal disease or complications, and children who previously received 1 or more doses of PCV7 (CDC, 2010). (See Immunizations, Chapter 31.)

CARE MANAGEMENT

Nursing care of the child with pneumonia is primarily supportive and symptomatic but necessitates thorough respiratory assessment

EVIDENCE-BASED PRACTICE

Nursing Interventions for Prevention of Ventilator-Associated Pneumonia in Children

Ask the Question

What nursing interventions prevent VAP in children?

Search for Evidence

Search Strategies

Search selection included English publications on nursing interventions for prevention of VAP in children and adolescents.

Databases Used

PubMed, AHRQ

Critically Analyze the Evidence

- Implementation of VAP bundle resulted in a decreased VAP rate from 5.6 infections per 1000 ventilator days at baseline to 0.3 per 1000 ventilator days (Bigham, Amato, Bondurrant, et al., 2009).
- Common VAP prevention interventions include (Bigham, Amato, Bondurrant, et al., 2009; Garland, 2010; Morrow, Argent, Jeena, et al., 2009; Norris, Barnes, and Roberts, 2009):
  - Change ventilator circuits and in-line suction catheters only when soiled.
  - Every 2 to 4 hours, drain condensate from ventilator circuit (use heated wire circuits to reduce rainout).
  - Rinse oral suction devices after use and store in a nonsealed plastic bag at the bedside.
  - Hand hygiene should be used before and after contact with ventilator circuit.
  - Wear PPE before providing care to patients when soiling from respiratory secretions is anticipated.
  - Every 2 to 4 hours, follow unit mouth care policy.
  - Unless contraindicated, elevate head of bed to 30 to 45 degrees.
  - Before repositioning patient, always drain ventilator circuit.
  - For patients older than 12 years, when possible, use ET tube with dorsal lumen above ET tube cuff to help suction secretions above the cuff.
  - Evaluate daily for possible extubation.
  - Avoid reintubation.
  - Provide deep vein thrombosis and peptic ulcer disease prophylaxis.
- Infants in supine position (infant lying on back with ET tube held upright in the vertical position) had increased colony counts or new organisms in tracheal aspirate than infants in lateral position (infant lying on side with ET tube at same level as the trachea) (Aly, Badawy, El-Kholy, et al., 2008).
- Staff education on VAP and improvements to practice changes can have a substantial impact on reducing VAP (Garland, 2010; Richardson, Hines, Dixon, et al., 2010; Turton, 2008).
- A 7-day versus 3-day ventilator circuit change was not associated with increased VAP rates (Samransamruajkit, Jirapaiboonsuk, Siritantiwat, et al., 2010).
- Use of low-sodium solution for airway care was associated with a decrease in VAP as well as chronic lung disease (Christensen, Henry, Baer, et al., 2010).
- In bronchoalveolar lavage fluid, PAI-1 levels can aid in early diagnosis of VAP (Srinivasan, Song, Wiener-Kronish, et al., 2011).
- Reduced mortality rates were observed in patients with VAP when silver-coated ET tube was used versus uncoated ET tube (Afessa, Shorr, Anzueto, et al., 2010).

Apply the Evidence: Nursing Implications

There is **good evidence** with **strong recommendations** for use of interventions to prevent VAP in children (Guyatt, Oxman, Vist, et al., 2008). Some of the prevention methods included in VAP bundles are hand hygiene, oral hygiene, use of PPE, and elevation of head of bed 30 to 45 degrees. Staff education and engagement in VAP prevention initiatives are important.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries

Describe the various interventions for prevention of VAP in children.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence

Integrate evidence into practice by using interventions for prevention of VAP in children.

Attitudes

Value the concept of evidence-based practice (EBP) as integral to determining best clinical practice

Appreciate strengths and weakness of evidence for preventions of VAP in children.

and administration of supplemental oxygen (as required), fluids, and antibiotics. The child's respiratory rate, rhythm, and depth, oxygenation, general disposition, and level of activity are frequently assessed. To prevent dehydration, fluids are frequently administered intravenously during the acute phase.

Nursing care of the child with a chest tube requires close attention to respiratory status, as noted previously; the chest tube and drainage device used are monitored for proper function (i.e., drainage is not impeded, vacuum setting is correct, tubing is free of kinks, dressing covering chest tube insertion site is intact, water seal is maintained [if used], and chest tube remains in place). Movement in bed and ambulation with a chest tube are encouraged according to the child's respiratory status, but children require frequent doses of an analgesic. Supplemental oxygen may be required in the acute phase of the illness and may be administered by nasal cannula, face mask, or flow-by. Children are usually more comfortable in a semi-erect position (Fig. 40-3) but should be allowed to determine the position of comfort. Lying on the affected side if the pneumonia is unilateral ("good lung up") splints the chest on that side and reduces the pleural rubbing that often causes discomfort. Fever is controlled by the cool environment and administration of antipyretic drugs. Children, especially infants, with ineffectual cough or difficulty handling secretions may require suctioning to maintain a patent airway. A simple bulb suction syringe is usually sufficient for clearing the nares and nasopharynx of infants, but mechanical suction should be readily available if needed. A noninvasive suction device (BBG nasal aspirator) may be used to suction the infant's nares without the danger of causing nasal trauma; the device may be connected to mechanical suction for best results. Older children can usually handle secretions without assistance. Chest percussion, postural drainage, and nebulized bronchodilator treatments may be prescribed depending on the child's condition. Chest percussion and postural drainage currently lack empirical support for improving the child's condition or decreasing the length of stay in children with community-acquired pneumonia. For the child being cared for at home, the nurse educates the parent regarding observation for worsening symptoms, antibiotic and antipyretic administration, and encouragement of oral fluid intake. If the child is ill, solid foods may be rejected; fluid intake is encouraged until the child feels well enough to eat solids. Return to school or day care is usually permitted according to the type of pneumonia, severity of illness, and health care practitioner recommendation. It should be emphasized that the infection may be transmitted to other children with close contact.

FIG 40-3 Child placed in semi-erect position is often more comfortable, and this position enhances diaphragmatic expansion.

The hospitalized child may be apprehensive, and the treatments and tests are frightening and stress producing. It is important to involve the entire family in the care as appropriate and to encourage questions and facilitate effective communication. Reducing anxiety and apprehension reduces psychologic distress in the child, and when the child is more relaxed, the respiratory efforts are lessened. Easing respiratory efforts makes the child less apprehensive, and encouraging the presence of the caregiver provides the child with a source of comfort and support.

OTHER RESPIRATORY TRACT INFECTIONS

Pertussis (Whooping Cough)

Pertussis, or whooping cough, is an acute respiratory tract infection caused by *Bordetella pertussis,* which in the past occurred primarily in children younger than 4 years who were not immunized. It is highly contagious and is particularly threatening in young infants, who have a higher morbidity and mortality rate. It can result in encephalopathy, seizures, and pneumonia. Infants younger than 6 months may not come to the health care practitioner with the typical cough; in this age-group, apnea is a common presenting manifestation (AAP Committee on Infectious Diseases, 2012). Likewise, older children are known to manifest the disease with a persistent cough and the absence of the characteristic whoop (see Table 33-2 for signs, symptoms, and management of pertussis). The incidence is highest in the spring and summer months, and a single attack confers lifetime immunity. The resurgence of pertussis in the United States, particularly among children 10 years old and older, has prompted concerns of the long-term effects of the pertussis vaccine. Consequently, two acellular pertussis booster vaccines have been approved for children: Boostrix (for persons ages 10 years and older) and Adacel (for persons ages 11 to 64 years). (See also Immunizations, Chapter 31.) Most children with pertussis can be managed at home; care is supportive in nature, including encouraging adequate hydration and administering antipyretics. When coughing spasms occur in small children, they can be frightening for the parent and family. Admission to the hospital occurs if respiratory symptoms are severe or if apnea occurs. Treatment with antibiotics (erythromycin, clarithromycin, or azithromycin) in the catarrhal stage may result in a milder form of the infection, but treatment also prevents spread to others (AAP Committee on Infectious Diseases, 2012). Family contacts may also be treated. Pertussis symptoms usually last for 6 to 10 weeks but may persist for longer.

Tuberculosis

Tuberculosis (TB) is the second leading cause of death from an infectious disease. Ten million to 15 million persons in the United States are infected with TB. Case rates of TB for all ages are higher in urban, low-income areas and among non-white racial and ethnic groups. In recent years, foreign-born children have accounted for more than one fourth of newly diagnosed cases of TB in children 14 years of age or younger in the United States (AAP Committee on Infectious Diseases, 2012). The following groups have the greatest rates of latent TB infection: immigrants, international adoptees, refugees from or travelers to high-prevalence regions (Asia, Africa, Latin America, and countries of the former Soviet Union), homeless individuals, and inmates of correctional facilities (AAP Committee on Infectious Diseases, 2012). In addition, adolescents and adults being treated with tumor necrosis factor (TNF)-alpha antagonists

for conditions such as inflammatory bowel disease or arthritis have been identified as having contracted TB; therefore it is recommended that screening for TB occurs in such persons before the use of TNF-alpha antagonists (AAP Committee on Infectious Diseases, 2012).

Tuberculosis is caused by *M. tuberculosis,* an acid-fast bacillus. Children are susceptible to the human *(M. tuberculosis)* and the bovine *(Mycobacterium bovis)* organisms. In parts of the world where TB in cattle is not controlled or milk is not pasteurized, the bovine type is a common source of infection.

Certain factors influence the degree to which the organism produces an altered state in the host. These factors include heredity (resistance to the infection may be genetically transmitted), gender (higher rates in adolescent girls), age (lower resistance in infants; higher incidence during adolescence), stress (emotional or physical), nutritional status, and intercurrent infection (especially human immunodeficiency virus [HIV], measles, and pertussis). Children with HIV infection have an increased incidence of TB disease, and all children with TB should be tested for HIV.

The source of TB infection in children is usually an infected member of the household or a frequent visitor to the home such as a babysitter or domestic worker. The airway is the usual portal of entry for the organism. In the lungs, a proliferation of epithelial cells surrounds and encapsulates the multiplying bacilli in an attempt to wall it off, thus forming the typical tubercle. Extension of the primary lesion at the original site causes progressive tissue destruction as it spreads within the lung, discharges material from foci to other areas of the lungs (e.g., bronchi, pleura), or produces pneumonia. Erosion of blood vessels by the primary lesion can cause widespread dissemination of the tubercle bacillus to near and distant sites (miliary TB). Extrapulmonary (miliary) TB may be manifested as malaise, fever, weight loss, superior lymphadenitis, meningitis, hepatomegaly, splenomegaly, and osteoarthritis (AAP Committee on Infectious Diseases, 2012). With the exception of meningitis, the treatment for extrapulmonary TB may be the same drug regimen as for pulmonary TB. Infants and children younger than 3 years are more likely to develop miliary TB.

Diagnostic Evaluation

Diagnosis of TB is based on information derived from physical examination, history, tuberculin skin testing, radiographic examinations, and cultures of the organism. The clinical manifestations of the disease are extremely variable (Box 40-11).

BOX 40-11 CLINICAL MANIFESTATIONS OF TUBERCULOSIS

May be asymptomatic or produce a broad range of symptoms:
- Fever
- Malaise
- Anorexia
- Weight loss (or failure to grow in child)
- Cough (may or may not be present; progresses slowly over weeks to months)
- Aching pain and tightness in the chest
- Hemoptysis (rare)

With progression:
- Increased respiratory rate
- Poor expansion of lung on the affected side
- Diminished breath sounds and crackles
- Dullness on percussion
- Persistent fever
- Pallor, anemia, weakness, and weight loss

The tuberculin skin test (TST) is the most important indicator of whether a child has been infected with the tubercle bacillus. The standard dose of purified protein derivative (PPD) is 5 tuberculin units, which is administered using a 27-gauge needle and a 1-mL syringe intradermally into the volar aspect of the forearm. Creation of a visible wheal is crucial to accurate testing. The AAP (AAP Committee on Infectious Diseases, 2012) recommends that administration of the TST and interpretation of the results be performed and read only by specially educated health care professionals. Universal testing of all children for TB is no longer recommended. A targeted testing method is employed wherein only children and adolescents at high risk for contracting the disease, in addition to patients at risk for progression to TB disease, are screened. A risk factor questionnaire (Box 40-12) has been developed to facilitate screening pediatric populations at high risk.

The IGRA (interferon gamma release assay) does not cross-react with the bacille Calmette-Guérin (BCG) and is the preferred test for the diagnosis of latent tuberculosis infection (LTBI) in an asymptomatic BCG-immunized child over the age of 4 years. The IGRA cannot distinguish between latent infection and TB disease, and a negative or indeterminate result does not exclude TB infection. The cost of the blood IGRA is considerably more than the TST, and it is reported to be more involved technically; therefore the TST remains the more favored option for testing as a public health intervention (Perez-Velez, 2012). The usefulness and ability of IGRA to detect TB infection in children younger than 2 years is limited. The recommendations for use of IGRA include the following (AAP Committee on Infectious Diseases, 2012):

- Children ≥5 years who have received the BCG vaccine
- Children ≥5 who are unlikely to return for further testing
- Nontuberculous mycobacterium disease is suspected and the TST is positive
- When additional evidence is necessary to increase compliance

A positive reaction indicates that the individual has been infected and has developed sensitivity to the tubercle bacillus. The test is usually positive 2 to 10 weeks after initial infection with the organism. It does not, however, confirm the presence of active disease. Once an individual reacts positively, he or she will always react positively. A previously negative reaction that becomes positive indicates that the person has been infected since the previous test. Prompt radiographic evaluation of all children with a positive TST reaction is recommended.

BOX 40-12 VALIDATED QUESTIONS FOR DETERMINING RISK OF LTBI IN CHILDREN IN THE UNITED STATES

- Has a family member or contact had tuberculosis disease?
- Has a family member had a positive tuberculin skin test result?
- Was your child born in a high risk country (countries other than the United States, Canada, Australia, New Zealand, or Western or Northern European countries)?
- Has your child traveled (had contact with resident populations) to a high risk country for more than 1 week?

From American Academy of Pediatrics (AAP) Committee on Infectious Diseases, Pickering L, editor: *Red book: 2012 report of the Committee on Infectious Diseases,* ed 29, Elk Grove Village, IL, 2012, Author.
LTBI, Latent tuberculosis infection.

The term *latent tuberculosis infection (LTBI)* is used to indicate infection in a person who has a positive TST, no physical findings of disease, and normal chest radiograph findings. The majority of children are asymptomatic when a positive skin test result is found, and most of them do not go on to develop the disease. The term tuberculosis disease or clinically active TB is used when a child has clinical symptoms or radiographic manifestations caused by the *M. tuberculosis* organism. A diagnosis of TB disease represents recent transmission of the *M. tuberculosis* organism and is an urgent event for public health. Prompt evaluation, treatment, and identification and treatment of contacts are key components to managing TB.

In 2010, the WHO recommended that previously treated patients should have access to drug-susceptibility testing and culture at the beginning of treatment to identify possible multidrug–TB resistance. The WHO also updated recommendations for individuals with HIV and TB; these include starting antiretroviral therapy within 8 weeks after the initiation of antituberculosis treatment and the use of a clinical algorithm to screen for TB in persons with HIV, those at high risk for HIV, or those living in congregate settings (Perez-Velez, 2012).

Therapeutic Management

Medical management of TB disease in children consists of adequate nutrition, pharmacotherapy, prevention of unnecessary exposure to other infections that further compromise the body's defenses, and sometimes surgical procedures. Family members and other contacts should also be assessed for symptoms by public health practitioners and treated accordingly.

The recommended drug regimen for LTBI in children and adolescents includes a daily dose of isoniazid (INH) for 9 months or, if daily treatment is not possible, 2 times per week with **directly observed therapy (DOT).** *DOT* means that a health care worker or other responsible, mutually agreed-on individual is present when medications are administered to the patient. An alternative schedule for children ages 12 years and older is to administer INH and rifapentine, once a week under strict DOT for 12 weeks (AAP Committee on Infectious Diseases, 2012).

For the child with clinically active TB disease, the goal is to achieve sterilization of the tuberculous lesion. Recommended drug therapy for treating TB disease includes combinations of INH, rifampin, pyrazinamide (PZA), and ethambutol. The AAP (AAP Committee on Infectious Diseases, 2012) recommends a 6-month regimen consisting of INH, rifampin, ethambutol, and PZA given daily for the first 2 months followed by INH and rifampin given 2 or 3 times a week by DOT for the remaining 4 months. DOT decreases the rates of relapse, treatment failures, and drug resistance and is recommended for treatment of children and adolescents with TB in the United States.

If the child is suspected of having multidrug-resistant TB, optimal therapy should consist of 4 antituberculous drugs to which the child's disease is susceptible administered daily (DOT) for 12 to 24 months from the time of culture conversion (AAP Committee on Infectious Diseases, 2012). Optimal therapy for TB in children with HIV infection has not been established, and consultation with a specialist is advised.

Surgical procedures may be required to remove the source of infection in tissues that are inaccessible to pharmacotherapy or that are destroyed by the disease. Orthopedic procedures may be performed for correction of bone deformities, and bronchoscopy may be done for removal of a tuberculous granulomatous polyp.

Prognosis. Most children recover from primary TB infection and are often unaware of its presence. However, very young children have a higher incidence of disseminated disease. TB is a serious disease during the first 2 years of life, during adolescence, and in children who are HIV positive. Except in cases of tuberculous meningitis, death seldom occurs in treated children. Antibiotic therapy has decreased the death rate and the hematogenous spread from primary lesions.

Prevention

The only definite means to prevent TB is to avoid contact with the tubercle bacillus. Maintaining an optimal state of health with adequate nutrition and avoiding fatigue and debilitating infections promote natural resistance but do not prevent infection. Pasteurization and routine testing of milk and elimination of diseased cattle have reduced the incidence of bovine TB.

Limited immunity can be produced by administration of bacille Calmette-Guérin (BCG), a live vaccine containing bovine bacilli with reduced virulence (attenuated). In most instances, positive tuberculin reactions develop after inoculation with BCG. The distribution of BCG is controlled by local or state health departments, and the vaccine is not used extensively, even in areas with a high prevalence of disease. BCG vaccination is not generally recommended for use in the United States. However, it may be recommended for long-term protection of infants and children with negative TST results who are not infected with HIV and who (1) are at high risk for continuing exposure to persons with infectious pulmonary TB or (2) are continuously exposed to persons with TB who have bacilli resistance to both INH and rifampin when the child cannot be removed from the environment or given antituberculosis drug therapy (AAP Committee on Infectious Diseases, 2012).

CARE MANAGEMENT

Children with TB receive their nursing care in ambulatory settings, outpatient departments, schools, and public health settings. Most children are not contagious and require only Standard Precautions. Children with no cough and negative sputum smears can be hospitalized in a regular patient room. However, Airborne Precautions and a negative-pressure room are required for children who are contagious and hospitalized with active TB disease. Infection control for hospital personnel in contagious cases should include the use of a personally fitted air-purifying N95 or N100 respirator (PAPR) for all patient contacts. (See AAP Committee on Infectious Diseases, 2012, for additional information on isolation of children with suspected or confirmed TB.)

Asymptomatic children with TB can attend school or day care facilities if they are receiving pharmacotherapy. They can return to regular activities as soon as effective therapy has been instituted, adherence to therapy has been documented, and clinical symptoms have diminished. Children receiving pharmacotherapy for TB can receive measles and other age-appropriate live virus vaccines unless they are receiving high-dose corticosteroids, are severely ill, or have specific contraindications to immunization.

Skin tests must be carried out correctly to obtain accurate results. The tuberculin is injected intradermally with the bevel of the needle pointing upward. A wheal 6 to 10 mm in diameter should form between the layers of the skin when the solution is injected properly. If the wheal is not formed, the procedure is repeated. The volar or dorsal surface of the forearm is the usual injection site. The reaction to the skin test is determined in 48 to 72 hours; reactions occurring

after 72 hours should be measured and considered the result. The size of the transverse diameter of induration, not the erythema, is measured. The diameter transverse to the long axis of the forearm is the only one standardized for measurement purposes (AAP Committee on Infectious Diseases, 2012).

Sputum specimens are difficult or impossible to obtain from infants and young children because they swallow any mucus coughed from the lower respiratory tract. The best means for obtaining material for smears or culture is by gastric washing (i.e., aspiration of lavaged contents from the fasting stomach with a nasogastric tube). The procedure is carried out and the specimen obtained early in the morning before the customary breakfast time. In some cases, an induced sputum specimen may be obtained by administering aerosolized normal saline for 10 to 15 minutes followed by chest percussion and postural drainage and suctioning of the nasopharynx for sputum collection.

Because the success of therapy depends on compliance with the drug regimen, parents are instructed about the importance and rationale for DOT. Case finding in the community and follow-up of known contacts—individuals from whom the affected child may have acquired the disease and persons who may have been exposed to the child with the disease—are essential control measures.

PULMONARY DYSFUNCTION CAUSED BY NONINFECTIOUS IRRITANTS

Foreign Body Aspiration

Small children characteristically explore matter with their mouth and are prone to aspirate foreign bodies (FBs). Small children also place objects such as beads, paper clips, small magnets, or food items in the nose, which can easily be aspirated into the trachea. FB aspiration can occur at any age but is most common in children 1 to 3 years of age. Severity is determined by the location, type of object aspirated, and extent of obstruction. For example, dry vegetable matter (e.g., a seed, nut, or piece of carrot or popcorn) that does not dissolve and that may swell when wet creates a particularly difficult problem. The high fat content of potato chips and peanuts may cause the added risk for lipoid pneumonia. "Fun foods" are the worst offenders in terms of potential for choking. Offending foods in the order of frequency of choking are hot dogs, round candies, peanuts or other nuts, grapes, cookies or biscuits, other meats, caramels, carrots, peas, apples, celery, popcorn, sunflower seeds, orange seeds, cherry pits, watermelon seeds, gum, and peanut butter. Other items include burst latex balloons, plastic or glass beads, marbles, pen or marker caps, button or disc batteries, and coins. Objects such as small lithium or cadmium batteries may cause esophageal or tracheal corrosion.

Diagnostic Evaluation

The diagnosis of FB aspiration is suspected on the basis of the history and physical signs. Initially, a FB in the air passages produces choking, gagging, wheezing, or coughing. Laryngotracheal obstruction most commonly causes dyspnea, cough, stridor, and hoarseness because of decreased air entry. Up to half of all children with FB ingestion may be asymptomatic. Cyanosis may occur if the obstruction becomes worse. Bronchial obstruction usually produces cough (frequently paroxysmal), wheezing, asymmetric breath sounds, decreased airway entry, and dyspnea. When an object is lodged in the larynx, the child is unable to speak or breathe. If the obstruction progresses, the child's face may become livid, and if the obstruction is total, the child can become unconscious and die of asphyxiation. If obstruction is partial, hours, days, or even weeks may pass without symptoms after the initial period. Secondary symptoms are related to the anatomic area in which the object is lodged and are usually caused by a persistent respiratory tract infection distal to the obstruction. FB aspiration should also be suspected in the presence of acute or chronic pulmonary lesions. Often, by the time secondary symptoms appear, the parents have forgotten the initial episode of coughing and gagging. Nasal FBs often manifest by unilateral purulent drainage that does not improve with time.

Radiographic examination reveals opaque FBs but is of limited use in localizing nonradiographic matter. Bronchoscopy is required for a definitive diagnosis of objects in the larynx and trachea. Fluoroscopic examination is valuable in detecting FBs in the bronchi. The mainstay of diagnosis and management of FBs is endoscopy. If there is doubt about the presence of an FB, endoscopy can be diagnostic and therapeutic.

Therapeutic Management

Foreign body aspiration may result in life-threatening airway obstruction, especially in infants because of the small diameters of their airways. Current recommendations for the emergency treatment of the choking child include the use of abdominal thrusts for children older than 1 year and back blows and chest thrusts for children younger than 1 year.

A FB is rarely coughed up spontaneously. Usually it must be removed instrumentally by endoscopy. Endoscopy and bronchoscopy require sedation with an agent such as IV propofol or midazolam. The procedure is carried out as quickly as possible because the progressive local inflammatory process triggered by the foreign material hampers removal. A chemical pneumonia soon develops, and vegetable matter begins to macerate within a few days, making it even more difficult to remove. After removal of the FB, the child is usually observed for any complications such as laryngeal edema and then discharged home within a matter of hours if vital signs are stable and recovery is satisfactory.

Prevention

Nurses are in a position to teach prevention in a variety of settings. They can educate parents singly or in groups about hazards of aspiration in relation to the developmental level of their children and encourage them to teach their children safety. Parents should be cautioned about behaviors that their children might imitate (e.g., holding foreign objects, such as pins, nails, and toothpicks, in their lips or mouth). (Prevention based on the child's age is discussed in Chapters 31 and 32.)

CARE MANAGEMENT

A major role of nurses caring for a child who has aspirated an FB is to recognize the signs of FB aspiration, observe for worsening of respiratory symptoms, and implement immediate measures to relieve an emergency obstruction. Choking on food or other material should not be fatal. Back blows and chest thrusts in infants and abdominal thrusts in children are simple procedures that can be used by both health care professionals and laypersons to save lives. To aid a child who is choking, nurses must recognize the signs of distress. A blind sweep of the child's mouth should never be performed because it may lodge the agent farther into the airway. Not every child who gags or coughs while eating is truly choking.

! NURSING ALERT

The child in severe distress (1) cannot speak, (2) becomes cyanotic, and (3) collapses. These three signs indicate that the child is truly choking and requires immediate action. The child can die within 4 minutes.

Aspiration Pneumonia

Aspiration pneumonia occurs when food, secretions, inert materials, volatile compounds, or liquids enter the lung and cause inflammation and a chemical pneumonitis. Aspiration of fluid or foods is a particular hazard in the child who has difficulty with swallowing or is unable to swallow because of paralysis, weakness, debility, congenital anomalies, or absent cough reflex or in the child who is force-fed, especially while crying or breathing rapidly. Clinical signs of the aspiration of oral secretions may not be distinguishable from those of other forms of acute bacterial pneumonia. For example, if vegetable matter has been aspirated, manifestations may not appear for several weeks after the event. Classic symptoms include an increasing cough or fever with foul-smelling sputum, deteriorating oxygenation, evidence of infiltrates on chest radiographs, and other signs of lower airway involvement. These deviations may persist for weeks, however, while the child starts to feel better. Rarely, aspiration causes immediate death from asphyxia; more often, the irritated mucous membrane becomes a site for secondary bacterial infection. In addition to fluids, food, vomitus, and nasopharyngeal secretions, other substances that may cause pneumonia are hydrocarbons, lipids, powder, and contrast dye or barium. The severity of the lung injury depends on the pH of the aspirated material.

CARE MANAGEMENT

Care of the child with aspiration pneumonia is the same as that described for the child with pneumonia from other causes. However, the major focus of nursing care is on prevention of aspiration. Proper feeding techniques should be carried out, and preventive measures should be used to prevent aspiration of any material that might enter the nasopharynx. The presence of a nasogastric feeding tube or a history of gastroesophageal reflux disease places the child at risk for aspiration. Nasogastric tubes used for feedings should be checked before the initiation of bolus feedings; continuous nasogastric tube feedings should also be evaluated periodically for proper tube placement. Children who are at risk for swallowing difficulties as a result of illness, physical debilitation, anesthesia, or sedation are kept on nothing by mouth (NPO) status until they can properly swallow fluids effectively. The child may receive nutrition by alternate means such as an enteral feeding tube. The child who is at risk for vomiting and incapable of protecting the airway should be positioned in a side-lying recovery position. Educating parents on its prevention is important.

Pulmonary Edema

Pulmonary edema (PE) is the movement of fluid into the alveoli and interstitium of the lungs caused by extravasation of fluid from the pulmonary vasculature (Mazor and Green, 2011). There are two main types of PE—cardiogenic and noncardiogenic.

Cardiogenic (hydrostatic, hemodynamic) PE is caused by an increase in pulmonary capillary pressure because of an increase in pulmonary venous pressure. It can be caused by excessive IV fluid administration, left ventricular failure, heart valve disorder (aortic regurgitation, aortic stenosis, mitral regurgitation), myocardial ischemia, myocarditis, sepsis, acute tachydysrhythmia, or coronary arteriosclerosis (Sovari and Ooi, 2008).

Noncardiogenic PE is caused by various conditions that result in increased pulmonary capillary permeability. Some subtypes of noncardiogenic PE include permeability PE (caused by ARDS or acute lung injury [ALI]), high altitude PE (caused by rapid ascension to heights above 12,000 feet), or neurogenic PE (after CNS insult such as seizures, head injury, or cerebral hemorrhage). Some less common forms of PE are reperfusion PE (after removal of thromboemboli from the lung or a lung transplant), reexpansion PE (caused by rapid reexpansion of a collapsed lung), or PE that results from opiate overdose (methadone or heroin), salicylate toxicity (chronic), aspiration (FB inhalation), inhalation injuries, near drowning, pulmonary embolism, viral infections, or pulmonary venoocclusive disease. Other causes include traumatic injury, organ dysfunction caused by sepsis, multiorgan failure, alcoholism or substance abuse, pregnancy (eclampsia), chronic renal impairment, malnutrition, hypertension, or a blood transfusion (transfusion-related ALI).

Pathophysiology

Fluid flows from the pulmonary vasculature into the alveolar interstitial space and then returns to the systemic circulation in a normal lung. Movement of this fluid is controlled by the net difference between hydrostatic and osmotic pressures and the permeability of the capillary membrane (Sovari and Ooi, 2008). Increased pulmonary hydrostatic pressure or increased permeability of the vascular membrane results in movement of fluid into the alveoli and interstitium of the lung. The pulmonary lymph system normally drains away any fluid from the alveoli, but when the amount of fluid present in the alveoli exceeds lymph drainage, PE occurs.

Symptoms include extreme shortness of breath, cyanosis, tachypnea, diminished breath sounds, anxiety, agitation, confusion, diaphoresis, orthopnea, respiratory crackles, expiratory wheezing (in young infants), heart murmur, third heart sound (S3) gallop, cool extremities, jugular venous distention, nocturnal dyspnea, cough, pink frothy sputum (if severe), tachycardia, hypertension, or hypotension (if caused by left ventricle dysfunction).

Therapeutic Management

Management of PE depends on the cause but can include oxygen therapy, peak end-expiratory pressure (PEEP) via continuous positive airway pressure (CPAP), and intubation with ventilatory support if respiratory failure occurs. If ventricular failure is the cause, medications such as diuretics, digoxin, positive inotropes, and vasodilators (nitroglycerin) may be started and the child may be placed on a fluid and sodium restriction. Morphine may be prescribed to relieve dyspnea. The primary goal of management is to determine why PE occurred and treat the underlying condition.

CARE MANAGEMENT

Nursing care of the child with PE is similar to that for any other acute respiratory condition. Pulse oximetry is monitored, and vital signs are observed closely for any deterioration. The nurse should note changes in oxygen saturation (Sao_2), end-tidal carbon dioxide (CO_2), and arterial blood gas (ABG) values. An ongoing assessment of the child's cardiopulmonary status is needed by checking lung sounds and observing respiratory rate, rhythm, depth, and effort. Oxygen, medications, and other respiratory treatments are administered as prescribed. Close monitoring of

intake and output, electrolytes, and comfort is important. The child should be monitored for restlessness, anxiety, and air hunger. Placing the child in a high Fowler position may help with lung expansion. Because this position places pressure on bony prominences in the sacrum and hips, pressure areas must be relieved at intervals. Most of the care of PE occurs in the intensive care unit, which is anxiety provoking for the child and family. They should be given the opportunity to express their fears and anxieties and to ask questions. (For other nursing care activities, see the following section on ARDS and ALI.)

Acute Respiratory Distress Syndrome and Acute Lung Injury

ARDS and ALI are potentially life-threatening inflammatory lung conditions that may occur in both children and adults. The syndromes may be caused by direct injury to the lungs or by systemic insults that lead indirectly to lung injury, categorized by acute onset of bilateral infiltrates consistent with PE, but there is no indication of elevated left atrial pressure. They result in hypoxemia and respiratory failure. Sepsis, trauma, viral pneumonia, aspiration, fat emboli, drug overdose, reperfusion injury after lung transplantation, smoke inhalation, and near-drowning, among others, have been associated with ALI and ARDS. Both conditions are characterized by respiratory distress and hypoxemia that occur within 72 hours of a serious injury or surgery in a person with previously normal lungs. Acute pulmonary inflammation with alveolar capillary membrane destruction results in significant hypoxemia. Mechanical ventilation is often required.

Diagnostic criteria were established by the American European Consensus Conference (Bernard, Artigas, Brigham, et al., 1994) and include radiographic evidence of bilateral alveolar infiltrates, the absence of left-sided heart failure, and hypoxemia. Hypoxemia is expressed in terms of the ratio of partial pressure of oxygen (Pao_2) to the fraction of inspired oxygen (Fio_2) (P/F ratio). ALI is differentiated from the more severe syndrome of ARDS by the severity of hypoxemia. In ALI, the P/F ratio is less than or equal to 300; in ARDS, the P/F ratio is less than or equal to 200. ARDS is the more severe in the spectrum of illnesses in relation to the degree of hypoxemia.

Pathologically, the hallmark of ARDS is increased permeability of the alveolar-capillary membrane that results in PE. During the acute phase of ARDS, inflammatory mediators damage the alveolocapillary membrane, with an increasing pulmonary capillary permeability with resulting interstitial edema. Later stages are characterized by pneumocyte and fibrin infiltration of the alveoli, with the start of either the healing process or fibrosis. When fibrosis occurs, the child may demonstrate respiratory distress and the need for mechanical ventilation. In ARDS, the lungs become stiff as a result of surfactant inactivation; gas diffusion is impaired; and eventually, bronchiolar mucosal swelling and congestive atelectasis occur. The net effect is decreased functional residual capacity, pulmonary hypertension (see Chapter 42), and increased intrapulmonary right-to-left shunting of pulmonary blood flow. Surfactant secretion is reduced, and the atelectasis and fluid-filled alveoli provide an excellent medium for bacterial growth. Hypoxemia or increased work of breathing may require ventilatory support.

The child with ARDS may first demonstrate only symptoms caused by an injury or infection, but as the condition deteriorates, hyperventilation, tachypnea, increasing respiratory effort, cyanosis, and decreasing oxygen saturation occur. At times, the developing hypoxemia is not responsive to oxygen administration.

Treatment involves supportive measures to maintain adequate oxygenation and pulmonary perfusion, treatment of infection (or the precipitating cause), and maintenance of adequate cardiac output. After the underlying cause has been identified, specific treatment (e.g., antibiotics for infection) is initiated. Many patients require mechanical ventilatory support. This is usually achieved invasively (i.e., after endotracheal intubation), but occasionally noninvasive ventilation is used in milder cases. Patients requiring invasive mechanical ventilation usually require sedation, at least initially, to allow for ventilatory synchrony. Fluid administration to maintain adequate intravascular volume and end-organ perfusion must be balanced against the desire to decrease lung fluid to improve oxygenation. The provision of adequate nutrition, maintenance of patient comfort, and prevention of complications such as gastrointestinal ulceration are essential. Psychologic support of the patient and family is also important.

It has been demonstrated that inappropriate use of mechanical ventilatory support may worsen the lung injury by causing volutrauma, barotrauma, atelectrauma, and biotrauma to the injured lungs. Protective ventilatory strategies using low tidal volumes (6 mL/kg ideal body weight) have been demonstrated to improve outcomes in adults and theoretically are also appropriate in children. PEEP is applied to decrease atelectasis and maintain an "open" lung. Permissive hypercapnia may also be used. Other strategies used in the support of patients with ARDS include use of the prone position, inhaled nitric oxide, inhaled prostaglandins, high-frequency oscillatory ventilation, and extracorporeal membrane oxygenation (ECMO), although evidence to support these therapies is scant.

Prognosis

The prognosis for patients with ARDS is improving. Nonetheless, the mortality rate remains high, and in children, it ranges from 18% to 49% (Albuali, Singh, Fraser, et al., 2007; Randolph, 2009). The precipitating disorder influences the outcome; the worst prognosis is associated with uncontrolled sepsis, bone marrow transplantation, cancer, and multisystem involvement with hepatic failure. Children who recover may have persistent cough and exertional dyspnea.

CARE MANAGEMENT

The child with ARDS is cared for in the intensive care unit during the acute stages of illness. Nursing care involves close monitoring of oxygenation and respiratory status as well as assessment of cardiac output, perfusion, fluid and electrolyte balance, and renal function (urinary output). Acid-base status and pulse oximetry are important evaluation tools. Diuretics may be administered to reduce pulmonary fluid, and vasodilators may be administered to decrease pulmonary vascular pressure. Nutritional support is often required because of the prolonged acute phase of the illness. Nursing management also includes monitoring the effects of the numerous parenteral fluids and drugs used to stabilize the child and monitoring for changes in the child's hemodynamic status. Most children with ARDS require invasive monitoring via a central venous catheter. The nursing care of the child with ARDS also involves close observance of skin condition, prevention of skin breakdown by pressure area relief, and passive range of motion for prevention of muscle atrophy and contractures. Respiratory distress is a frightening situation for both the child and the parents, and attention to their psychologic needs is a major element in the care of these children. The child is often sedated during the acute phase of the illness, and weaning from sedation requires close monitoring for anxiety reduction and comfort.

Smoke Inhalation Injury

A number of noxious substances that may be inhaled are toxic to humans. They are primarily products of incomplete combustion and cause more deaths from fires than flame injuries. The severity of the injury depends on the nature of the substances generated by the material burned, whether the victim is confined in a closed space, and the duration of contact with the smoke. Three distinct syndromes of pulmonary complications may occur in children with inhalation injury: (1) early carbon monoxide (CO) poisoning, airway obstruction, and PE; (2) ARDS occurring at 24 to 48 hours or later in some cases; and (3) late complications of bronchopneumonia and pulmonary emboli (Antoon and Donovan, 2011). Smoke inhalation results in three types of injury: heat, chemical, and systemic.

Heat injury involves thermal injury to the upper airway. Air has low specific heat; therefore the injury goes no farther than the upper airway. Reflex closure of the glottis prevents injury to the lower airway.

Chemical injury involves gases that may be generated during the combustion of materials such as clothing, furniture, and floor coverings. Acids, alkalis, and their precursors in smoke can produce chemical burns. These substances can be carried deep into the respiratory tract, including the lower respiratory tract, in the form of insoluble gases. Soluble gases tend to dissolve in the upper respiratory tract.

Synthetic materials are especially toxic, producing gases such as oxides of sulfur and nitrogen, acetaldehyde, formaldehyde, hydrocyanic acid, and chlorine. Heated plastics are the source of extremely toxic vapors, including (1) chlorine and hydrochloric acid from polyvinylchloride, and (2) hydrocarbons, aldehydes, ketones, and acids from polyethylene. Irritant gases such as nitrous oxide and carbon dioxide combine with water in the lungs to form corrosive acids; aldehydes cause denaturation of proteins, cellular damage, and edema of pulmonary tissues. Chemical burns to the airways are similar to burns on the skin, except they are painless because the tracheobronchial tree is relatively insensitive to pain.

Inhalation of small amounts of noxious irritants produces alveolar and bronchiolar damage that can lead to obstructive bronchiolitis. Severe exposure causes further injury, including alveolocapillary damage with hemorrhage, necrotizing bronchiolitis, inhibited secretion of surfactant, and formation of hyaline membranes—manifestations of ARDS.

Systemic injury occurs from gases that are nontoxic to the airways (e.g., CO, hydrogen cyanide). However, these gases cause injury and death by interfering with or inhibiting cellular respiration. CO is responsible for more than half of all fatal inhalation poisonings in the United States. CO is a colorless, odorless gas with an affinity for hemoglobin 230 times greater than that of oxygen. When it enters the bloodstream, CO combines readily with hemoglobin to form carboxyhemoglobin (COHb). Because it is released less readily, tissue hypoxia reaches dangerous levels before oxygen is available to meet tissue needs.

! NURSING ALERT

The oxygen saturation ($Sa0_2$) obtained by pulse oximetry will be normal because the device measures only oxygenated and deoxygenated hemoglobin; it does not measure dysfunctional hemoglobin, such as COHb.

Accidental CO poisoning is usually a result of exposure to fumes of heaters or smoke from structural fires, although poorly ventilated recreational vehicles with improperly operated or maintained gas lamps or stoves and cooking in underventilated areas with charcoal grills are also frequent causes. CO is produced by incomplete combustion of carbon or carbonaceous material such as wood or charcoal.

The signs and symptoms of CO poisoning are secondary to tissue hypoxia and vary with the level of COHb. Mild manifestations include headache, visual disturbances, irritability, and nausea; more severe intoxication causes confusion, hallucinations, ataxia, and coma. The bright, cherry red lips and skin often described are less often observed; pallor and cyanosis are seen more frequently.

Therapeutic Management

Treatment of children with smoke inhalation injury is largely symptomatic. The most widely accepted treatment is placing the child on humidified 100% oxygen as quickly as possible and monitoring for signs of respiratory distress and impending failure. Baseline ABGs and COHb levels are obtained. Pao_2 may be within normal limits unless there is marked respiratory depression. If CO poisoning is confirmed, 100% oxygen is continued until COHb levels fall to the nontoxic range of about 10%. If CO poisoning is severe, the patient may benefit from hyperbaric oxygen therapy. Hyperbaric oxygen therapy may be useful in the treatment of neurologic complications related to CO poisoning. Pulmonary care may be facilitated by bronchodilators, inhaled corticosteroids, humidification, and chest percussion and postural drainage to enhance the removal of necrotic material, minimize bronchoconstriction, and avoid atelectasis. Bronchoscopy may be needed to clear heavy secretions.

Respiratory distress may occur early in the course of smoke inhalation as a result of hypoxia, or patients who are breathing well on admission may suddenly develop respiratory distress. Therefore intubation equipment should be readily available. Transient edema of the airways can occur at any level in the tracheobronchial tree. Assessment and localization of the obstruction should be accomplished before severe swelling of the head, neck, or oropharynx occurs. Intubation is often necessary when (1) severe burns in the area of the nose, mouth, and face increase the likelihood of developing oropharyngeal edema and obstruction; (2) vocal cord edema causes obstruction; (3) the patient has difficulty handling secretions; and (4) progressive respiratory distress requires artificial ventilation. Controversy surrounds tracheostomy, but many prefer this procedure when the obstruction is proximal to the larynx and reserve nasotracheal intubation for lower tract involvement.

CARE MANAGEMENT

Nursing care of the child with inhalation injury is the same as that for any child with respiratory distress. Vital signs and other respiratory assessments (oxygenation, work of breathing, acid-base status) are performed frequently, and the pulmonary status is carefully observed and maintained. Chest physical therapy is often part of the therapy, as well as mechanical ventilation if needed. Fluid requirements for children experiencing inhalation injury are greater than for those with surface burns alone; however, one concern is the development of PE. Therefore accurate monitoring of fluid intake and output is essential.

In addition to observation and management of the physical aspects of inhalation injury, the nurse also deals with the psychologic needs of a frightened child and distraught parents. As with any accidental injury, the parents may feel overwhelming guilt even

when the injury occurred through no fault of their own. Parents need support, reassurance, and information regarding the child's condition, treatment, and progress.

The nurse can provide anticipatory guidance and educate families on prevention of inhalation injuries and the importance of CO detectors in the home.

Environmental Tobacco Smoke Exposure

Numerous investigations indicate that parental or family smoking is an important cause of morbidity in children. Children exposed to (secondhand) passive or environmental tobacco smoke have an increased number of respiratory illnesses, increased respiratory symptoms (i.e., cough, sputum, and wheezing), and reduced performance on pulmonary function tests (PFTs). AOM and OME are also increased in children who have smoking parents. Indoor exposure to tobacco smoke has been linked to asthma in children. Among children with asthma, there is an association between parental cigarette smoking and asthma exacerbations, trips to the emergency department (ED), medication use, and impaired recovery after hospitalization for acute asthma. Maternal cigarette smoking is associated with increased respiratory symptoms and illnesses in children; decreased fetal growth; increased births of low-birth-weight, preterm, and stillborn infants; and a greater incidence of sudden infant death syndrome (SIDS). Antenatal maternal smoking has emerged as a significant risk factor for SIDS (AAP Task Force on Sudden Infant Death Syndrome, 2005; Zhang and Wang, 2012). The risk for diagnosis of early-onset asthma in the first 3 years of life is associated with in utero exposure to maternal smoking; grandmaternal smoking was also associated with an increased risk for early-onset asthma in the grandchild even if the mother did not smoke during pregnancy (Li, Langholz, Salam, et al., 2005). Exposure to tobacco smoke during childhood may also contribute to the development of chronic lung disease in the adult.

CARE MANAGEMENT

Nurses must provide information about the hazards of environmental smoke exposure in all of their interactions with children and their family members. This information is especially important for children with respiratory and allergic illnesses. In families in which smokers refuse to quit, appropriate guidance is provided for reducing smoke in the child's environment (see Family-Centered Care box). Nurses should set an example for children and families and become advocates for "no smoking" ordinances in public places, prohibition of advertising tobacco products in the media, and inclusion of health warnings of sidestream smoke on tobacco products.* Nurses have an important role in providing parents with affordable smoking cessation education resources, including the appropriate use of smoking cessation pharmacologic aids (Sheahan and Free, 2005). Nurses also have a role in educating adolescents about avoiding using tobacco products or smoking marijuana.

LONG-TERM RESPIRATORY DYSFUNCTION

Asthma

Asthma is a chronic inflammatory disorder of the airways characterized by recurring symptoms, airway obstruction, and bronchial hyperresponsiveness (National Asthma Education and Prevention Program [NAEPP], 2007). In susceptible children, inflammation causes recurrent episodes of wheezing, breathlessness, chest tightness, and cough, especially at night or in the early morning. The airflow limitation or obstruction is reversible either spontaneously or with treatment. Inflammation causes an increase in bronchial hyperresponsiveness to a variety of stimuli (NAEPP, 2007). Recognition of the key role of inflammation has made the use of antiinflammatory agents, especially inhaled corticosteroids, a major component in the treatment of asthma.

Asthma is classified into four categories based on the symptom indicators of disease severity. These categories are *intermittent, mild persistent, moderate persistent,* and *severe persistent.* Symptoms increase in frequency or intensity until the last category of severe persistent asthma (Box 40-13). These categories provide a stepwise approach to the pharmacologic management, environmental control, and educational interventions needed for each category (NAEPP, 2007). The stepwise approach is meant to assist in the clinical decision-making approach to effective individualized management of the child's symptoms. These categories emphasize the multifaceted aspect of the disease for consideration of effects on present quality of life and functional capacity and the future risk for adverse events (NAEPP, 2007).

Asthma prevalence, morbidity, and mortality are increasing in the United States, especially among African Americans (Akinbami, Moorman, Garbe, et al., 2009). These increases may result from worsening air pollution, poor access to medical care, or underdiagnosis and undertreatment. Asthma is the most common chronic disease of childhood, the primary cause of school absences, and the third leading cause of hospitalizations in children younger than 15 years. Although the onset of asthma may occur at any age, 80% to 90% of children have their first symptoms before 4 or 5 years of age. Boys are affected more frequently than girls until adolescence, when the trend reverses.

Etiology

Studies of children with asthma indicate that allergies influence both the persistence and the severity of the disease. In fact, **atopy,** or the

FAMILY-CENTERED CARE

*Decreasing Childhood Exposure to Environmental Tobacco Smoke**

- Maintain a smoke-free home.
- Avoid exposing an infant to environmental smoke.
- Use an air-purifying filter in the home where smoking is unavoidable.
- Encourage exclusive breastfeeding for the first 6 months.
- If smoking cessation is in progress by breastfeeding mother, suggest she change upper clothing after smoking and before breastfeeding infant.
- Do not smoke around children.
- Change clothing after smoking and before holding an infant in close proximity.
- Restrict smoking to an isolated area of the house where the children do not play or sleep.
- Do not smoke in motor vehicles with children.
- Do not smoke in rooms children use.
- Do not allow visitors to smoke in the home.

*For further information on the effects of secondhand smoke on child health, go to www.cdc.gov/tobacco/secondhand_smoke/index.htm.

*For further information on the effects of secondhand smoke on child health, go to www.cdc.gov/Features/WorldCancerDay.

BOX 40-13 ASTHMA SEVERITY CLASSIFICATION IN CHILDREN: AGES 0 TO 11 YEARS*

Step 5 or 6: Severe Persistent Asthma
- Continual symptoms throughout the day
- Frequent nighttime symptoms (>1 time/wk ages 0-4 years and 7 nights/wk, ages 5 years and older)
- PEF: <60%
- FEV_1: <75% of predicted value
- Interference with normal activity: extremely limited
- Use of short-acting β-agonist for symptom control: several times a day

Step 3 or 4: Moderate Persistent Asthma
- Daily symptoms
- Nighttime symptoms: 3 to 4 times a month (ages 0-4 years), >1/wk but not nightly (ages 5-11 years)
- PEF: 60% to 80% of predicted value (ages 5 years and older)
- FEV_1: 75% to 80% (ages 5 years and older)
- PEF variability: >30%
- Interference with normal activity: some limitation
- Use of short-acting β-agonist for symptom control: daily

Step 2: Mild Persistent Asthma
- Symptoms >2 times/wk but <1 time/day
- Nighttime symptoms: 1 to 2 times a month (ages 0-4 years), 3 to 4 times a month (ages 5-11 years)
- PEF or FEV_1: ≥80% of predicted value
- PEF variability: 20% to 30%
- Interference with normal activity: minor limitation
- Use of short-acting β-agonist for symptom control: >2 days/wk but not daily

Step 1: Intermittent Asthma
- Symptoms ≤2 days/wk
- Nighttime symptoms (awakenings): ≤2 nights per month
- PEF or FEV_1: ≤80% of predicted value
- PEF variability: <20%
- Interference with normal activity: none
- Use of short-acting β-agonist for symptom control: <2 days/wk

From National Asthma Education and Prevention Program (NAEPP): *Guidelines for the diagnosis and management of asthma: summary report 2007,* from www.nhlbi.nih.gov/guidelines/asthma/index.htm. *FEV_1,* Forced expiratory volume in 1 second; *PEF,* peak expiratory flow.

*The presence of one clinical feature of severity is sufficient to place a patient in that category. An individual should be assigned to the most severe grade in which any feature occurs. The characteristics in this box are general and may overlap because asthma is highly variable. An individual's classification may change over time. Risk factors for each category are not presented in this box. See the original table shown in the 2007 NAEPP reference for additional classification data. Asthma treatment should not be based on this box.

genetic predisposition for the development of an immunoglobulin E (IgE)–mediated response to common aeroallergens, is the strongest identifiable predisposing factor for developing asthma (NAEPP, 2007). However, 20% to 40% of children with asthma have no evidence of allergic disease. In addition to allergens, other substances and conditions can serve as triggers that may exacerbate asthma (Box 40-14). Evidence shows that viral respiratory infections, including RSV infection, may also have a significant role in the development and expression of asthma (NAEPP, 2007).

BOX 40-14 TRIGGERS TENDING TO PRECIPITATE OR AGGRAVATE ASTHMATIC EXACERBATIONS

- Allergens
  - Outdoor—Trees, shrubs, weeds, grasses, molds, pollens, air pollution, spores
  - Indoor—Dust or dust mites, mold, cockroach antigen
- Irritants—Tobacco smoke, wood smoke, odors, sprays
- Exposure to occupational chemicals
- Exercise
- Cold air
- Changes in weather or temperature
- Environmental change—Moving to new home, starting new school, etc.
- Colds and infections
- Animals—Cats, dogs, rodents, horses
- Medications—Aspirin, nonsteroidal antiinflammatory drugs (NSAIDs), antibiotics, β-blockers
- Strong emotions—Fear, anger, laughing, crying
- Conditions—Gastroesophageal reflux, tracheoesophageal fistula
- Food additives—Sulfite preservatives
- Foods—Nuts, milk/dairy products
- Endocrine factors—Menses, pregnancy, thyroid disease

Pathophysiology

There is general agreement that inflammation contributes to heightened airway reactivity in asthma. The mechanisms contributing to airway inflammation are multiple and involve a number of different pathways. It is unlikely that asthma is caused by either a single cell or a single inflammatory mediator; rather, it appears that asthma results from complex interactions among inflammatory cells, mediators, and the cells and tissues present in the airways (NAEPP, 2007). However, recognition of the importance of inflammation has made the use of antiinflammatory agents a key component of asthma therapy.

Another important component of asthma is bronchospasm and obstruction. The mechanisms responsible for the obstructive symptoms in asthma include (1) inflammatory response to stimuli; (2) airway edema and accumulation and secretion of mucus; (3) spasm of the smooth muscle of the bronchi and bronchioles, which decreases the caliber of the bronchioles; and (4) airway remodeling, which causes permanent cellular changes (NAEPP, 2007) (Fig. 40-4).

Airflow is determined by the size of the airway lumen, degree of bronchial wall edema, mucus production, smooth muscle contraction, and muscle hypertrophy. Bronchial constriction is a normal reaction to foreign stimuli; however, with asthma, it is abnormally severe, producing impaired respiratory function. Because the bronchi normally dilate and elongate during inspiration and contract and shorten on expiration, the respiratory difficulty is more pronounced during the expiratory phase of respiration.

Increased resistance in the airway causes forced expiration through the narrowed lumen. The volume of air trapped in the lungs increases as airways are functionally closed at a point between the alveoli and the lobar bronchi. This trapping of gas

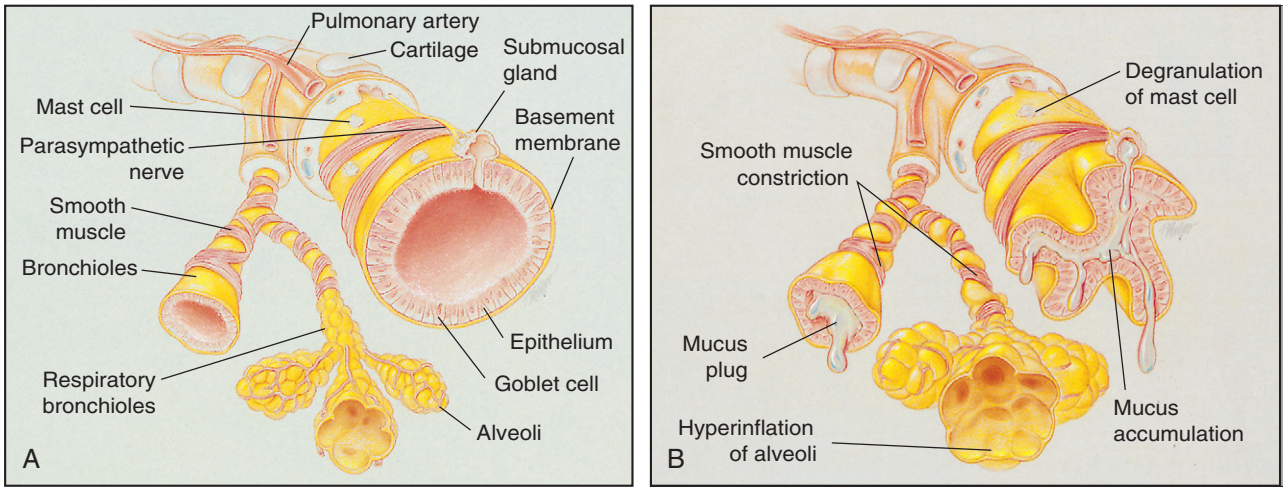

FIG 40-4 Airway obstruction caused by asthma. **A,** A normal lung. **B,** Bronchial asthma: thick mucus, mucosal edema, and smooth muscle spasm causing obstruction of small airways; breathing becomes labored, and expiration is difficult. (Adapted from Des Jardins T, Burton GG: *Clinical manifestations and assessment of respiratory disease,* ed 3, St Louis, 1995, Mosby.)

forces the individual to breathe at higher and higher lung volumes. Consequently, the person with asthma fights to inspire sufficient air. This expenditure of effort for breathing causes fatigue, decreased respiratory effectiveness, and increased oxygen consumption. The inspiration occurring at higher lung volumes hyperinflates the alveoli and reduces the effectiveness of the cough. As the severity of obstruction increases, there is a reduced alveolar ventilation with carbon dioxide retention; hypoxemia; respiratory acidosis; and, eventually, respiratory failure.

Chronic inflammation may also cause permanent damage (airway remodeling) to airway structures, which cannot be prevented by and is not responsive to current treatments (NAEPP, 2007).

Diagnostic Evaluation

The classic manifestations of asthma are dyspnea, wheezing, and coughing. An attack may develop gradually or appear abruptly and may be preceded by a URI. The age of the child is often a significant factor because the first attack frequently occurs before the age of 5 years, with some children manifesting clinical signs and symptoms in infancy. In infancy, an attack usually follows a respiratory infection. Some children may experience a prodromal itching at the front of the neck or over the upper part of the back just before an attack, especially if the attack is related to allergies (Box 40-15).

! NURSING ALERT

Shortness of breath with air movement in the chest restricted to the point of absent breath sounds (silent chest) accompanied by a sudden rise in respiratory rate is an ominous sign indicating ventilatory failure and imminent respiratory arrest.

The diagnosis is determined primarily on the basis of clinical manifestations, history, physical examination, and, to a lesser extent, laboratory tests. Generally, chronic cough in the absence of infection or diffuse wheezing during the expiratory phase of respiration is sufficient to establish a diagnosis.

Pulmonary function tests provide an objective method of evaluating the presence and degree of lung disease, as well as the response

BOX 40-15 CLINICAL MANIFESTATIONS OF ASTHMA

Cough
- Hacking, paroxysmal, irritative, and nonproductive
- Becomes rattling and productive of frothy, clear, gelatinous sputum

Respiratory-Related Signs
- Shortness of breath
- Prolonged expiratory phase
- Audible wheeze
- May have a malar flush and red ears
- Lips deep dark red color
- Possible progression to cyanosis of nail beds or circumoral cyanosis
- Restlessness
- Apprehension
- Sweating may be prominent as the attack progresses
- Posture—Older children may sit upright with shoulders in a hunched-over position, hands on the bed or chair, and arms braced (tripod position)
- Speech—May speak in short, panting, broken phrases

Chest
- Hyperresonance on percussion
- Coarse, loud breath sounds
- Wheezes throughout the lung fields
- Prolonged expiration
- Crackles
- Generalized inspiratory and expiratory wheezing; increasingly high pitched

With Repeated Episodes
- Barrel chest
- Elevated shoulders
- Use of accessory muscles of respiration
- Facial appearance: flattened malar bones, circles beneath the eyes, narrow nose, prominent upper teeth

GUIDELINES

*Interpreting Peak Expiratory Flow Rates**

- Green (80% to 100% of personal best) signals *all clear.* Asthma is under reasonably good control. No symptoms are present, and the routine treatment plan for maintaining control can be followed.
- Yellow (50% to 79% of personal best) signals *caution.* Asthma is not well controlled. An acute exacerbation may be present. Maintenance therapy may need to be increased. Call the health care practitioner if the child stays in this zone.
- Red (below 50% of personal best) signals a *medical alert.* Severe airway narrowing may be occurring. A short-acting bronchodilator should be administered. Notify the health care practitioner if the peak expiratory flow rate does not return immediately and stay in yellow or green zones.

*These zones are guidelines only. Specific zones and management should be individualized for each child.

to therapy. Spirometry can generally be performed reliably on children by the age of 5 or 6 years. The NAEPP (2007) recommends that spirometry testing be done at the time of initial assessment of asthma, after treatment is initiated and symptoms have stabilized, and at least every 1 to 2 years to assess the maintenance of airway function.

Another measurement to consider is the peak expiratory flow rate (PEFR), which measures the maximum flow of air that can be forcefully exhaled in 1 second. PEFR is measured in liters per minute using a peak expiratory flow meter (PEFM). Three zones of measurement are typically used to interpret PEFR. The zone system is patterned after a traffic light to make the categories easy to understand and remember (see Guidelines box). Each child needs to establish his or her personal best value. A personal best value should be established during a 2- to 3-week period when the child's asthma is stable. During this period, the child records the PEFR at least twice a day. After the personal best value has been established, the child's current PEFR on any occasion can be compared with the personal best value. Although it can be a helpful tool in assessing a child's asthma control, it is important to note that its results depend on the child's ability to use the PEFM and willingness to participate. In some cases, a low PEFR may not truly mean that the child's asthma is poorly controlled. Each individual child's PEFR varies according to age, height, gender, and race.

Bronchoprovocation testing—direct exposure of the mucous membranes to a suspected antigen in increasing concentrations—helps identify inhaled allergens. Exposure to methacholine (methacholine challenge), histamine, or cold or dry air may be performed to assess airway responsiveness or reactivity. Exercise challenges may be used to identify children with exercise-induced bronchospasm. These tests are highly specific and sensitive and should be done under close observation in a qualified laboratory or clinic.

Skin prick testing (SPT) and serologic testing (with quantification of sIgE) for allergen-specific immunoglobulin E (sIgE) may be used to identify environmental allergens that trigger asthma (Sicherer, Wood, and AAP Section on Allergy and Immunology, 2012). It is recommended that all patients with year-round asthma symptoms be tested with skin tests or laboratory blood analysis to determine sensitization to perennial allergens (e.g., house dust mites, cats, dogs, cockroaches, molds, and fungus) (NAEPP, 2007).

In addition to these tests, other tests may be performed, including laboratory tests (complete blood count [CBC] with differential) and chest radiographs. The CBC may show a slight elevation in the white blood cell count during acute asthma, but elevations to more than 12,000/mm^3 or an increased percentage of band cells may indicate a respiratory tract infection. The presence of eosinophilia of greater than 500/mm^3, on the other hand, tends to suggest an allergic or inflammatory disorder.

Frontal and lateral radiographs may show infiltrates and hyperexpansion of the airways, with the anteroposterior diameter on physical examination indicating an increased diameter (suggestive of barrel chest). Additional diagnostic tests for conditions such as gastroesophageal reflux may be carried out to determine whether they may contribute to asthma symptoms. Radiography may assist in ruling out a respiratory tract infection.

Therapeutic Management

The overall goals of asthma management are to maintain normal activity levels, maintain normal pulmonary function, prevent chronic symptoms and recurrent exacerbations, provide optimal drug therapy with minimal or no adverse effects, and assist the child in living as normal and happy a life as possible. This includes facilitating the child's social adjustments in the family, school, and community and normal participation in recreational activities and sports. To accomplish these goals, several treatment principles need to be followed (NAEPP, 2007):

- A continuous care approach with regular visits to the health care provider is necessary to control symptoms and prevent exacerbations.
- Prevention of exacerbations includes avoiding triggers, avoiding allergens, and using medications as needed.
- Therapy includes efforts to reduce underlying inflammation and to relieve or prevent symptomatic airway narrowing.
- Therapy includes patient education, environmental control, pharmacologic management, and the use of objective measures to monitor the severity of disease and guide the course of therapy.

Allergen Control. Nonpharmacologic therapy is aimed at the prevention and reduction of exposure to airborne allergens and irritants. House dust mites and other components of house dust are frequent agents identified in children who are allergic to inhalants. The cockroach, another common household inhabitant, is an important allergen in many locations. Exterminating live cockroaches, carefully cleaning kitchen floors and cabinets, putting food away after eating, and taking trash out in the evening are essential measures to control cockroaches. The mouse allergen is the most recent allergen to be identified in the homes of inner-city children with asthma. The role of cat and dog dander in allergen-induced asthma has also been studied. Although some studies suggest sensitized persons should carefully evaluate having such pets in the household, the overall data are inconsistent on the effect of cat or dog exposure and subsequent asthma development (Chen, Tischer, Schnappinger, et al., 2010). Additional sources of pollutants include ozone, particulate matter produced by tobacco smoke, wood-burning stoves, pesticides, lead, mold spores, nitrogen dioxide, and sulfur dioxide; these are believed to contribute to asthma morbidity in children and should be avoided or minimized. Living in homes close to busy roads, damp homes with mold, and exposure to tobacco smoke are significant contributing factors in the development of asthma in infants and small children (Heinrich, 2011). Recommendations for controlling allergens are found in the Patient Teaching box.

Skin testing identifies specific allergens so steps can be taken to eliminate or avoid them. Often, simply removing the offending environmental allergens or irritants (e.g., removing carpeting from the

PATIENT TEACHING

"Allergy-Proofing" the Home and Community

- Keep humidity between 30% and 50%; use dehumidifier or air conditioner if available; keep air conditioners clean and free of mold; do not use vaporizers or humidifiers.
- Encase pillows in zippered allergen-impermeable covers or wash pillows in hot water every week.
- Encase mattress and box springs in zippered allergen-impermeable cover.
- Use foam rubber mattress and pillows or Dacron pillows and synthetic blankets.
- Wash bed linens every 7 to 10 days in hot water (at least 54.4° C).
- Encase polyester comforters in allergen-impermeable covers or wash in hot water (at least 54.4° C) every week; if possible, do not use comforters and use cotton blankets.
- Store nothing under the bed; keep clothing in a closet with the door shut.
- Use washable window shades; avoid heavy curtains; if curtains are used, launder them frequently.
- Remove all carpeting if possible; if not possible, vacuum carpet once or twice a week while the child wears a mask; have child remain out of the room while vacuuming occurs and for 30 minutes after vacuuming.
- If possible, use a central vacuum cleaner with a collecting bag outside of the home or use cleaner filters (e.g., high-efficiency particulate air [HEPA] filters).
- Have air and heating ducts cleaned annually; change or clean air filters every 3 months; cover heating vents with filter material (e.g., cheesecloth) to prevent circulation of dust, especially when heat is turned on after summer.
- Use wipeable furniture (wood, plastic, vinyl, or leather) in place of upholstered furniture; avoid rattan or wicker furniture.
- Keep child indoors while lawn is being mowed, bushes/trees are being trimmed, or pollen count is high.
- Keep windows and doors closed during pollen season; use air conditioner if possible or go to places that are air conditioned, such as libraries and shopping malls, when the weather is hot.
- Wet-mop bare floors weekly; wet-dust and clean child's room weekly; child should not be present during cleaning activities.
- Limit or avoid child's exposure to tobacco and wood smoke; do not allow cigarette smoking in the house or car; select day care centers, play areas, and shopping malls that are smoke-free.
- Avoid cellar (basement) as a play area if it is damp, and use a dehumidifier in damp basement.
- Use pesticide sprays, roach bait traps, and boric acid powder to kill cockroaches; if living in an apartment or adjacent housing, encourage neighbors to work together to get rid of cockroaches and mice.
- Decrease child's exposure to air pollution from vehicle exhaust, outdoor grills, and environmental tobacco. Limit outside play on ozone alert days.

home of a child sensitive to mold and dust particles) will decrease the frequency of asthma episodes. Dehumidifiers or air conditioners may control nonspecific factors that trigger an episode, such as extremes of temperature.

Drug Therapy. Pharmacologic therapy is used to prevent and control asthma symptoms, reduce the frequency and severity of asthma exacerbations, and reverse airflow obstruction. A stepwise approach is recommended based on the severity of the child's asthma. Because inflammation is considered an early and persistent feature of asthma, therapy is directed toward long-term suppression of inflammation.

Asthma medications are categorized into two general classes: *long-term control medications* (preventive medications) to achieve and maintain control of inflammation; and *quick-relief medications* (rescue medications) to treat symptoms and exacerbations (NAEPP, 2007).

Quick-relief and long-term medications are often used in combination. Inhaled corticosteroids, cromolyn sodium and nedocromil, long-acting β_2-agonists, methylxanthines, and leukotriene modifiers are used as long-term control medications. Short-acting β_2-agonists, anticholinergics, and systemic corticosteroids are used as quick-relief or rescue medications.

Many asthma medications are given by inhalation with a nebulizer or a metered-dose inhaler (MDI). The MDI should always be attached to a spacer, especially when an inhaled corticosteroid is administered, to prevent yeast infections in the mouth. The spacer and holder can be equipped with a mask or a mouthpiece (Fig. 40-5). Pharmaceutical companies are currently mandated to produce inhalers that do not contain chlorofluorocarbons (CFCs) as the propellant because CFCs have been linked to damage and depletion of the earth's ozone level. Several currently available CFC-free MDI devices use dry powder (and are called *dry powder inhalers*); these include the Diskus inhaler and the Turbuhaler. These devices are

FIG 40-5 Child using metered-dose inhaler with spacer and face mask.

breath activated, and the child needs to inhale as quickly and deeply as possible to use them effectively. The Diskhaler and Aerosolizer are similar, but with the Aerosolizer, the medication must be loaded into the inhaler before use. Children who have difficulty using MDIs or other inhalers can receive their asthma medications via a nebulizer, which administers the medication via compressed air or oxygen. Children are instructed to breathe normally with the mouth open to provide a direct route to the trachea.

Corticosteroids are antiinflammatory drugs used to treat reversible airflow obstruction, control symptoms, and reduce bronchial

hyperresponsiveness in chronic asthma. Inhaled corticosteroids are used as first-line therapy in children older than 5 years. Clinical studies of corticosteroids have indicated significant improvement of all asthma parameters, including decreases in symptoms, emergency visits, and medication requirements (NAEPP, 2007).

Corticosteroids may be administered parenterally, orally, or by inhalation. Oral medications are metabolized slowly, with an onset of action up to 3 hours after administration and peak effectiveness occurring within 6 to 12 hours. Oral systemic steroids may be given for short periods (e.g., 3- or 10-day "bursts") to gain prompt control of inadequately controlled persistent asthma or to manage severe persistent asthma. These drugs should be given in the lowest effective dose. These medications have few side effects (cough, dysphonia, and oral thrush), and strong evidence indicates that they improve the long-term outcomes for children of all ages with mild or moderate persistent asthma. Some studies have monitored children for 6 years after starting inhaled corticosteroids, and they indicate that when used at recommended doses, they do not have long-term significant effects on growth, bone mineral density, ocular toxicity, or suppression of the adrenal-pituitary axis (NAEPP, 2007). However, primary care providers should frequently monitor the growth of children and adolescents taking corticosteroids to assess the systemic effects of these drugs and make appropriate reductions in dosages or changes to other types of asthma therapy when necessary. Inhaled corticosteroids include budesonide and fluticasone.

β-Adrenergic agonists (short acting) (primarily albuterol, levalbuterol [Xopenex], and terbutaline) are used for treatment of acute exacerbations and for the prevention of exercise-induced bronchospasm. These drugs bind with the β-receptors on the smooth muscle of airways, where they activate adenylate cyclase and convert adenosine monophosphate (AMP) to cyclic AMP (cAMP). It is believed that the increased cAMP enhances binding of intracellular calcium to the cell membrane, reducing the availability of calcium and thus allowing smooth muscle to relax. Other effects of the drug help stabilize mast cells to prevent release of mediators. Most β-adrenergics used in asthma therapy affect predominantly the β_2-receptors, which help eliminate bronchospasm. β_1-receptor effects, such as increased heart rate and gastrointestinal disturbances, have been minimized. Albuterol is given orally (liquid or pill) or via a nebulizer or inhaler. Levalbuterol is given via nebulizer only. Terbutaline is given orally, via nebulizer, subcutaneously, or intravenously. The inhaled drugs have a more rapid onset of action than oral forms. Inhalation also reduces troublesome systemic side effects, including irritability, tremor, nervousness, and insomnia.

Salmeterol (Serevent) is a *long-acting β_2-agonist* (bronchodilator) that is used twice a day (no more frequently than every 12 hours). This drug is added to antiinflammatory therapy and used for long-term prevention of symptoms, especially nighttime symptoms, and exercise-induced bronchospasm. Salmeterol is not used in children younger than 12 years, and it is not used to treat acute symptoms or exacerbations. The 2007 NAEPP guidelines recommend the addition of a long-acting β_2-agonist (e.g., salmeterol) to a low- or medium-dosage inhaled corticosteroid to improve lung function and asthma symptoms and decrease the need for a short-acting β_2-agonist. Currently, the FDA is requiring studies be conducted by drug manufacturers to evaluate the safety of long-acting β_2-agonists (LABAs) when combined with inhaled corticosteroids versus inhaled corticosteroids alone. LABAs can increase the risk for severely worsening asthma symptoms, potentially leading to hospitalizations and death (Food and Drug Administration [FDA], 2011).

Theophylline is a methylxanthine drug used for decades to relieve symptoms and prevent asthma attacks; however, it is now used primarily in the ED when the child is not responding to maximal therapy. Therapeutic levels should be obtained with this drug because it has a narrow therapeutic window.

Cromolyn sodium is a medication used in maintenance therapy for asthma. It stabilizes mast cell membranes; inhibits activation and release of mediators from eosinophil and epithelial cells; and inhibits the acute airway narrowing after exposure to exercise, cold dry air, and sulfur dioxide. It does not result in immediate relief of symptoms and has minimal side effects (occasional coughing on inhalation of the powder formulation). It may be given via nebulizer or MDI. *Nedocromil sodium* inhibits the bronchoconstrictor response to inhaled antigens and inhibits the activity of and release of inflammatory cell types such as histamine, leukotrienes, and prostaglandins. The drug has few side effects and is used for maintenance therapy in asthma; it is not effective for reversal of acute exacerbations and is not used in children younger than 5 years.

Leukotrienes are mediators of inflammation that cause increases in airway hyperresponsiveness. Leukotriene modifiers (e.g., zafirlukast [Accolate] and montelukast sodium [Singulair]) block inflammatory and bronchospasm effects. These drugs are not used to treat acute episodes but are given orally in combination with β-agonists and steroids to provide long-term control and prevent symptoms in mild persistent asthma. Montelukast is approved for children 12 months old and older, and zafirlukast is approved for children 7 years old and older.

Anticholinergics (atropine and ipratropium [Atrovent]) may also be used for relief of acute bronchospasm. However, these drugs have adverse side effects that include drying of respiratory secretions, blurred vision, and cardiac and CNS stimulation. The primary anticholinergic drug used is ipratropium, which does not cross the blood-brain barrier and therefore elicits no CNS effects. Ipratropium, when used in combination with albuterol, has been shown to be effective during acute severe asthma in significantly improving lung function and reducing hospitalizations in children coming to the ED.

A fairly new asthma drug, omalizumab (Xolair), is a *monoclonal antibody* that blocks the binding of IgE to mast cells. Blocking this interaction eventually inhibits the inflammation that is associated with asthma. It is used in patients with moderate to persistent asthma who have confirmed perennial aeroallergen sensitivity and have had poor control of symptoms on inhaled steroids. Many patients with asthma are atopic and possess specific IgE antibodies to allergens responsible for airway inflammation. Xolair has been approved for use in children 12 years old and older. The drug is administered once or twice a month by subcutaneous injection. Efficacy of omalizumab is not immediate. In early 2007, the FDA added a "black box warning" to the drug, which highlights the risk for anaphylaxis; however, recent studies indicate the risk for anaphylaxis is reported to occur infrequently. More than half of all anaphylactic reactions occurred in the first 2 hours after administration (FDA, 2009; Thomson and Chaudhuri, 2012). In summary, omalizumab is considered effective for children and adults 12 years of age and older whose asthma symptoms are poorly controlled with inhaled corticosteroids (Thomson and Chaudhuri, 2012).

Some children with severe asthma and a history of severe life-threatening episodes may need a primary care practitioner prescription for an EpiPen (subcutaneous injectable epinephrine).

Exercise. Exercise-induced bronchospasm (EIB) is an acute, reversible, usually self-terminating airway obstruction that develops during or after vigorous activity, reaches its peak 5 to 10 minutes after stopping the activity, and usually stops in another 20 to 30 minutes. Patients with EIB have cough, shortness of breath, chest

pain or tightness, wheezing, and endurance problems during exercise, but an exercise challenge test in a laboratory is necessary to make the diagnosis.

The problem is rare in activities that require short bursts of energy (e.g., baseball, sprints, gymnastics, skiing) and more common in those that involve endurance exercise (e.g., soccer, basketball, distance running). Swimming is well tolerated by children with EIB because they are breathing air fully saturated with moisture and because of the type of breathing required in swimming.

Children with asthma are often excluded from exercise by parents, teachers, and health care practitioners, as well as by the children themselves because they are reluctant to provoke an attack. However, this practice can seriously hamper peer interaction and physical health. Exercise is advantageous for children with asthma, and most children can participate in activities at school and in sports with minimal difficulty, provided their asthma is under control. Appropriate prophylactic treatment with β-adrenergic agents or cromolyn sodium before exercise usually permits full participation in strenuous exertion.

Breathing Exercises. Breathing exercises and physical training help produce physical and mental relaxation, improve posture, strengthen respiratory musculature, and develop more efficient patterns of breathing. For motivated children, breathing exercises and controlled breathing are of value in preventing overinflation and improving efficiency of the cough. However, these exercises are not recommended during acute, uncomplicated exacerbation of asthma.

Hyposensitization. The role of hyposensitization in childhood asthma has become controversial. In the past, immunotherapy was used for seasonal allergies and when single substances were identified as the offending allergen. It is not recommended for allergens that can be eliminated, such as foods, drugs, and animal dander.

The NAEPP guidelines (2007) recommend immunotherapy for asthma patients in the following situations:

- When there is evidence of a relationship between asthma symptoms and unavoidable exposure to an allergen to which the patient is sensitive
- When symptoms occur all year or at least during a major portion of the year
- When symptom control is difficult with drug therapy because multiple medications are required, the patient is not responsive to available drugs, or the patient refuses to take the medications

Injection therapy is usually limited to clinically significant allergens. The initial dose of the offending allergen(s), based on the size of the skin reaction, is injected subcutaneously. The amount is increased at weekly intervals until a maximum tolerance is reached, after which a maintenance dose is given at 4-week intervals. This may be extended to 5- or 6-week intervals during the off-season for seasonal allergens. Successful treatment is continued for a minimum of 3 years and then stopped. If no symptoms appear, acquired immunity is assumed; if symptoms recur, treatment is reinstituted. Hyposensitization injections should be administered only with emergency equipment and medications readily available in the event of an anaphylactic reaction.

Status Asthmaticus. Status asthmaticus is a medical emergency that can result in respiratory failure and death if untreated. Children who continue to display respiratory distress despite vigorous therapeutic measures, especially the use of sympathomimetics (e.g., albuterol, epinephrine), are considered to be in status asthmaticus. The condition may develop gradually or rapidly, often coincident with complicating conditions, such as pneumonia or a respiratory virus, that can influence the duration and treatment of the exacerbation.

! NURSING ALERT

A child with asthma who sweats profusely, remains sitting upright, and refuses to lie down is in severe respiratory distress. Also, a child who suddenly becomes agitated or an agitated child who suddenly becomes quiet may have serious hypoxia and requires immediate intervention.

Therapy for status asthmaticus is aimed at improving ventilation, decreasing airway resistance and relieving bronchospasm, correcting dehydration and acidosis, allaying child and parent anxiety related to the severity of the event, and treating any concurrent infection. Humidified oxygen is recommended and should be given to maintain an oxygen saturation greater than 90%. Inhaled aerosolized short-acting β_2-agonists are recommended for all patients. Three treatments of β_2-agonists spaced 20 to 30 minutes apart are usually given as initial therapy, and continuous administration of β_2-agonists may be initiated. A systemic corticosteroid (oral, IV, or IM) may also be given to decrease the effects of inflammation. An anticholinergic agent such as ipratropium bromide may be added to the aerosolized solution of the β_2-agonist. Anticholinergics have been shown to result in additional bronchodilation in patients with severe airflow obstruction. An IV infusion is often initiated to provide a means for hydration and to administer medications. Correction of dehydration, acidosis, hypoxia, and electrolyte disturbance is guided by frequent determination of arterial pH, blood gases, and serum electrolytes.

Additional therapies in acute asthma attacks include the use of IV magnesium sulfate, a potent muscle relaxant that acts to decrease inflammation and improves pulmonary function and peak flow rate among pediatric patients treated in the ED with moderate to severe asthma. Heliox may be administered to decrease airway resistance and thereby decrease the work of breathing; heliox can be delivered via a nonrebreathing face mask from premixed tanks, which may be blended in a stand-alone unit or within a ventilator. Heliox may be used in acute exacerbations as an adjunct to β_2-agonist and IV corticosteroid therapy to improve pulmonary function until the two latter medications have time to take full effect in decreasing bronchospasm; whereas the effects of heliox are usually seen within 20 minutes of administration, other drugs may take longer to exert the desired effect. Ketamine, a dissociative anesthetic, is believed to cause smooth muscle relaxation and decrease airway resistance caused by severe bronchospasm in acute asthma; it may be administered as an adjunct to other therapies mentioned previously.

Antibiotics should not be used to treat acute asthma attacks except when a bacterial infection resulting from another condition such as pneumonia or sinusitis is present (NAEPP, 2007). A child suspected of having status asthmaticus is usually seen in the ED and is often admitted to a pediatric intensive care unit for close observation and continuous cardiorespiratory monitoring. A key component in the prevention of morbidity is helping the child, parents, teachers, coaches, and other adults recognize features of deteriorating respiratory status, use the correct rescue drugs effectively, and immediately place the child with deteriorating respiratory status into the care of health care professionals instead of waiting to see if the asthma improves on its own. For the child going into early status asthmaticus, immediate medical care is

required to prevent irreversible respiratory failure and possible death (see Nursing Care Plan).

Prognosis. Although deaths from asthma have been relatively uncommon since the 1980s, the rate of death from asthma increased steadily in the United States until it peaked in the mid-1990s. Asthma-related deaths decreased between 1996 and 2005 by approximately 3.9% per year (Akinbami, Moorman, Garbe, et al., 2009). Data for the year 2008 indicate a significant increase in asthma symptoms, ED visits, and hospitalization among boys from birth to 4 years of age. African-American children have hospitalization and death rates 3 times higher than those of white and Hispanic children (Liu, Covar, Spahn, et al., 2011). Most asthma deaths in children occur in the home, school, or community before lifesaving medical care can be administered.

Some children's asthma symptoms may improve at puberty, but up to two thirds of children with asthma continue to have symptoms through puberty and into adulthood. The prognosis for control or disappearance of symptoms varies in children from those who have

NURSING CARE PLAN

The Child with Acute Asthma Exacerbation

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
Ineffective Airway Clearance related to inflammation and constriction (spasm) of bronchial tree	Child will exhibit effective ventilatory capacity (specify).	Allow child to assume position of comfort (tripod or other)	To promote maximum ventilatory function
Child's Defining Characteristics	Child will breathe easily without dyspnea.	Administer oxygen by face mask to maintain oxygen saturation >90%	To enhance oxygenation of tissues
(Subjective and Objective Data)		Provide reassurance that symptoms will be managed and air hunger will subside	To decrease anxiety related to hypoxia
Dyspnea		Administer rescue medications (as prescribed) (NAEPP, 2007):	To open constricted airways and allow air exchange
Diminished breath sounds (air movement)		Inhaled β_2-agonist by metered-dose inhaler or aerosolized nebulization (up to three treatments in first 60 minutes) *or*	To maintain adequate tissue oxygenation
Adventitious breath sounds (wheezing)		Inhaled high-dose β_2-agonist (albuterol) and anticholinergic (ipratropium bromide [as age appropriate]) in nebulized form with oxygen (as necessary to keep saturation >90%)	
Difficulty vocalizing		Administer oral corticosteroid	To decrease inflammation
Changes in respiratory rate and rhythm		Assess child's response to rescue medications	To determine need for more aggressive interventions
Related Factors		Administer the above rescue medications ordered as appropriate until optimum response is obtained	To control asthma symptoms and improve oxygenation
Allergen exposure		Observe for exacerbation of asthma symptoms	To prevent recurrence of acute episode
Allergic airway		Encourage small amounts of clear oral fluids as condition allows	To maintain hydration
Respiratory tract infection		For severe, unresponsive exacerbation, initiate peripheral intravenous line	To maintain hydration and administer medications
		Titrate or wean oxygen concentration according to patient's response to rescue medications (based on work of breathing and oxygen saturation)	To prevent hyperoxemia
		Collaboratively evaluate cause of asthma exacerbation and treat if infection	To prevent recurrence
		Provide discharge instructions for continued control of asthma symptoms	To educate for management of symptoms and prevention of exacerbations
		Review home medication use	To provide sense of control
		Review written action plan for asthma symptom control	To enhance self-esteem
		Review signs and symptoms requiring immediate medical attention	
		Control or eradicate allergens, irritants, and other precipitating factors	
		Follow up with health care practitioner	

rare and infrequent attacks to those who are constantly wheezing or are subject to status asthmaticus. In general, when symptoms are severe and numerous, when symptoms have been present for a long time, and when there is a family history of allergy, there is a greater likelihood of a poor prognosis. Risk factors that may predict the persistence of symptoms into childhood (from infancy) include atopy, male gender, exposure to environmental tobacco, and maternal history of asthma. Many children who outgrow their exacerbations continue to have airway hyperresponsiveness and cough as adults. Furthermore, airway hyperresponsiveness in adults appears to be associated with decreased lung function.

The adolescent age-group appears to be the most vulnerable, with the greatest increase occurring in children 10 to 14 years of age. No reliable data exist to explain this increase. Factors that have been postulated include exposure of atopic persons to more allergens (particularly in large urban centers), change in severity of the disease, abuse of drug therapy (toxicity), failure of families and practitioners to recognize the severity of asthma, and psychologic factors such as denial and refusal to accept the disease. On the other hand, studies have shown that children living in rural areas and farming communities have a decreased incidence of asthma and allergy (Liu, Covar, Spahn, et al., 2011).

Risk factors for asthma deaths include early onset, frequent attacks, difficult-to-manage disease, adolescence, history of respiratory failure, psychologic problems (refusal to take medications), dependency on or misuse of asthma drugs (high use), presence of physical stigmata (barrel chest, intercostal retractions), and abnormal PFT results.

CARE MANAGEMENT

The nursing care of the child with asthma begins with a review of the child's health history; the home, school, and play environment; parent and child attitudes about the child's condition; and a comprehensive physical assessment with focus on the respiratory system. Nursing care of children with asthma involves both acute and long-term care. Nurses who are involved with children in the home, hospital, school, outpatient clinic, or health care practitioner's office play an important role in helping children and their families learn to live with the condition. The disease can be managed so that it does not require hospitalization or interfere with family life, physical activity, or school attendance. The nursing process in the care of the child with asthma is outlined in the Nursing Care Plan.

Physical assessment of asthma involves the same observations and techniques described in Chapter 29. In addition, the nurse notes and evaluates physical characteristics of a chronic respiratory condition, including chest configuration (e.g., barrel chest), posturing, and type of breathing. A history of the current and previous episodes and precipitating factors or events is important.

Nurses may perform a variety of functions in asthma care. These may include asthma education in the primary care setting and in schools and other community settings, care of the child with asthma in the acute care setting, ambulatory care, emergency department, and intensive care. Nurses also obtain information on how asthma affects the child's everyday activities and self-concept, the child's and family's adherence to the prescribed therapy, and their personal treatment goals. Every effort is made to build a partnership between the child and family and the health care team, and effective communication is an essential part of this partnership. In particular, the child's and family's satisfaction with asthma control and with the quality of care should be assessed. The nurse should also assess the child's and family's perception of the severity of the disease and their level of social support.

One of the major emphases of nursing care is outpatient management by the family. Parents are taught how to prevent exacerbations, to recognize and respond to symptoms of bronchospasm, to maintain health and prevent complications, and to promote normal activities. The nurse should determine any cultural or ethnic beliefs or practices that influence self-management and that may necessitate modifications in educational approaches to meet the family's needs. Inconsistent home care, either on the part of the child or the parents, often leads to unnecessary ED visits for management (Volpe, Smith, and Sultan, 2011). Parents and older children often need education reinforced about the maintenance aspect of asthma management; children benefit from drug therapy even when asthma manifestations are not evident.

Provide Acute Asthma Care. Children who are admitted to the hospital with acute asthma are ill, anxious, and uncomfortable. The importance of continual observation and assessment cannot be overemphasized.

When β_2-agonists, supplemental oxygen, and corticosteroids are given, the child is monitored closely and continuously for relief of respiratory distress and signs of side effects or toxicity. Pulse oximetry is monitored along with rate and depth of breathing, auscultation of air movement, adventitious sounds, and any signs of respiratory distress (e.g., nasal flaring, tachypnea, retractions). The child on supplemental oxygen requires intermittent or continuous oxygenation monitoring depending on severity of respiratory compromise and initial oxygenation status. The child in status asthmaticus should be placed on continuous cardiorespiratory (including blood pressure) and pulse oximetry monitoring. Oral fluid intake may be limited during the acute phase; IV fluid replacement may be required to provide adequate tissue hydration.

Older children may be more comfortable standing (Fig. 40-6), sitting upright, or leaning slightly forward (Fig. 40-7). Shortness of breath makes talking difficult.

The calm, efficient presence of a nurse helps reassure children that they are safe and will be cared for during this stressful period. It is important to assure children that they will not be left alone and that their parents are allowed to remain with them. Parents need

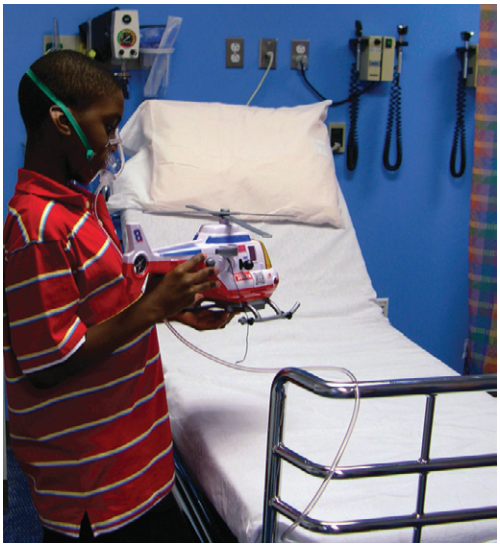

FIG 40-6 Child with asthma is allowed play activity as tolerated.

NURSING CARE PLAN

The Child with Asthma

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
Risk for Suffocation related to interaction between individual and triggering factors (allergens, respiratory tract infection, exercise, irritants, emotions, temperature changes) **Child's Defining Characteristics *(Subjective and Objective Data)*** Wheezing Dry cough Labored respirations Dyspnea Intercostal retractions Complaints of tightness in chest, shortness of breath Bronchial inflammation and airway constriction	Child will have adequate airway exchange. Family and child will assume responsibility for asthma symptom management.	Assist child and family in recognizing factors such as allergens, irritants, temperature changes, and upper respiratory infections that trigger asthma symptoms Assist child (according to developmental age) and family in recognizing early signs of an asthmatic episode (use PEFM) Educate child and family in use of inhaled corticosteroids and bronchodilator Educate child and family regarding proper use of rescue medications in case of illness exacerbation Educate child and family regarding proper use of MDI with spacer, aerosolized nebulizer, and PEFM (know child's personal best)	To avoid asthma exacerbations To control symptoms with medication To control symptoms and minimize shortness of breath To prevent illness exacerbations and hospitalization; to prevent side effects from improper use of certain asthma drugs To help child and family effectively manage asthma symptoms independently
Interrupted Family Processes related to child with chronic illness **Child's and Family's Defining Characteristics *(Subjective and Objective Data)*** Anxiety Disruptive family interactions with child and members Family conflicts Inadequate child support Child's health status ignored Family ignoring other members' needs for those of child with asthma	Family will cope with effects of disease. Family will provide child appropriate protective environment.	Provide family and child (as age appropriate) explanations about the disease and management Cooperate with family to develop written action plan for asthma management Discuss facilitators and barriers to effective asthma management Encourage family and child (as age appropriate) to discuss impact of illness on family's lifestyle Evaluate family resources for asthma management in relation to the following: Access to health care Medication availability in home and school (or day care as appropriate) Allergen exposure control and eradication	To provide adequate information To provide realistic expectations To provide family and child sense of control To assist family members in understanding their role as being vital in management of asthma To provide opportunity to verbalize frustrations and challenges of having child with chronic illness To enhance family's ability to cope with child's chronic illness

MDI, Metered-dose inhaler; *PEFM,* peak expiratory flow meter.

reassurance and want to be informed of their child's condition and therapies. They may believe that they have in some way contributed to the child's condition or could have prevented the episode. Reassurance regarding their efforts expended on the child's behalf and their parenting capabilities can help alleviate their stress. Efforts to reduce parental apprehension will also reduce the child's distress. Anxiety is easily communicated to the child from parents and members of the staff.

Avoid Allergens. One goal of asthma management is avoidance of an exacerbation. Parents need to know how to avoid allergens that precipitate asthma episodes. The nurse assists the parent in modifying the environment to reduce contact with the offending allergen(s). Parents are cautioned to avoid exposing a sensitive child to excessive cold, wind, and other extremes of weather; smoke (open fire or tobacco); sprays; scents; and other irritants. Foods known to provoke symptoms should be eliminated from the diet.

Approximately 2% to 6% of children with asthma are sensitive to aspirin; therefore nurses should caution parents to use other analgesic–antipyretic drugs for discomfort or fever and to read package labeling. Although aspirin is not routinely given to children in the United States, salicylate compounds are in other common medicines such as Pepto-Bismol. Children with aspirin-induced asthma may also be sensitive to nonsteroidal antiinflammatory drugs and tartrazine (yellow dye number 5, a common food coloring).

! NURSING ALERT

Parents are encouraged to avoid administering aspirin to any child unless specifically recommended by and under the supervision of a health care practitioner. Acetaminophen is safe for children and is the analgesic of choice.

Relieve Bronchospasm. Teach parents and older children to recognize early signs and symptoms of an impending attack so it

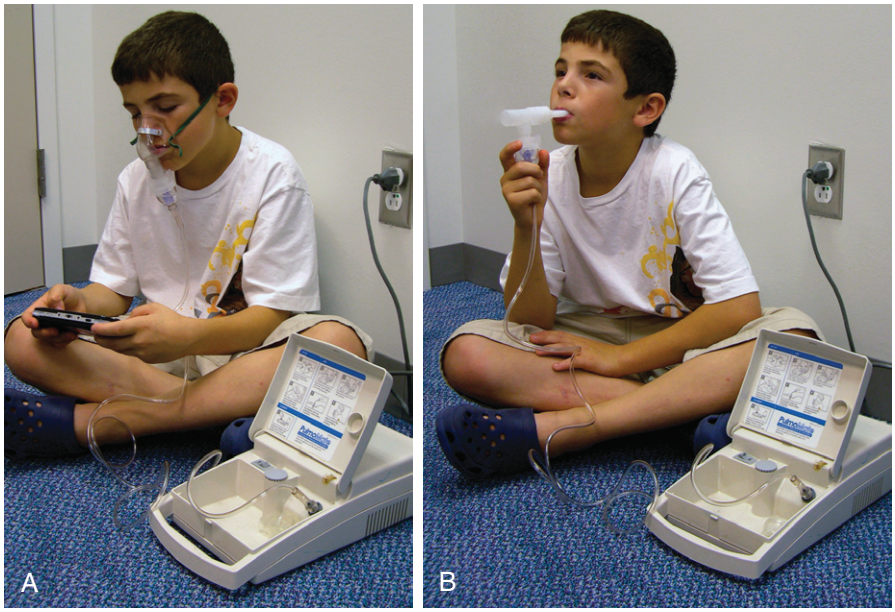

FIG 40-7 Children with asthma may take a nebulized aerosol treatment with a mask **(A)** or mouthpiece **(B).** (Courtesy Texas Children's Hospital, Houston.)

can be controlled before symptoms become distressing. Most children can recognize prodromal symptoms well before an attack (≈6 hours) and implement preventive therapy. Objective signs that parents may observe include rhinorrhea, cough, low-grade fever, irritability, itching (especially in front of the neck and chest), apathy, anxiety, sleep disturbance, abdominal discomfort, and loss of appetite. A variety of easy-to-use, inexpensive PEFMs are available for use in the home and at school to assess changes in pulmonary function (see Patient Teaching box). In general, children 5 years of age and older are able to use a PEFM successfully. However, young children need to be supervised while they are learning to use their PEFM, and their technique should be checked frequently to ensure it is correct. Children should use the same peak flow meter over time because different brands can give significantly different values. The use of a PEFM provides objective monitoring regarding the severity of asthma and can decrease asthma episodes, health care visits, and missed school days (Burkhart, Rayens, Revelette, et al., 2007).

The family should obtain a PEFM and learn to use this device to monitor the child's asthma if the child is 5 years of age and older. A written *asthma action plan* that includes the three peak flow meter zones and the child's asthma medications may be obtained from the child's primary care provider. A home asthma action plan may reduce the risk for asthma death by 70% (Liu, Covar, Spahn, et al., 2011). Medications used for asthma exacerbations are also included in the asthma plan. This action plan should be used to make decisions about asthma management at home and at school. The nurse may assist the child and family in understanding the written action plan, emphasizing that the child and family determine the success of the plan, not the health care professionals. Teach parents how to read labels on prepared foods and snacks to determine the presence of allergens.

Children who use a nebulizer, MDI, Diskus, or Turbuhaler to deliver drugs need to learn how to use the device correctly. The MDI device delivers medication directly to the airways; therefore the child needs to learn to breathe slowly and deeply for better distribution to narrowed airways (see Patient Teaching box on. p. 1234).

PATIENT TEACHING

Instructions for Use of a Peak Expiratory Flow Meter

- Before each use, make certain the sliding marker or arrow on the PEFM points to zero or is at the bottom of the numbered scale.
- Stand up straight.
- Remove gum or any food from the mouth.
- Close your lips tightly around the mouthpiece. Be sure to keep your tongue away from the mouthpiece.
- Blow out as hard and as quickly as you can, a "fast, hard puff."
- Note the number by the marker on the numbered scale.
- Repeat entire routine 3 times; wait 30 seconds between each routine.
- Record the highest of the three readings, not the average.
- Measure the PEFR close to the same time and same way each day (e.g., morning and evening; before or 15 minutes after taking medication).
- Keep a chart of your PEFRs.

PEFM, Peak expiratory flow meter; *PEFR,* peak expiratory flow rate.

A spacer or AeroChamber device should be used with MDI inhalers. These devices allow the parent or child to deliver the medication from the MDI and slowly inhale it. Spacers also help prevent yeast infections in the mouth when corticosteroids are inhaled via an MDI (see Fig. 40-5).

The child and parents also need to be cautioned about the adverse effects of prescribed drugs and the dangers of overuse of β_2-agonists. They should know that it is important to use these drugs when needed but not indiscriminately or as a substitute for avoiding the symptom-provoking allergen.

MEDICATION ALERT

Long-acting β-adrenergic inhalers (salmeterol) should be used only as directed (usually every 12 hours) and not more frequently. They are not intended to relieve acute asthmatic symptoms.

PATIENT TEACHING

*Use of a Metered-Dose Inhaler**

Steps for Checking How Much Medicine Is in the Canister

1. If the canister is new, it is full.
2. If the canister has been used repeatedly, it might be empty. (Check product label to see how many inhalations should be in each canister.)
3. The most accurate way to determine how many doses remain in a MDI is to count and record each actuation as it is used.
4. Many dry powder inhalers have a dose-counting device or dose indicator on the canister to let you know when the canister is empty.
5. Do not place inhalers with hydrofluoroalkanes in water to determine whether doses remain; it will destroy them.

Steps for Using the Inhaler with Mouthpiece

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Attach spacer, as appropriate.
4. Tilt the head back slightly and breathe out slowly.
5. With the inhaler in an upright position, insert the mouthpiece:
   a. About 3 to 4 cm (1-1½ inches) from the mouth *or*
   b. Into the mouth, forming an airtight seal between the lips and the mouthpiece
6. At the end of a normal expiration, depress the top of the inhaler canister firmly to release the medication (into the mouth) and breathe in slowly (about 3 to 5 seconds). Relax the pressure on the top of the canister.
7. Hold the breath for at least 5 to 10 seconds to allow the aerosol medication to reach deeply into the lungs.
8. Remove the inhaler and breathe out slowly through the nose.
9. Wait 1 minute between puffs (if an additional puff is needed) when using a bronchodilator.

Steps for Using the Inhaler with an AeroChamber (see Fig. 40-5)

1. Remove the cap and hold inhaler upright.
2. Shake the inhaler.
3. Attach the AeroChamber.
4. With the inhaler in an upright position, insert the mouthpiece into the back of the AeroChamber.
5. Apply the AeroChamber mask to child's face and make sure there is a good seal.
6. Have child breathe slow, regular breaths. Depress the top of the inhaler canister firmly to release the medication (into the AeroChamber) as the child breathes slowly in and out. Relax the pressure on the top of the canister.
7. Hold the AeroChamber in place over the child's face until six breaths have been taken. Give one puff at a time.
8. Remove the inhaler and AeroChamber.
9. Wait 1 minute between puffs (if an additional puff is needed) when using a bronchodilator.

Common Problems for Children Using Inhalers

- Child refuses or resists treatment.
- Inhalation is too rapid.
- Child is unable to coordinate the spray with inhalation.
- Breath is not held long enough after inhalation.

*Inhaled dry powder such as budesonide (Pulmicort) requires a different inhalation technique. To use a dry powder inhaler, the base of the device is turned until a click is heard. It is important to close the mouth tightly around the mouthpiece of the inhaler and inhale rapidly.
MDI, Metered-dose inhaler.

The child should be protected from a respiratory tract infection that can trigger an attack or aggravate the asthmatic state, especially in young children whose airways are mechanically smaller and more reactive. Annual influenza vaccinations are recommended for all children. Pneumococcal vaccines should also be maintained. Equipment used for the child, such as nebulizers, must be kept absolutely clean to decrease the chances of contamination with bacteria and fungi.

Breathing exercises and controlled breathing are taught and encouraged for motivated children, and the nurse should provide information concerning activities that promote diaphragmatic breathing, side expansion, and improved mobility of the chest wall. Play techniques that can be used for younger children to extend their expiratory time and increase expiratory pressure include blowing cotton balls or a Ping-Pong ball on a table, blowing a pinwheel, blowing bubbles, or preventing a tissue from falling by blowing it against the wall.

Self-care and asthma self-management programs are important in helping the child and family cope with asthma. They are based on the following principles:

- Asthma is a common disease that can be controlled with appropriate drug therapy, environmental control, education, and management skills.
- It is much easier to prevent than to treat an asthma episode, and adherence to a therapeutic program is necessary to prevent exacerbations
- Children with asthma can live full and active lives.

Self-contained programs and brochures for patient education are available from the Asthma and Allergy Foundation of America* and the American Lung Association.† The National Heart, Lung, and Blood Institute‡ provides educational materials for asthma education in the school setting and also copies of the *Guidelines for the Diagnosis and Management of Asthma* for the health care practitioner (NAEPP, 2007). Another publication designed for health care practitioners, *Pediatric Asthma: Promoting Best Practice,* can be obtained from the American Academy of Allergy Asthma & Immunology.§

Support Child or Adolescent and Family. The nurse working with children with asthma can provide support in a number of ways. Many children voice frustration because their exacerbations interfere with their daily activities and social lives. Children need education on their condition and reassurance from the health care team that they can learn to control and cope with their asthma and live a normal life.

Children in disruptive family situations (divorce, separation, violence, custodial battles) may disregard their daily asthma medication

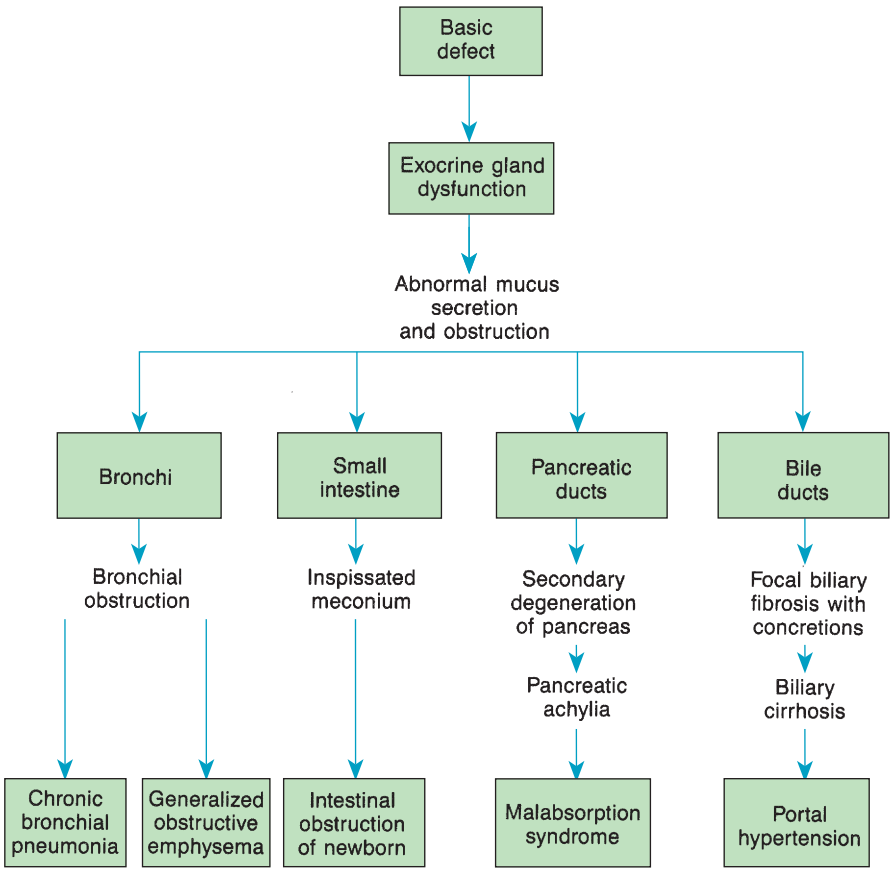

FIG 40-8 Various effects of exocrine gland dysfunction in cystic fibrosis.

regimen or may be at higher risk as a result of neglect by adults who are in charge of their care. Adolescents struggling with a sense of identity and body image often regard asthma as a condition that will "go away," especially if there is a time lapse between symptoms, and may abandon the therapeutic regimen. Referral for counseling and guidance is appropriate when the child's or adolescent's life is potentially in harm's way and the therapeutic regimen for asthma is abandoned because of personal or family crises.

The task of living day to day with affected children involves the entire family. There are periodic crises and the ever-present threat of a crisis, requiring parental vigilance; sleepless nights; frequent trips to the health care provider, ED, or hospital; and often overwhelming medical expenses. Throughout these stresses, parents are encouraged to promote as normal a life as possible for their children.

Cystic Fibrosis

Cystic fibrosis (CF) is inherited as an autosomal recessive trait; the affected child inherits the defective gene from both parents, with an overall risk of one in four if both parents carry the gene. The mutated gene responsible for CF is located on the long arm of chromosome 7. This gene codes a protein of 1480 amino acids called the **cystic fibrosis transmembrane regulator (CFTR).** The CFTR protein is related to a family of membrane-bound glycoproteins. The glycoproteins constitute a cAMP-activated chloride channel and regulate other chloride and sodium channels at the surfaces of the epithelial cells.

Pathophysiology

Cystic fibrosis is characterized by several clinical features, which are increased viscosity of mucous gland secretions, a striking elevation of sweat electrolytes, an increase in several organic and enzymatic constituents of saliva, and abnormalities in autonomic nervous system function. Although both sodium and chloride are affected, the defect appears to be primarily a result of abnormal chloride movement; the CFTR appears to function as a chloride channel. Children with CF demonstrate an increase in sodium and chloride in both saliva and sweat. This characteristic is the basis for the sweat chloride diagnostic test. The sweat electrolyte abnormality is present from birth, continues throughout life, and is unrelated to the severity of the disease or the extent to which other organs are involved.

The primary factor, and the one that is responsible for many of the clinical manifestations of the disease, is mechanical obstruction caused by the increased viscosity of mucous gland secretions (Fig. 40-8). Instead of forming a thin, freely flowing secretion, the mucous glands produce a thick mucoprotein that accumulates and dilates them. Small passages in organs such as the pancreas and bronchioles become obstructed as secretions precipitate or coagulate to form concretions in glands and ducts. The earliest postnatal manifestation of CF is often meconium ileus in the newborn, in which the small intestine is blocked with thick, puttylike, tenacious, mucilaginous meconium.

In the pancreas, the thick secretions block the ducts, eventually causing pancreatic fibrosis. This blockage prevents essential

pancreatic enzymes from reaching the duodenum, which causes marked impairment in the digestion and absorption of nutrients. The disturbed function is reflected in bulky stools that are frothy from undigested fat **(steatorrhea)** and foul smelling from putrefied protein **(azotorrhea).**

The incidence of diabetes mellitus (DM) (cystic fibrosis–related diabetes [CFRD]) is greater in children with CF than in the general population, which may be caused by changes in pancreatic architecture and diminished blood supply over time. CFRD is reported to be the most common complication associated with CF; by age 30 years, approximately 50% of people with CF will develop diabetes, which is associated with increased morbidity (sixfold) and mortality and poor lung function (O'Riordan, Dattani, and Hindmarsh, 2010). The primary characteristic of CFRD is severe insulin deficiency as a result of β-cell dysfunction; however, CFRD also may demonstrate fluctuating insulin resistance, especially during acute illness. Thus CFRD has characteristics of both type 1 DM and type 2 DM but is considered to be its own entity (Moran, Brunzell, Cohen, et al., 2010; O'Riordan, Dattani, and Hindmarsh, 2010). The positive correlation between nutritional status and optimal pulmonary function in patients with CF has been described; the presence of adequate insulin appears to be a key factor in maintaining an adequate nutritional status. Experts continue to recommend a high-fat, high-calorie diet in CF patients, and at this time there is no evidence to support a change in this diet for patients with CFRD (O'Riordan, Dattani, and Hindmarsh, 2010). Dietary guidelines are described further in the Borowitz, Baker, and Stallings (2002) and the Michel, Maqbool, Hanna, et al. (2009) references.

An uncommon gastrointestinal complication associated with CF is prolapse of the rectum, which occurs in infancy and childhood and is related to large, bulky stools; malabsorption; and increased intra-abdominal pressure secondary to paroxysmal cough. This is seen less frequently in children who receive pancreatic enzymes. Affected children of all ages are subject to intestinal obstruction from inspissated or impacted feces. Gumlike masses can obstruct the bowel and produce a partial or complete obstruction, a condition that is referred to as distal intestinal obstruction syndrome.

Pulmonary complications are present in almost all children with CF, but the onset and extent of involvement are variable. Symptoms are produced by stagnation of mucus in the airways, with eventual bacterial colonization leading to destruction of lung tissue. The abnormally viscous and tenacious secretions are difficult to expectorate and gradually obstruct the bronchi and bronchioles, causing scattered areas of bronchiectasis, atelectasis, and hyperinflation. The stagnant mucus also offers a favorable environment for bacterial growth. The most common pathogens are *Pseudomonas aeruginosa, Burkholderia cepacia, S. aureus, H. influenzae, Escherichia coli,* and *Klebsiella pneumoniae.*

The reproductive systems of both males and females with CF are affected. Females with CF have normal fallopian tubes and ovaries. Fertility can be inhibited by highly viscous cervical secretions, which act as a plug, blocking sperm entry. Women with CF who become pregnant have an increased incidence of premature labor and birth and infant low birth weight. Favorable nutritional status and pulmonary function are positively correlated with favorable pregnancy outcomes. Most men (95%) with CF are sterile, which may be caused by blockage of the vas deferens with abnormal secretions or by failure of normal development of the wolffian duct structures (vas deferens, epididymis, and seminal vesicles), resulting in decreased or absent sperm production.

Growth and development are often affected in children with moderate to severe forms of CF. Physical growth may be restricted as a result of decreased absorption of nutrients, including vitamins and fat; increased oxygen demands for pulmonary function; and delayed bone growth. The often seen pattern is one of growth failure (failure to thrive) with increased weight loss despite an increased appetite and gradual deterioration of the respiratory system. Clinical manifestations of CF are listed in Box 40-16.

BOX 40-16 CLINICAL MANIFESTATIONS OF CYSTIC FIBROSIS

Meconium Ileus*
- Abdominal distention
- Vomiting
- Failure to pass stools
- Rapid development of dehydration

Gastrointestinal Manifestations
- Large, bulky, loose, frothy, extremely foul-smelling stools
- Voracious appetite (early in disease)
- Loss of appetite (later in disease)
- Weight loss
- Marked tissue wasting
- Growth failure
- Distended abdomen
- Thin extremities
- Sallow skin
- Evidence of deficiency of fat-soluble vitamins A, D, E, and K
- Anemia

Pulmonary Manifestations
- Initial signs:
  - Wheezing respirations
  - Dry, nonproductive cough
- Eventually:
  - Increased dyspnea
  - Paroxysmal cough
  - Evidence of obstructive emphysema and patchy areas of atelectasis
- Progressive involvement:
  - Overinflated, barrel-shaped chest
  - Cyanosis
  - Clubbing of fingers and toes
  - Repeated episodes of bronchitis and bronchopneumonia

*In about 10% of cases.

Diagnostic Evaluation

Traditionally, the diagnosis of CF was based on a positive sweat chloride test result, absence of pancreatic enzymes, radiography, COPD, and family history. Newer diagnostic methods make it possible to diagnose CF early in infancy so therapies can be implemented to increase the child's overall survival and quality of life. In addition to the sweat chloride test and factors just listed, diagnosis may be confirmed by any one of the following: newborn screening, DNA identification of mutant genes, and abnormal nasal potential difference measurement.

Universal newborn screening for CF is now required by law or rule in all of the continental United States, Hawaii, and Alaska (National Newborn Screening and Genetics Resource Center, 2013). The newborn screening test consists of an immunoreactive trypsinogen (IRT) analysis performed on a dried spot of blood, which may be followed by direct analysis of DNA for the presence of the ΔF508 mutation or other mutations on the same dried blood spot. Benefits of early screening and detection include earlier nutritional intervention for identified infants; disadvantages include the parental anxiety false-positive results may generate. Children who were identified and treated early in infancy with aggressive nutritional support had improved height and weight well into adolescence.

Although the technology is available to conduct carrier screening for the general population, this issue remains controversial, and widespread implementation of carrier screening programs is not recommended. An in utero diagnosis of CF is also possible based on detection of two CF mutations in the fetus.

The consistent finding of abnormally high sodium and chloride concentrations in the sweat is a unique characteristic of CF. Parents may report that their infant tastes "salty" when they kiss him or her. The quantitative sweat chloride test (pilocarpine iontophoresis) involves stimulating the production of sweat with a special device (involves stimulation with 3-mA electric current), collecting the sweat on filter paper, and measuring the sweat electrolytes. The quantitative analysis requires a sufficient volume of sweat (>75 mg). Two separate samples are collected to ensure the reliability of the test for any individual. Normally, sweat chloride content is less than 40 mEq/L, with a mean of 18 mEq/L. A chloride concentration greater than 60 mEq/L is diagnostic of CF; in infants younger than 3 months, a sweat chloride concentration greater than 40 mEq/L is highly suggestive of CF. In some situations, DNA testing may be substituted for the sweat test. The presence of a mutation known to cause CF on each CFTR gene predicts with a high degree of certainty that the individual has CF; however, multiple CFTR mutations may also be present and detected with DNA assay. More than 1800 different mutations have been found on the CF gene.

Chest radiography reveals characteristic patchy atelectasis and obstructive emphysema. PFTs are sensitive indexes of lung function, providing evidence of abnormal small airway function in CF. Other diagnostic tools that may aid in diagnosis include stool fat or enzyme analysis. Stool analysis requires a 72-hour sample with accurate recording of food intake during that time. Radiographs, including a contrast (dye) enema, are used for diagnosis of meconium ileus.

Therapeutic Management

Improved survival among patients with CF during the past 2 decades is attributable largely to antibiotic therapy and improved nutritional and respiratory management. Goals of CF therapeutic management are to (1) prevent or minimize pulmonary complications, (2) ensure adequate nutrition for growth, (3) encourage appropriate physical activity, and (4) promote a reasonable quality of life for the child and the family. A multidisciplinary approach to treatment is needed to accomplish these goals.

Management of Pulmonary Problems. Management of pulmonary problems is directed toward prevention and treatment of pulmonary infection by improving ventilation, removing mucopurulent secretions, and administering antimicrobial agents. Many children develop respiratory symptoms by 3 years of age. The large amounts and viscosity of respiratory secretions in children with CF contribute to the likelihood of respiratory tract infections. Recurrent pulmonary infections in children with CF result in greater damage to the airways; small airways are destroyed, causing bronchiectasis.

The most common pathogens responsible for pulmonary infections are *P. aeruginosa, B. cepacia, S. aureus, H. influenzae, E. coli,* and *K. pneumoniae. P. aeruginosa* and *B. cepacia* are particularly pathogenic for children with CF, and infections with these organisms are difficult to clear from the system. In addition, children with CF who are chronically colonized with these organisms have poorer survival rates than children who are not colonized. Colonization and infection with methicillin-resistant *S. aureus* (MRSA) has recently emerged as a critical factor in lung infection and pulmonary function in patients with CF. Patients with MRSA require longer hospitalization and multiple antibiotic regimens (Ren, Morgan, Konstan, et al., 2007). Fungal colonization with *Candida* or *Aspergillus* organisms in the respiratory tract is also common in patients with CF.

Until recently, CPT has been the cornerstone of airway clearance; however, other airway clearance therapies (ACTs) have replaced this modality; these treatments often require more active involvement by the patient (Newton, 2009). The ACTs include the following: percussion and postural drainage, positive expiratory pressure (PEP), active-cycle-of-breathing technique, autogenic drainage, oscillatory PEP, high-frequency chest compressions (HFCC), and exercise. Studies have demonstrated that no particular ACT has any advantage over the other in relation to outcomes of sputum production; however, it is recommended that individualized assessment occur to determine the best ACT for each patient (Flume, Robinson, O'Sullivan, et al., 2009). It is not within the scope of this chapter to discuss the many different ACTs.

Airway clearance therapies such as percussion and postural drainage are usually performed on average twice daily (on rising and in the evening) and more frequently if needed, especially during pulmonary infection. The Flutter mucus clearance device is a small handheld plastic pipe with a stainless-steel ball on the inside that facilitates removal of mucus. It has the advantage of increasing sputum expectoration and being used without an assistant. Handheld percussors may be used to loosen secretions. Another method to clear mucus is high-frequency chest compression in which the child temporarily wears a mechanical vest device that provides high-frequency chest wall oscillation. Some children and adolescents with an implantable port may experience localized pain with the vest.

Patients with CF have been found to regress when conventional percussion and postural drainage is discontinued. Forced expiration, or "huffing," with the glottis partially closed helps move secretions from the small airways so that subsequent coughing can move secretions forcefully from the large airways. Several studies indicate that this maneuver enhances the pulmonary function of patients with CF. Autogenic drainage involves a variety of breathing techniques, which older children can use to force mucus in lower lobes up into the airways so it can be successfully expelled. Another mucus-clearing technique involves use of a positive expiratory pressure mask; this technique involves breathing into a mask attached to a one-way valve, which creates resistance—as the patient exhales, the airway is kept open by the pressure and mucus is forced into the upper airway for expulsion.

Bronchodilator medication delivered in an aerosol opens bronchi for easier expectoration and is administered before percussion and postural drainage when the patient exhibits evidence of reactive airway disease or wheezing. Another aerosolized medication is recombinant human deoxyribonuclease (DNase, known generically as *dornase alfa* [Pulmozyme]), which decreases the viscosity of mucus. It is well tolerated and has no major adverse effects; minor reactions are voice alterations and laryngitis. This medication, given daily via nebulization generally before or with percussion and postural drainage, has resulted in improvements in spirometry, PFTs, dyspnea scores, and perceptions of well-being and has reduced the viscosity of sputum.

Nebulized hypertonic saline (6%-7%) has been shown to be effective in improving airway hydration and increases mucus clearance in patients with CF; this treatment, however, causes bronchospasm and may not be recommended for patients with severe disease (Redding, 2009).

Physical exercise is an important adjunct to daily ACT. Exercise stimulates mucus excretion and provides a sense of well-being and increased self-esteem. Any aerobic exercise that the patient enjoys should be encouraged. The ultimate aim of exercise is to increase

lung vital capacity, remove secretions, increase pulmonary blood flow, and maintain healthy lung tissue for effective ventilation.

Pulmonary infections are treated as soon as they are recognized. In patients with CF, characteristic signs of pulmonary infection—fever, tachypnea, and chest pain—may be absent; therefore a careful history and physical examination are essential. The presence of anorexia, weight loss, and decreased activity alerts the practitioner to pulmonary infection and the need for an antibiotic regimen. Aerosolized antibiotics such as tobramycin, ticarcillin, and gentamicin are beneficial for patients with frequent pulmonary exacerbations (Redding, 2009).

Intravenous antibiotics may be administered at home as an alternative to hospitalization. The use of peripherally inserted central catheters (PICCs) for the administration of antibiotics in children with CF is a viable option with limited complications and fewer needle punctures to obtain blood specimens and to maintain often lengthy treatment with parenteral antibiotics. Alternatively, an implanted port offers the advantage of access for blood draws and antibiotic infusion. When pulmonary function does not improve with outpatient management, hospitalization may be recommended for continued antibiotic therapy and vigorous postural drainage. Some health care practitioners hospitalize patients for IV antibiotic therapy and percussion and postural drainage periodically (a "tune up) to keep them well; others may be treated on an outpatient basis. Oxygen administration is used for children with acute episodes but must be used cautiously because many children with CF have chronic carbon dioxide retention, and the unsupervised use of oxygen can be harmful. With repeated infection and inflammation, bronchial cysts and emphysema may develop. These cysts may rupture, resulting in a pneumothorax.

! NURSING ALERT

Signs of a pneumothorax are usually nonspecific and include tachypnea, tachycardia, dyspnea, pallor, and cyanosis. A subtle drop in oxygen saturation (measured by pulse oximetry) may be an early sign of pneumothorax.

Children with a specific CF mutation (G551D) may benefit by taking ivacaftor (Kalydeco). This CF transmembrane conductance regulator (CFTR) modulator allows salt and fluid to move through the airways and prevent the buildup of thick mucus in the airways, with concomitant improvement of pulmonary function. This drug was recently approved by the FDA for children over 6 years of age (Pettit, 2012).

Blood streaking of the sputum is usually associated with increased pulmonary infection and often requires no specific treatment. Hemoptysis greater than 250 mL/24 hr for an older child (less for a younger child) indicates a potentially life-threatening event and needs to be treated immediately. Sometimes bleeding can be controlled with bed rest, IV antibiotics, replacement of acute blood loss, IV conjugated estrogens (Premarin) or vasopressin (Pitressin), and correction of any coagulation defects with vitamin K or fresh-frozen plasma. If hemoptysis persists, the site of bleeding should be localized via bronchoscopy and cauterized or embolized.

Treatment of nasal polyps includes intranasal corticosteroids, oral antihistamines, and decongestants. If these measures are ineffective, surgical interventions such as cauterization may be necessary.

Because pulmonary damage in patients with CF is believed to be caused by the inflammatory process that occurs with frequent infections, the use of corticosteroids has been studied; however, treatment with corticosteroids for prolonged periods has been associated with linear growth restriction, glucose tolerance abnormalities, and cataract formation. Antiinflammatory medications such as ibuprofen are becoming more important in the treatment of CF, but careful monitoring for adverse effects (gastrointestinal bleeding) is essential.

Management of Gastrointestinal Problems. The principal treatment for **pancreatic insufficiency** is replacement of pancreatic enzymes, which are administered with meals and snacks to ensure that digestive enzymes are mixed with food in the duodenum. Enteric-coated products prevent the neutralization of enzymes by gastric acids, thus allowing activation to occur in the alkaline environment of the small bowel. The amount of enzymes depends on the severity of the insufficiency, the child's response to enzyme replacement, and the health care practitioner's philosophy. Usually one to five capsules (or 2500 lipase units per kg) are administered with a meal, and a smaller amount is taken with snacks. Capsules can be swallowed whole or taken apart and the contents sprinkled on a small amount of food to be taken at the beginning of the meal. The amount of enzyme is adjusted to achieve normal growth and a decrease in the number of stools to one or two per day. Pancreatic enzymes should be taken within 30 minutes of eating. The enteric-coated beads should not be chewed or crushed because destroying the enteric coating can lead to inactivation of the enzymes and excoriation of oral mucosa. The powder form should be used cautiously because inhalation of the powder may precipitate acute bronchospasm and, if mixed with food, predigests the food, making it unpalatable.

Children with CF require a well-balanced, high-protein, high-caloric diet (because of their impaired intestinal absorption). In fact, they often require up to 150% of the recommended daily allowances to meet their needs for growth. Breastfeeding with enzyme supplementation should be continued whenever possible for parents who prefer this method and, when necessary, supplemented with a higher-calorie-per-ounce formula. For formula-fed infants, commercial cow's milk–based formulas are usually adequate, although frequently a partial hydrolysate formula with medium-chain triglycerides (e.g., Pregestimil, Alimentum) may be recommended. Enzymes are mixed into cereal or fruit, such as applesauce. Because the uptake of fat-soluble vitamins is decreased, water-miscible forms of these vitamins (A, D, E, and K) are given along with multivitamins and the enzymes. When high-fat foods are eaten, the child is encouraged to add extra enzymes. Growth failure despite adequate nutritional support may indicate deterioration of pulmonary status. Patients with CF may experience frequent anorexia as a result of the copious amounts of mucus produced and expectorated, persistent cough, effect of medications, fatigue, and sleep disruption. They may be placed on nighttime supplemental gastrostomy or nasogastric tube feedings or, rarely, parenteral alimentation in an effort to build up nutritional reserves if there has been a history of inability to maintain weight.

Meconium ileus and meconium ileus equivalent, or total or partial intestinal obstruction, can occur at any age. Constipation is often the result of a combination of malabsorption (either from inadequate pancreatic enzyme dosage or a failure to take the enzymes), decreased intestinal motility, and abnormally viscous intestinal secretions. These problems usually do not require surgical intervention and may be treated with GoLYTELY or Colyte (osmotic solutions given orally or by nasogastric tubes), other laxatives, stool softeners, or rectal administration of meglumine diatrizoate (Gastrografin).

Rectal prolapse occurs only in a small number of individuals; fewer are affected as result of early diagnosis and administration of

pancreatic enzymes (Egan, 2011). The first episode of rectal prolapse is frightening to both the parents and child. Its reduction usually requires immediate guidance and intervention, which is managed by simply guiding the rectum back into place with a gloved, lubricated finger. Further management usually involves attempting to decrease the bulk of daily stools through enzyme replacement.

Children with CF often experience transient or chronic gastroesophageal reflux, which should be treated with the appropriate histamine-receptor antagonist and gastrointestinal motility drug, dietary modifications, and an upright position after feedings and meals (Hazle, 2010).

Management of Endocrine Problems. The management of CFRD is critical in the therapeutic treatment of the child with CF. CFRD presents a combination of insulin resistance and insulin deficiency, with unstable glucose homeostasis in the presence of acute lung infection and treatment. Children with CFRD require close monitoring of blood glucose, administration of oral glucose-lowering agents or insulin injections, and diet and exercise management; children with CF may be at increased risk for glucose management problems as a result of decreased nutrient absorption, anorexia, and severity of pulmonary illness. The prevalence of CFRD increases with age, and there is increased morbidity and mortality among children with CFRD compared with those without. Microvascular complications such as retinopathy and nephropathy may occur in children and adolescents with CFRD (O'Riordan, Dattani, and Hindmarsh, 2010). However, ketoacidosis is reported to be rare in individuals with CFRD (Egan, 2011). Children with CFRD should perform **self–blood glucose monitoring (SBGM)** 3 times daily and should be on an insulin regimen. Target glucose levels should be the same as for any other patient with diabetes. There is no evidence that oral glycemic agents are effective. During acute CF exacerbations, the nondiabetic child should be monitored closely for hyperglycemia; glycosylated hemoglobin is reportedly a poor predictor of CFRD, so an oral glucose tolerance test is the preferred screening tool (Moran, Brunzell, Cohen, et al., 2010).

Bone health is of concern in children and adults with CF. The pancreatic insufficiency of CF and chronic steroid use present potential risks for less-than-optimum bone growth in such children. Assessment of bone health by history and bone mass density evaluation should be considered in assessing the child's (8 years old and older) health status to detect and prevent osteoporosis and osteopenia.

Prognosis. The median predicted survival age for the patient with CF in 2009 was 37.4 years, and approximately 45% of patients are 18 years old and older (Cystic Fibrosis Foundation, 2011). Lung, heart, pancreas, and liver transplantation have increased survival rates among some patients with CF. Heart-lung and double-lung transplants have been successfully performed in children with advanced pulmonary vascular disease and hypoxia. The obstacles surrounding this technique are availability of donated organs; complications from surgery; pulmonary infections; and recurrence of obstructive bronchiolitis, which decreases transplanted lung function.

Despite considerable progress and a recent surge in new treatment modalities, CF remains a progressive and incurable disease. The pulmonary involvement ultimately determines the patient's outcome because pancreatic enzyme deficiency is less of a problem if adequate nutrition is ensured. With advances in technology, parents and adolescents are challenged to set future goals that may include college, careers, social relationships, and marriage. Concurrently, they are faced with increasing morbidity and higher rates of CF complications as they grow older.

CARE MANAGEMENT

Assessment of the child with CF involves both pulmonary and gastrointestinal observations. Pulmonary assessment is the same as that described for asthma, with special attention to lung sounds, observation of cough, and evidence of decreased activity or fatigue. Gastrointestinal assessment primarily involves observing the frequency and nature of the stools and abdominal distention. The observer is also alert to evidence of growth failure (e.g., weight loss, muscle wasting, pallor, anorexia, decreased activity [from baseline norm]). Family members are interviewed to determine the child's or adolescent's eating and eliminating habits and to confirm a history of frequent respiratory tract infections or bowel obstruction in infancy.

The nurse assesses the newborn for feeding and stooling patterns, which may indicate a potential problem such as meconium ileus. The nurse also participates in diagnostic testing such as the initial newborn screening, IRT, DNA analysis, or sweat chloride test.

Parents are often anxious and puzzled about the diagnostic tests and the possible implications of the test results. They need careful explanations of the disease, how it might affect their family, and what they can do to provide the best possible care for their child. It is crucial to involve the parents in the follow-up for early diagnostic testing; the neonate may require several follow-up visits in the first few weeks of life if initial test results are not conclusive.

The uncertainty, fear, and initial shock associated with the diagnosis are overwhelming to parents. They must face the impact of the chronic, life-threatening nature of the disease and the prospect of intensive treatment, for which they must assume a major part of the responsibility and for which they are ill prepared. They often fear that they will be unable to provide the care the child needs.

Hospital Care. Most patients with CF require hospitalization only for treatment of pulmonary infection, uncontrolled diabetes, or a coexisting medical problem that cannot be treated on an outpatient basis. Therefore, when patients with CF are hospitalized, Standard Precautions with meticulous hand washing should be implemented to decrease the health care–associated infection (HAI) spread of organisms to the CF patient and among other hospitalized CF patients (especially when MRSA is prevalent). Contact Precautions may be required for specific infections.

When the child with CF is hospitalized for diagnosis or treatment of pulmonary complications, aerosol therapy, percussion, and postural drainage are instituted or continued. Respiratory therapists often initiate, supervise, and provide these treatments; however, it is the nurse's responsibility to monitor the patient's tolerance to the procedure and evaluate the effectiveness of the procedure in relation to treatment goals. The nurse may at times administer aerosol therapy, perform chest percussion and postural drainage, assist with ACTs such as the mechanical vest, and teach breathing exercises. Chest percussion and postural drainage should not be performed before or immediately after meals. Planning percussion and postural drainage so it does not coincide with meals is difficult in the hospital situation but is essential to the effectiveness of this treatment.

Nursing assessments, including observation of respiratory pattern, work of breathing, and lung auscultation, are vital assessments. Noninvasive pulse oximetry provides valuable data about the patient's oxygenation status. Supplemental oxygen therapy is administered to the child with mild or moderate respiratory distress, and the child requires frequent assessment of the tolerance to the procedure.

One of the nursing challenges in the care of the child with CF is encouraging compliance with the therapeutic medication regimen,

which often involves a significant number of medications—pancreatic enzymes; vitamins A, D, E, and K; oral antifungals for *Candida* infection; antihistamines; antiinflammatory agents; and oral antibiotics. This may be overwhelming to the child. Factor in multiple inhaled bronchodilators, ACTs and postural and aerosol treatments, blood glucose monitoring and insulin administration, various other medications, and increased mucus production during the acute phase, and it is common for the child with CF to rebel and be noncompliant with this regimen. Gentle coaxing, positive reinforcement, and frank negotiation may be required to enlist cooperation for effective medication compliance.

The diet for the child with CF represents another challenge; careful planning with a pediatric dietitian and the child's input may help decrease the loss of appetite and weight loss that are often part of the condition. Children in the early stages of CF often have a good appetite. With infection and increased lung involvement, their appetite diminishes, and eventually it becomes a challenge to tempt failing appetites. When dietary intake fails to meet the child's needs for growth, enteral feedings or supplements may be considered. These feedings may be administered via a gastrostomy tube during the night to minimize the disruption of daily activities, including school. A skin-level feeding gastrostomy affords the child few activity restrictions and minimal disruption of body image compared with a nasogastric tube or conventional gastrostomy tube. The child and parents are encouraged to not perceive this therapy as a last-ditch effort but as an adjunct therapy to maintain optimum growth and prevent excessive weight loss. Some children have a nasogastric tube placed before bedtime and receive enteral feeds overnight, removing the tube in the morning so that it does not interfere with regular activities.

The child or adolescent needs support during the many treatments and tests that are a part of the hospitalization. IV fluids, IV antibiotics and antifungals, PICC line placement or port accessing, and blood tests are almost always a part of the acute care treatment, and the child soon associates hospitalization with these stress-provoking procedures.

Depression, anxiety, and disturbed self-image may occur in children and adolescents with CF; older adolescents and young adults with severe symptoms may be especially prone to depression as a result of the realization of the poor prognosis and the reality of unmet life expectations and goals.

Providing support to both the child and the family is essential. Skilled nursing care and sympathetic attention to the emotional needs of the child and family help them cope with the stresses associated with repeated respiratory tract infections and hospitalizations.

The care of the child or adolescent who is immobilized as a result of CF requires the same care and attention as the child with immobility from any other chronic or acute illness, including skin care, bowel management, passive range of motion, and positioning.

Home Care. Most children and adolescents with CF can be managed at home. The goals of care include normalization and daily activities, including school and peer involvement. The care plan should be flexible so that family activities are disrupted as little as possible. Parents may initially require assistance finding and contacting durable medical equipment companies that will provide home care equipment. They also need opportunities to learn how to use the equipment and to solve problems they may encounter while delivering therapy at home. A home health care provider may be required for assistance with the many medications required for maintenance of the condition, and total parenteral nutrition may also be provided through a home health care provider. Care coordination is an important nursing role in the care of the child and adolescent with CF; as adolescents transition to adulthood, the primary care by one physician may cease to exist and the individual may have to consult multiple specialists to deal with the multiorgan problems often experienced; the care coordinator has an important role in assisting the adolescent and family with this aspect of care.

Patients and family members need education about the preferred diet of nutritious meals with tolerated fat, increased protein and carbohydrate, and the administration of pancreatic enzymes. For infants and young children, the enzymes can be mixed with pureed fruit, such as applesauce, and fed with a spoon. Capsules are usually suitable for older children. It is important to stress to parents that the enzymes, in the amount regulated to the child's needs, should be administered at the beginning of all meals and snacks. For enteral feeds administered overnight, enzymes are generally administered at the start and finish of the feeds.

One of the most important aspects of educating parents for home care is teaching techniques for the removal of mucus (ACT, vest, forced expiration) and breathing exercises. The success of a therapy program depends on conscientious performance of these treatments regularly as prescribed. The number of times these therapies are performed each day is determined on an individual basis, and often parents readily learn to adjust the number and intensity of the treatments to the child's needs. For pulmonary infection, home IV antibiotics may be prescribed pending verification of insurance coverage and availability of an agency with adequate staff to perform multiple daily home antibiotic infusions. With use of the venous access devices, such as PICC lines, and implanted ports, the parents and child can be taught the technique of direct administration into the IV line.

Families also need information about medications and possible side effects. Children receiving multiple antibiotics may require serum drug levels to ensure therapeutic dosing.

If the child has CFRD, education on SBGM, insulin therapy, diet control, and possible complications related to this is needed. Follow-up with a pediatric endocrinologist is recommended.

Children and adolescents with CF should receive routine primary care with special attention to diet, growth and development, and immunizations. Primary care providers should be alert to any weight loss or flattening in the growth curve associated with loss of appetite, which could indicate a pulmonary exacerbation in children with CF. Anticipatory guidance concerning issues of discipline, how to incorporate aspects of the treatment regimen into the school environment, and delayed pubertal development are also important considerations for the primary care provider.

Home palliative care for the child or adolescent with CF who is in the terminal stages may be carried out with the assistance of palliative care or hospice as appropriate (see Chapter 36).

The nurse can assist the family in contacting resources that provide help to families with affected children. Various special child health services, many local clinics, private agencies, service clubs, and other community groups often offer equipment and medications either free or at reduced rates. The Cystic Fibrosis Foundation*

*6931 Arlington Road, Bethesda, MD 20814-3205; 301-951-4422 or 800-FIGHT CF; www.cff.org. In Canada: Canadian Cystic Fibrosis Foundation, 2221 Yonge St., Suite 601, Toronto, Ontario, Canada M4S 2B4; 800-378-2233 (toll free in Canada only); www.cysticfibrosis.ca. For information about specialized medications, especially dornase alfa, and equipment for CF and other pulmonary diseases, contact the Cystic Fibrosis Services Pharmacy, 6931 Arlington Road, 2nd floor, Bethesda, MD; 800-541-4959; www.cfservicespharmacy.com.

has chapters throughout the United States that provide education and services to families and professionals.

Family Support. One of the most challenging aspects of providing care for the family of a child or adolescent with CF is meeting the emotional needs of the child and family. The diagnosis, treatment, and prognosis for CF are often associated with many problems and frustrations. The diagnosis can evoke feelings of guilt and self-recrimination in parents.

The long-range problems for an infant, child, or adolescent with CF are those encountered in any chronic illness (see Chapter 36). Both the child and the family must make many adjustments, the success of which depends on their ability to cope and on the quality and quantity of support they receive from outside sources. It is often the nurse who assesses the home situation, organizes and coordinates these services, and collects the data needed to evaluate the effectiveness of the services.

The persistent need for treatment several times a day places tremendous strain on the family. When the child is young, a family member must perform postural drainage and other ACTs. Children often balk at these treatments, and the parents are placed in the position of insisting on adherence. The stress and anxiety related to this routine may produce feelings of resentment in both the child and the family members. When possible, occasional trusted respite care should be available to allow parents to leave the situation for short periods without undue anxiety about the child's welfare.

The affected child or adolescent may become resentful about the disease, its relentless routine of therapy, and the necessary curtailment it places on activities and relationships. The child's activities are interrupted or built around treatments, medications, and diet. This imposes hardships and influences the child's quality of life. The child should be encouraged to attend school, seek employment when old enough, and join age-appropriate peer groups to foster a life that is as normal and productive as possible. Sports are often an important part of the child's and adolescent's life; interaction with peers includes valuable life experiences, especially to adolescents. The child or adolescent with CF should be encouraged to participate in sports activities in as much as physical and pulmonary health allows. Exercise is encouraged to increase pulmonary vital capacity, promote muscle development, and enhance cardiovascular function.

As the disease progresses, however, family stress should be expected and the patient may become angry and may resist medical therapy. It is important for the nurse to recognize the family's changing needs and the grief they may experience as the CF worsens. Families should be made aware of resources for counseling. Patients need to be guided into activities that enable them to express anger, sorrow, and fear without guilt.

Transition to Adulthood. As life expectancy continues to rise for children and adolescents with CF, issues related to marriage, sexuality, childbearing, and career choice become more pressing. Male patients must be informed at some point that they will often be unable to produce offspring. It is important that the distinction be made between sterility and impotence. Normal sexual relationships can be expected. Female patients may be able to bear children but should be informed of the possible deleterious effects on the respiratory system created by the burden of pregnancy. They also need to know that their children will be carriers of the CF gene. Adolescent females may need counseling concerning the use of oral contraceptives and other contraceptive options (Hazle, 2010).

Adolescents with CF are encouraged to take personal ownership and management of the illness to maximize their life's potential. Many adolescents and young persons with the illness enroll in college or vocational and technical training school and complete degrees either by distance learning or by attending a local school. Young people are encouraged to set life goals and live normal lives to the extent their illness allows.

Anticipatory grieving and other aspects related to care of a child with a terminal illness are also part of nursing care. For example, it is important to prepare the child and family members for end-of-life decisions and care when appropriate.

Obstructive Sleep-Disordered Breathing

Pediatric obstructive sleep-disordered breathing reportedly affects between 10% and 12% of children ages 2 to 8 years; **obstructive sleep apnea syndrome (OSAS)** may occur in as many as 2% of all children (Benninger and Walner, 2007b). Others report OSAS incidence of 1.2% in elementary school–age children (Bixler, Vgontzas, Lin, et al., 2009). Obstructive sleep-disordered breathing is said to form a continuum of sleep-disordered breathing ranging from partial obstruction of the upper airway to continuous episodes of complete upper airway obstruction, with the most severe form being OSAS (Benninger and Walner, 2007b). OSAS is defined by the American Thoracic Society (1996) as a disorder of breathing during sleep with prolonged partial upper airway obstruction or complete obstruction that disrupts normal respiration during sleep and normal sleep patterns. Common symptoms include habitual snoring, interrupted or disturbed sleep patterns, enuresis, and daytime neurobehavioral problems (AAP, 2012). OSAS is to be distinguished from primary snoring, which is snoring without obstructive apnea, frequent sleep arousals, or abnormalities in gas exchange. Children with OSAS usually do not exhibit daytime sleepiness as do adults, with the possible exception of obese children. If left untreated, obstructive sleep-disordered breathing may result in complications such as failure to thrive, cardiovascular problems, hypertension, poor learning, and neurobehavioral problems such as attention deficit hyperactivity disorder (AAP, 2012).

The diagnosis of obstructive sleep-disordered breathing is made by an overnight in-laboratory sleep study (polysomnography), which provides evidence of sleep disturbance, respiratory pauses, and changes in oxygenation. The six-channel polysomnography can be performed in children of all ages with videotaping or audiotaping, and abbreviated (vs. full night sleep study) polysomnography, nocturnal oximetry, or daytime nap polysomnography may be useful; however, these latter methods do not predict the severity of OSAS (AAP, 2012). Polysomnography can distinguish between OSAS and primary snoring (Owens, 2011).

The most recent AAP clinical practice guideline recommends adenotonsillectomy for OSAS as long as the child has no contraindications for surgery (AAP, 2012). Evidence indicates that tonsillectomy or adenoidectomy alone may not be sufficient to resolve OSAS because residual lymphoid tissue may contribute to continual obstruction (AAP, 2012). Complications of these surgical interventions are discussed previously in this chapter. The AAP (2012) recommends that high risk patients undergoing adenotonsillectomy be monitored as inpatients postoperatively for complications. CPAP may be helpful in older children with sleep-disordered breathing whose condition persists after surgical intervention. CPAP is a long-term therapy with frequent assessments to evaluate the required amount of pressure and the overall effectiveness of the intervention. The most recent AAP guidelines (2012) also recommend the use of topical intranasal corticosteroids for children with mild OSAS (defined as an apnea hypopnea index [AHI] of less than 5 per hour).

Surgical interventions such as tracheotomy may be required for children with craniofacial syndromes, such as Goldenhar, Pierre Robin, Apert, and Crouzon syndromes, in which there is partial or complete upper airway obstruction.

Nursing care of the child with sleep-disordered breathing involves early detection by observation of the infant's or child's sleep patterns and active participation in the diagnostic polysomnography. Important nursing roles are inserting the pH probe into the esophagus, ensuring accurate placement by radiography, and monitoring the sleep study and the patient's response to diagnostic therapy. Counseling families of children with sleep-disordered breathing may involve dietary counseling for exercise programs and weight management, use of the CPAP equipment, and direct postoperative care after the surgical intervention of tonsillectomy or adenoidectomy. Some children may resist wearing CPAP devices and will need encouragement to do this. The nurse can be instrumental in helping the child and family cope with the chronic illness diagnosis if intervention such as CPAP is required.

RESPIRATORY EMERGENCY

Respiratory Failure

Effective pulmonary gas exchange requires clear airways, normal lungs and chest wall, and adequate pulmonary circulation. Anything that affects these functions or their relationships can compromise respiration. In general, the term respiratory insufficiency is applied to two situations: (1) when there is increased work of breathing but gas exchange function is near normal; and (2) when normal blood gas tensions cannot be maintained and hypoxemia and acidosis develop secondary to carbon dioxide retention.

Respiratory failure is defined as the inability of the respiratory apparatus to maintain adequate oxygenation of the blood with or without carbon dioxide retention. This process involves pulmonary dysfunction that generally results in impaired alveolar gas exchange, which can lead to hypoxemia or hypercapnia. Respiratory failure is the most common cause of cardiopulmonary arrest in children. Respiratory arrest is the complete cessation of respiration. **Apnea** is the cessation of breathing for more than 20 seconds or for a shorter period when associated with hypoxemia or bradycardia. Apnea can be (1) central, in which respiratory efforts are absent; (2) obstructive, in which respiratory efforts are present; and (3) mixed, in which both central and obstructive components are present (see Apparent Life-Threatening Event, Chapter 31) Respiratory dysfunction may have an abrupt or an insidious onset. Respiratory failure can occur as an emergency situation or may be preceded by gradual and progressive deterioration of respiratory function. Most clinical manifestations are nonspecific and are affected by variations among individual patients and differences in the severity and duration of inadequate gas exchange.

Diagnostic Evaluation

The diagnosis of respiratory failure is determined by the combined application of three sources of information:

1. Presence or history of a condition that might predispose the patient to respiratory failure
2. Observation of respiratory failure
3. Measurement of ABGs and pH

Nursing observation and judgment are vital to the recognition and early management of respiratory failure. Nurses must be able to assess a situation and initiate appropriate action within moments. Signs of respiratory failure are listed in Box 40-17.

BOX 40-17 CLINICAL MANIFESTATIONS OF RESPIRATORY FAILURE

Cardinal Signs
- Restlessness
- Tachypnea
- Tachycardia
- Diaphoresis (except in neonates)

Early But Less Obvious Signs
- Mood changes such as euphoria or depression
- Headache
- Altered depth and pattern of respirations
- Hypertension
- Exertional dyspnea
- Anorexia
- Increased cardiac output and renal output
- Central nervous system symptoms (decreased efficiency, impaired judgment, anxiety, confusion, restlessness, irritability, depressed level of consciousness)
- Nasal flaring
- Chest wall retractions
- Expiratory grunt
- Wheezing or prolonged expiration

Signs of More Severe Hypoxia
- Hypotension or hypertension
- Dimness of vision
- Somnolence
- Stupor
- Coma
- Dyspnea
- Depressed respirations
- Bradycardia
- Cyanosis, peripheral or central

Therapeutic Management

The interventions used in the management of respiratory failure are often dramatic, requiring special skills and emergency procedures. If respiratory arrest occurs, the primary objectives are to recognize the situation and immediately initiate resuscitative measures, such as airway positioning, administration of oxygen, cardiopulmonary resuscitation (CPR), suctioning, CPAP or BiPAP, or intubation. When the situation is not an arrest, the suspicion of respiratory failure is confirmed by assessment; the severity may be defined by ABG analysis. Interventions such as administering supplemental oxygen, positioning, stimulation, suctioning, and early intubation may avert an arrest. When the severity is established, an attempt is made to determine the underlying cause by thorough evaluation.

The principles of management are to (1) maintain ventilation and maximize oxygen delivery, (2) correct hypoxemia and hypercapnia, (3) treat the underlying cause, (4) minimize extrapulmonary organ failure, (5) apply specific and nonspecific therapy to control oxygen demands, and (6) anticipate complications. Monitoring the patient's condition closely is critical.

CARE MANAGEMENT

For families whose child has a respiratory arrest, support is aimed at keeping the family informed of the child's status and helping them cope with a near-death experience or an actual death (see Chapter 36). Knowing that their child requires CPR is a frightening and often overwhelming experience for parents. Uncertainty regarding the outcome—both mortality and morbidity—is a primary concern. Traditionally, family members are not allowed to be present during resuscitation efforts in the ED. However, studies indicate that family presence during emergencies alleviates the family's anger about being separated from the patient during a crisis, reduces their anxiety, eliminates doubts about what was done to help the patient, and facilitates the grieving process if the patient dies (Mangurten, Scott, Guzzetta, et al., 2006).

Regardless of whether an institution permits parental presence during CPR, nurses must consider the needs, fears, and concerns of family members during this situation. If family presence is not permitted, nurses should arrange for someone to remain with the family during CPR. After the child's recovery or death, the family will continue to need support and thorough medical information regarding lifesaving measures, the prognosis if the child survives, and the cause of death if the child dies.

KEY POINTS

- Acute infection of the respiratory tract is the most common cause of illness in infancy and childhood.
- The incidence and severity of respiratory tract infections are influenced by the infectious agents involved, the child's age, and the child's natural defenses.
- Common respiratory tract infections of childhood include nasopharyngitis, pharyngitis (including tonsillitis), influenza, infectious mononucleosis, and AOM.
- Croup syndromes involve acute inflammation and variable degrees of obstruction of the epiglottis, larynx, or trachea.
- The primary goals in the care of children with croup are observation for signs of respiratory distress and relief of laryngeal inflammation.
- Common infections of the lower airways are bacterial tracheitis, bronchitis, and RSV-bronchiolitis.
- Pneumonias are classified according to site (lobar, bronchial, or interstitial) or by etiologic agent (viral, bacterial, or mycoplasmal) or are associated with aspiration of foreign material.
- In TB, susceptibility to the bacillus can be influenced by heredity, age, stress, poor nutrition, and intercurrent infection.
- Secondhand smoke exposure is a major environmental pollutant contributing to respiratory illness in children.
- Asthma is the leading cause of chronic illness in children.
- General therapeutic management of asthma includes assessment of asthma severity, allergen control, drug therapy, symptom management, and sometimes hyposensitization.
- Support for the family of the child with asthma includes education about the disease and its therapy and facilitation of self-management.
- CF is the most common inherited disease in children.
- The diagnosis of CF is based on newborn screening finding of elevated IRT, DNA analysis showing a CFTR mutation, and a positive sweat chloride test (increased sweat electrolyte content).

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Identify children at increased risk of developing nutritional disorders.
- Outline a nutritional counseling plan for vitamin or mineral deficiency or excess.
- Describe the characteristics of infants and small children that affect their ability to adapt to fluid loss or gain.
- Formulate a plan of care for the infant with acute diarrhea.
- Compare and contrast the inflammatory bowel diseases.
- Identify the routes of transmission for hepatitis A, B, and C.
- Describe the nursing care of the child with hepatitis.
- Formulate a plan for teaching parents preoperative and postoperative care of the child with a cleft lip, cleft palate, or both.
- Formulate a plan of care for the child with an obstructive gastrointestinal disorder.
- Identify nutritional therapies for the child with a malabsorption syndrome.
- Outline a teaching plan designed to prevent transmission of intestinal parasites.
- Identify the principles in the emergency treatment of accidental poisoning.
- Name four sources of lead in the environment.
- Describe the nursing care of the child with lead poisoning.
- Describe the nursing care of the child with appendicitis.

NUTRITIONAL DISORDERS

Reports of severe nutritional disorders in childhood in most developed countries are uncommon, yet small numbers of children who may experience a nutritional deficiency of some type often exist. The 2008 Feeding Infants and Toddlers Study (FITS) found that usual nutrient intake of infants, toddlers, and preschoolers (ages 0 to 47 months) met or exceeded energy and protein requirements based on the Dietary Reference Intakes (DRIs) and the 2005 Dietary Guidelines for Americans (Butte, Fox, Briefel, et al., 2010). According to the study, a small but significant number of infants were at risk for inadequate intake of iron and zinc. Dietary fiber intakes in toddlers and preschoolers were low, and saturated fat intakes exceeded recommendations for the majority of preschoolers (Butte, Fox, Briefel, et al., 2010). There are reports of an increased dependence on fortified foods and supplements in toddlers to meet nutritional requirements rather than meeting such needs with a wide variety of fruits, vegetables, and whole grains (Fox, Reidy, Novak, et al., 2006).

The findings of these studies and other similar reports are important for nurses who work with infants and children. Nurses must work to promote healthy nutrition habits early in children's lives through proper education of families and children about healthy lifestyle habits, including diet and exercise for health promotion and prevention of morbidities associated with poor micronutrient intake and sedentary lifestyle.

Vitamin Imbalances

Although true vitamin deficiencies are rare in the United States, subclinical deficiencies are commonly seen in population subgroups in which either maternal or child dietary intake is imbalanced and contains inadequate amounts of vitamins. Vitamin D–deficiency rickets, once rarely seen because of the widespread commercial availability of vitamin D–fortified milk, increased before the turn of the century. Populations at risk include the following:

- Children who are breastfed exclusively by mothers with an inadequate intake of vitamin D or breastfed exclusively longer than 6 months without adequate maternal vitamin D intake or supplementation
- Children with dark skin pigmentation who are exposed to minimal sunlight because of socioeconomic, religious, or

cultural beliefs or housing in urban areas with high levels of pollution
- Children with diets that are low in sources of vitamin D and calcium
- Individuals who use milk products not supplemented with vitamin D (e.g., yogurt,* raw cow's milk) as the primary source of milk

The American Academy of Pediatrics (AAP) (2008) recommends that infants who are breastfed exclusively receive 400 IU of vitamin D beginning shortly after birth to prevent rickets and vitamin D deficiency. Vitamin D supplementation should continue until the infant is consuming at least 1 L/day (or 1 quart/day) of vitamin D–fortified formula (AAP, 2008). Nonbreastfed infants who are taking less than 1 L/day of vitamin D–fortified formula should also receive a daily vitamin D supplement of 400 IU. Inadequate maternal ingestion of cobalamin (vitamin B_{12}) may contribute to infant neurologic impairment when exclusive breastfeeding (past 6 months) is the only source of the infant's nutrition. A correlation between the incidence of childhood upper respiratory infections and vitamin D deficiency has been found, but the implications of the findings have yet to be completely understood (Taylor and Camargo, 2011; Walker and Modlin, 2009).

Children may also be at risk for vitamin deficiencies secondary to disorders or their treatment. For example, vitamin deficiencies of the fat-soluble vitamins A and D may occur in malabsorptive disorders such as cystic fibrosis and short bowel syndrome. Preterm infants may develop rickets in the second month of life as a result of inadequate intake of vitamin D, calcium, and phosphorus. Children receiving high doses of salicylates may have impaired vitamin C storage. Environmental tobacco smoke exposure has been implicated in decreased concentrations of ascorbate in children; therefore increased intake of sources of vitamin C should be encouraged even in children minimally exposed to environmental tobacco smoke (Preston, Rodriguez, and Rivera, 2003). Children with chronic illnesses resulting in anorexia, decreased food intake, or possible nutrient malabsorption as a result of multiple medications should be evaluated carefully for adequate vitamin and mineral intake in some form (parenteral or enteral).

Children with sickle cell disease are reported to have suboptimal intakes (according to DRI recommendations) of vitamins E and D, folate, calcium, and fiber, which decrease significantly with increasing age. Poor dietary intake was a significant factor in the findings of the study (Kawchak, Schall, Zemel, et al., 2007). One study found that children with intestinal failure who were being transitioned from parenteral to enteral nutrition had at least one vitamin and mineral deficiency; vitamin D was the most common deficiency identified, and zinc and iron were the most common minerals identified as being deficient (Yang, Duro, Zurakowski, et al., 2011).

Vitamin A deficiency has been reported with increased morbidity and mortality in children with measles. However, a Cochrane review of studies wherein a single dose of vitamin A was administered to children with measles found no decrease in mortality. Children with measles younger than the age of 2 years who received two doses of vitamin A (200,000 IU) on consecutive days did have decreased mortality rates and a reduced rate of pneumonia-specific mortality (Huiming, Chaomin, and Meng, 2005). Complications from diarrhea and infections are often increased in infants and children with vitamin A deficiency. Although scurvy (caused by a deficiency of vitamin C) is rare in developed countries, cases have been reported in children who were fed an organic diet deficient in vegetables and fruits (Burk and Molodow, 2007).

An excessive dose of a vitamin is generally defined as 10 or more times the Recommended Dietary Allowance (RDA), although the fat-soluble vitamins, especially vitamins A and D, tend to cause toxic reactions at lower doses. With the addition of vitamins to commercially prepared foods, the potential for **hypervitaminosis** has increased, especially when combined with the excessive use of vitamin supplements. Hypervitaminosis of vitamins A and D presents the greatest problems because these fat-soluble vitamins are stored in the body. High intakes of vitamin A have been linked to physeal growth arrest, which can lead to osteoporosis, fracture, and metaphyseal irregularity (Saltzman and King, 2007). Chronic hypervitaminosis A may result in signs and symptoms of headache; vomiting; dry, itching desquamating skin; anorexia; fissures at the corner of the mouth; weight loss; bulging fontanels; and neurologic signs such as irritability and stupor (Zile, 2011). An excessive intake of vitamin A in pregnant women has also been linked to fetal defects (Zile, 2011). Vitamin D is the most likely of all vitamins to cause toxic reactions in relatively small overdoses. The water-soluble vitamins, primarily niacin, B_6, and C, can also cause toxicity. Poor outcomes in infants (e.g., fatal hypermagnesemia) have been associated with megavitamin therapy with high doses of magnesium oxide, and severe anemia and thrombocytopenia have resulted from megadoses of vitamin A.

One vitamin supplement that is recommended for all women of childbearing age is a daily dose of 0.4 mg of folic acid, the usual RDA. Folic acid taken before conception and during early pregnancy can reduce the risk of neural tube defects such as spina bifida by as much as 70%. Drugs such as oral contraceptives and antidepressants may decrease folic acid absorption; thus adolescent girls taking such medications should consider supplementation. (See Spina Bifida (Myelomeningocele, Chapter 49.)

Mineral Imbalances

A number of minerals are essential nutrients. The macrominerals refer to those with daily requirements greater than 100 mg and include calcium, phosphorus, magnesium, sodium, potassium, chloride, and sulfur. Microminerals, or trace elements, have daily requirements of less than 100 mg and include several essential minerals and those in which the exact role in nutrition is still unclear. The greatest concern with minerals is deficiency, especially iron deficiency anemia (see Chapter 43). However, other minerals that may be inadequate in children's diets, even with supplementation, include calcium, phosphorus, magnesium, and zinc. Low levels of zinc can cause nutritional growth failure (failure to thrive [FTT]). Some of the macrominerals may be overlooked inadvertently when a child with intestinal failure or recent surgery is making the transition from total parenteral to enteral intake.

An imbalance in the intake of calcium and phosphorous may occur in infants who are given whole cow's milk instead of infant formula; neonatal tetany may be observed in such cases. Whole cow's milk is also a poor source of iron, and inadequate intake of iron from other food sources such as iron-fortified cereal may cause iron deficiency anemia.

The regulation of mineral balance in the body is a complex process. Dietary extremes of mineral intake can cause a number of mineral-mineral interactions that could result in unexpected deficiencies or excesses. For example, excessive amounts of one mineral such as zinc can result in a deficiency of another mineral such as copper even if sufficient amounts of copper are ingested. Thus

*Yogurt does not contain adequate amounts of vitamins A and D (unless specifically fortified with these vitamins) but is an acceptable source of calcium and phosphorus.

megadose intake of one mineral may cause an inadvertent deficiency of another essential mineral by blocking its absorption in the blood or intestinal wall or competing with binding sites on protein carriers needed for metabolism.

Deficiencies can also occur when various substances in the diet interact with minerals. For example, iron, zinc, and calcium can form insoluble complexes with phytates or oxalates (substances found in plant proteins), which impair the bioavailability of the mineral. This type of interaction is important in vegetarian diets because plant foods such as soy are high in phytates. Contrary to popular opinion, spinach is not an ideal source of iron or calcium because of its high oxalate content. Factors that affect iron absorption are listed in Chapter 32.

Children with certain illnesses are at greater risk for growth failure, especially in relation to bone mineral deficiency as a result of the treatment of the disease, decreased nutrient intake, or decreased absorption of necessary minerals. Those at risk for such deficiencies include children who are receiving or have received radiation and chemotherapy for cancer; children with human immunodeficiency virus (HIV), sickle cell disease, cystic fibrosis, gastrointestinal (GI) malabsorption, or nephrosis; and extremely low–birth-weight (ELBW) and very low–birth-weight (VLBW) preterm infants.

CARE MANAGEMENT

Identification of adequacy of nutrient intake is the initial nursing goal and requires assessment based on a dietary history and physical examination for signs of deficiency or excess (see Nutrition, Chapter 32, and Nutritional Assessment, Chapter 29). After assessment data are collected, this information is evaluated against standard intakes to identify areas of concern. DRIs are one source of standard nutrient intakes (see Chapter 32, Dietary Guidelines).

Standardized growth reference charts should be used in infants, children, and adolescents to compare and assess growth parameters such as height and head circumference with the percentile distribution of other children at the same ages. The World Health Organization (WHO) growth chart is a standardized growth reference now recommended for infants and toddlers up to 24 months of age. This growth chart includes head circumference, height, and weight references that were derived from healthy children in six different countries around the world. These growth standards are based on the growth of healthy breastfed infants throughout the first year of life. The Centers for Disease Control and Prevention (CDC) growth charts are now recommended for children 2 to 19 years of age (Grummer-Strawn, Reinold, Krebs, et al., 2010).

Infants should be breastfed for the first 6 months and preferably for 1 year, be introduced to some solid foods after about 4 to 6 months, and receive iron-fortified cereal for at least 18 months (see Chapter 31). Vitamin B_{12} supplementation is recommended if the breastfeeding mother's intake of the vitamin is inadequate or if she is not taking vitamin supplements (Dunham and Kollar, 2006). If the infant is being breastfed exclusively after 4 months (when fetal iron stores are depleted), iron supplementation (1 mg/kg/day) is recommended until appropriate iron-containing complementary foods such as iron-fortified cereal are introduced (Baker, Greer, and AAP Committee on Nutrition, 2010). The introduction of solids for vegetarian infants may occur using the same guidelines as for other children (see Chapter 32). A variety of foods should be introduced during the early years to ensure a well-balanced intake. Infants who are identified as having particular nutritional deficits should be identified; a multidisciplinary approach should be taken for identifying the deficit and the etiology, and a plan established with the caregiver to promote adequate growth and development.

Protein-Energy Malnutrition (Severe Childhood Undernutrition)

Malnutrition continues to be a major health problem in the world today, particularly in children younger than 5 years of age. However, lack of food is not always the primary cause of malnutrition. In many developing and underdeveloped nations, diarrhea (gastroenteritis) is a major factor. Additional factors are bottle-feeding (in poor sanitary conditions), inadequate knowledge of proper child care practices, parental illiteracy, economic and political factors, climate conditions, cultural and religious food preferences, and simply a lack of adequate food. Müller and Krawinkel (2005) point out that poverty is the underlying cause of malnutrition. The most extreme forms, or protein-energy malnutrition (PEM), are kwashiorkor and marasmus. Some authorities suggest that severe malnutrition encompasses more than protein-energy deficits and thus prefer the term *severe childhood undernutrition (SCU)*. Another term used is *severe acute malnutrition (SAM)*. Entities such as the WHO continue to use the term *protein-energy malnutrition*. SCU may also be subdivided into edematous (kwashiorkor) and nonedematous (marasmus) types.

In the United States milder forms of PEM are seen as a result of primary malnutrition, although the classic cases of marasmus and kwashiorkor may also occur. Unlike in developing countries, where the main reason for PEM is inadequate food, in the United States PEM occurs despite ample dietary supplies (see Failure to Thrive, Chapter 31). It may also be seen in people with chronic health problems such as cystic fibrosis, renal dialysis, cancer, and GI malabsorption; in elderly adults who have chronic malnutrition; and in people with acute illnesses such as prolonged, untreated anorexia nervosa. Kwashiorkor has been reported in the United States in children fed only a rice beverage diet (Rice Dream) and few solid foods and in infants who were fed nonstandard infant diets such as flour water, corn porridge, molasses, and nondairy creamer (Katz, Mahlberg, Honig, et al., 2005; Tierney, Sage, and Shwayder, 2010). Kwashiorkor has also been reported in the United States when infants have been fed inappropriate food as a result of parental (caretaker) nutritional ignorance, a perceived cow's milk–based formula intolerance, family social chaos, or cow's milk intolerance. Therefore it is important that health care workers not assume that PEM cannot occur in developed countries; a comprehensive dietary history should be obtained in any child with clinical features resembling PEM.

Kwashiorkor

Kwashiorkor has been defined primarily as a deficiency of protein with an adequate supply of calories. A diet consisting mainly of starch grains or tubers provides adequate calories in the form of carbohydrates but an inadequate amount of high-quality proteins. However, some evidence supports a multifactorial etiology, including cultural, psychologic, and infective factors, that may interact to place the child at risk for kwashiorkor. Some experts suggest that kwashiorkor may result from the interplay of nutrient deprivation, response to infection and oxidative stress, and environmental stresses, which combined produce an imbalanced response to such insults (Penny, 2008). It often occurs subsequent to an infectious outbreak of measles and dysentery. There is further evidence that oxidative stress occurs in children with kwashiorkor, resulting in free radical damage, which may precipitate cellular changes, resulting in edema and muscle wasting. The role of the essential fatty acid

arachidonic acid in lipid metabolism, altered leukotriene production, and oxidative stress in kwashiorkor has yet to be fully understood, but abnormal essential fatty acid metabolism seems to have an interactive role in its development (Penny, 2008).

Taken from the Ga language (Ghana), the word *kwashiorkor* means "the sickness the older child gets when the next baby is born" and aptly describes the syndrome that develops in the first child, usually between 1 and 4 years of age, when weaned from the breast after the second child is born.

The child with kwashiorkor has thin, wasted extremities and a prominent abdomen from edema **(ascites).** The edema often masks severe muscular atrophy, making the child appear less debilitated than he or she actually is. The skin is scaly and dry and has areas of depigmentation. Several dermatoses may be evident, partly resulting from the vitamin deficiencies. Permanent blindness often results from the severe lack of vitamin A. Mineral deficiencies especially iron, calcium, and zinc, are common. Acute zinc deficiency is a common complication of severe PEM and results in skin rashes, loss of hair, impaired immune response and susceptibility to infections, digestive problems, night blindness, changes in affective behavior, defective wound healing, and impaired growth. Its depressant effect on appetite further limits food intake. The hair is thin, dry, coarse, and dull. Depigmentation is common, and patchy alopecia may occur.

Diarrhea (persistent diarrhea malnutrition syndrome) commonly occurs from a lowered resistance to infection and further complicates the electrolyte imbalance. Low levels of cytokines (protein cells involved in the primary response to infection) have been reported in children with kwashiorkor, suggesting that such children have a blunted immune response to infection. A large number of deaths in children with kwashiorkor occur in those who develop HIV infection. GI disturbances such as fatty infiltration of the liver and atrophy of the acini cells of the pancreas occur. Anemia is also a common finding in malnourished children. Protein deficiency increases the child's susceptibility to infection, which eventually results in death. Fatal deterioration may be caused by diarrhea and infection or by circulatory failure.

Marasmus

Marasmus results from general malnutrition of both calories and protein. It is common in underdeveloped countries during times of drought, especially in cultures where adults eat first; the remaining food is often insufficient in quality and quantity for the children.

Marasmus is usually a syndrome of physical and emotional deprivation and is not confined to geographic areas where food supplies are inadequate. It may be seen in children with growth failure in whom the cause is not solely nutritional but primarily emotional. Marasmus may be seen in infants as young as 3 months of age if breastfeeding is not successful and there are no suitable alternatives. Marasmic kwashiorkor is a form of PEM in which clinical findings of both kwashiorkor and marasmus are evident; the child has edema, severe wasting, and stunted growth. In marasmic kwashiorkor the child has inadequate nutrient intake and superimposed infection. Fluid and electrolyte disturbances, hypothermia, and hypoglycemia are associated with a poor prognosis.

Marasmus is characterized by gradual wasting and atrophy of body tissues, especially of subcutaneous fat. The child appears to be very old, with loose and wrinkled skin, unlike the child with kwashiorkor, who appears more rounded from the edema. Fat metabolism is less impaired than in kwashiorkor; thus deficiency of fat-soluble vitamins is usually minimal or absent. In general the clinical manifestations of marasmus are similar to those seen in kwashiorkor with the following exceptions: with marasmus there is no edema from hypoalbuminemia or sodium retention, which contributes to a severely emaciated appearance; no dermatoses caused by vitamin deficiencies; little or no depigmentation of hair or skin; moderately normal fat metabolism and lipid absorption; and a smaller head size and slower recovery after treatment. There is also an abnormal regulation of the sodium-potassium pump, resulting in an increase in intracellular sodium and a decrease in potassium (Penny, 2008).

The child is fretful, apathetic, withdrawn, and so lethargic that prostration frequently occurs. Intercurrent infection with debilitating diseases such as tuberculosis, parasitosis, HIV, and dysentery is common.

Therapeutic Management

The treatment of PEM includes providing a diet with high-quality proteins, carbohydrates, vitamins, and minerals. When PEM occurs as a result of persistent diarrhea, three management goals are identified:

1. Rehydration with an oral rehydration solution (ORS) that also replaces electrolytes
2. Administration of antibiotics to prevent intercurrent infections
3. Provision of adequate (energy intake) nutrition by either breastfeeding or a proper weaning diet

Local protocols are used in developing countries to deal with PEM. Penny (2008) and Alderman and Shekar (2011) recommend a three-phase treatment protocol: (1) acute or initial phase in the first 2 to 10 days involving initiation of treatment for oral rehydration, diarrhea, and intestinal parasites; prevention of hypoglycemia and hypothermia; and subsequent dietary management; (2) recovery or rehabilitation (2 to 6 weeks) focusing on increasing dietary intake, iron fortification, and weight gain; and (3) follow-up phase, focusing on care after discharge in an outpatient setting to prevent relapse and promote weight gain, provide developmental stimulation, and evaluate cognitive and motor deficits. In the acute phase care is taken to prevent fluid overload; the child is observed closely for signs of food or fluid intolerance. The refeeding syndrome may occur if intake progresses too rapidly; cardiac failure may cause sudden death in a child who has been malnourished and refed too rapidly (Grover and Ee, 2009). Severe hypophosphatemia may develop during the first week of initiating feedings and is considered to be the hallmark of refeeding syndrome (Alderman and Shekar, 2011). Signs and symptoms include weakness, arrhythmias, altered levels of consciousness, seizures, cardiorespiratory failure, and sudden death.

Vitamin and mineral supplementation is required in most cases of PEM; vitamin A, zinc, and copper are recommended; iron supplementation is not recommended until the child is able to tolerate a steady food source. In addition, the child is observed for signs of skin breakdown, which should be treated to prevent infection. Breastfeeding is encouraged if the mother and child are able to do so effectively; in some cases partial supplementation with a modified cow's milk–based formula may be necessary.

The WHO (2006) issued a statement recognizing the importance of breastfeeding for the first 6 months in developing countries where HIV is prevalent among childbearing women and children. It recognizes that appropriate sources of food and water for infants may not be available after the 6 months are concluded and that the risk for malnutrition is greater among such children than the theoretic risk of HIV. However, the organization does recommend that

breastfeeding continue after 6 months with the introduction of complementary foods, provided they are safe for child consumption. In severely malnourished children a modest energy food source is given initially, followed by a high-protein and energy food source; severely malnourished children do not tolerate a high-energy and high-protein source initially. A number of food sources may be provided to treat PEM. They include ORSs (ReSoMal), amino acid–based elemental food, and ready-to-feed foods that do not require the addition of water (to minimize contaminated water consumption); parenteral and oral antibiotics are often part of the standard treatment for PEM (Amadi, Mwiya, Chomba, et al., 2005; Ciliberto, Sandige, Ndekha, et al., 2005).

CARE MANAGEMENT

Because PEM appears early in childhood, primarily in children 6 months to 2 years of age, and is associated with early weaning, a low-protein diet, delayed introduction of complementary foods, and frequent infections (Grover and Ee, 2009; Müller and Krawinkel, 2005), it is essential that nursing care focus on *prevention* of PEM through parent education about feeding practices during this crucial period. Prevention should also focus on the nutritional health of pregnant women because this directly impacts the health of their unborn children. Breastfeeding is the optimal method of feeding for the first 6 months. The immune properties naturally found in breast milk not only nourish infants but also help prevent opportunistic infections, which may contribute to PEM. Providing for essential physiologic needs such as appropriate nutrient intake, protection from infection, adequate hydration, skin care, and restoration of physiologic integrity is paramount. Additional nursing care focuses on education about and administration of childhood vaccinations to prevent illness, promotion of nutrition and well-being for the lactating mother, encouragement and participation in well-child visits for infants and toddlers, appropriate food sources for children being weaned from breastfeeding, and education regarding sanitation practices to prevent childhood GI diseases.

Poor skin integrity further increases the chance of infections, hypothermia, water loss, and skin breakdown. Tube feedings may be required for infants too weak to breastfeed or bottle-feed. Oral rehydration with an approved ORS is commonly used in cases of PEM in which diarrhea and infection are not immediately life threatening.

One approach that has gained acceptance for treating childhood malnutrition in developing countries is the home-based use of ready-to-use therapeutic food (RUTF). RUTF is a paste based on peanut butter and dried skim milk with vitamins and minerals; it requires no mixing with water or milk. The packaged RUTF can be stored without refrigeration. Studies have demonstrated improved survival rates in malnourished children (Amthor, Cole, and Manary, 2009; Ciliberto, Sandige, Ndehka, et al., 2005). Some of the reported advantages of home-based (community-based) treatment include that children are not exposed to hospital-acquired infections and may receive the RUTF from village health aides (Kapil, 2009).

It is imperative that nurses be at the forefront in educating and reinforcing healthy nutrition habits in parents of small children to prevent malnutrition. Because children with marasmus may experience emotional starvation as well, care should be consistent with that for children with FTT.

The WHO has published guidelines for the treatment and management of children with severe acute malnutrition (Ashworth, Khanum, Jackson, et al., 2003; Grover and Ee, 2009). These guidelines include a two-phase program with a 10-step guide to treating the child with malnutrition.

Food Allergy

In late 2010 the National Institute of Allergy and Infectious Diseases (NIAID), working with 34 other professional organizations, published new evidence-based guidelines for the diagnosis and management of food allergy. A food allergy is defined by the NIAID as "an adverse health effect arising from a specific immune response that occurs reproducibly on exposure to a given food" (Boyce, Assa'ad, Burks, et al., 2010, p. 1108). Food allergens are defined as specific components of food or ingredients in food such as a protein that are recognized by allergen-specific immune cells eliciting an immune reaction that results in the characteristic symptoms (Boyce, Assa'ad, Burks, et al., 2010). A food intolerance is said to exist when a food or food component elicits a reproducible adverse reaction but does not have an established or likely immunologic mechanism (Boyce, Assa'ad, Burks, et al., 2010). The example given suggests that a person may have an immune-mediated allergy to cow's milk protein, but the person who is unable to digest the lactose in cow's milk is considered to be intolerant, not allergic, to it. The NIAID guidelines classify food allergy according to the following: food-induced anaphylaxis, GI food allergies, and specific syndromes; cutaneous reactions to foods; respiratory manifestation; and Heiner syndrome (Boyce, Assa'ad, Burks, et al., 2010). The exact prevalence of food allergies in children is reported to be much lower than that which parents report. Approximately 6% of children may experience food allergic reactions in the first 2 to 3 years of life; 1.5% will have an allergy to eggs, 2.5% to cow's milk, and 1% to peanuts (Sampson and Leung, 2011). Seafood allergies in children are reported to be low in the United States: 0.2% for fish and 0.5% for crustaceans (Boyce, Assa'ad, Burks, et al., 2010). Diagnosed allergy to milk and eggs was found to be 2.2% in a Danish study and 1.6% in a Norwegian study. The NIAID report further points out that most children will eventually be able to tolerate milk, eggs, soy, and wheat; far fewer will ever tolerate tree nut and peanuts (Boyce, Assa'ad, Burks, et al., 2010). The NIAID report indicates that 50% to 90% of all presumed food allergies are not actually allergies. The NIAID's (Boyce, Assa'ad, Burks, et al., 2010) guidelines also recommend the following:

- Infants should be breastfed exclusively until 4 to 6 months of age.
- Soy formula is not recommended to prevent the development of food allergy.
- Introduction of complementary foods should not be delayed beyond 6 months of age.
- Hydrolyzed formula (versus cow's milk) may be used in at-risk infants to prevent or modify food allergy.
- Maternal diet during pregnancy or lactation should not be restricted to prevent food allergy.
- Children should be vaccinated with the measles, mumps, and rubella (MMR) and measles, mumps, rubella, and varicella (MMRV) vaccines (even with egg allergy [unless severe reaction occurred]).
- Patients with severe egg allergy reactions should not receive the influenza vaccine without consulting the primary practitioner for an analysis of the risks versus benefits.

A summary of the NIAID guidelines is provided by McBride (2011).

The clinical manifestations of food allergy may be divided as follows (AAP, 2009):

Systemic—Anaphylactic, growth failure

GI—Abdominal pain, vomiting, cramping, diarrhea

Respiratory—Cough, wheezing, rhinitis, infiltrates
Cutaneous—Urticaria, rash, atopic dermatitis

Food allergies usually occur either as an immunoglobulin E (IgE)–mediated or non–IgE-mediated immune response; some toxic reactions may occur as a result of a toxin found within the food. Food allergy is caused by exposure to allergens, usually proteins (but not the smaller amino acids), that are capable of inducing IgE antibody formation (sensitization) when ingested. Sensitization refers to the initial exposure of an individual to an allergen, resulting in an immune response; subsequent exposure induces a much stronger response that is clinically apparent. Consequently food allergy typically occurs after the food has been ingested one or more times. The NIAID report (Boyce, Assa'ad, Burks, et al., 2010) indicates that sensitization alone is not sufficient to classify as a food allergy; rather an immune-mediated response *and* manifestation of specific sign and symptoms are necessary to categorize an individual as having a food allergy. The most common food allergens are listed in Box 41-1.

Oral allergy syndrome occurs when a food allergen (commonly fruits and vegetables) is ingested and there is subsequent edema and pruritus involving the lips, tongue, palate, and throat. Recovery from symptoms is usually rapid. Immediate GI hypersensitivity is an IgE-mediated reaction to a food allergen; reactions include nausea, abdominal pain, cramping, diarrhea, vomiting, anaphylaxis, or all of these. Additional food allergies seen in young children include allergic eosinophilic esophagitis, allergic eosinophilic gastroenteritis, food protein–induced proctocolitis, and food protein–induced enterocolitis.

Food allergy or hypersensitivity may also be classified according to the interval between ingestion and the manifestation of symptoms: immediate (within minutes to hours) or delayed (2 to 48 hours) (AAP, 2009).

Food allergies can occur at any time but are common during infancy because the immature intestinal tract is more permeable to proteins than the mature intestinal tract, thus increasing the likelihood of an immune response. Allergies in general demonstrate a genetic component: children who have one parent with an allergy have a 50% or greater risk of developing one; children who have both parents with an allergy have up to a 100% risk of developing one. Allergy with a hereditary tendency is referred to as *atopy*. Some infants with atopy can be identified at birth from elevated levels of IgE in umbilical cord blood.

Deaths have been reported in children who experienced an anaphylactic reaction to food. Onset of the reactions occurred shortly after ingestion (5 to 30 minutes). In most of the children the reactions did not begin with skin signs such as hives, red rash, and flushing but rather mimicked an acute asthma attack (wheezing, decreased air movement in airways, dyspnea). Watch children with food anaphylaxis closely because a biphasic response has been recorded in a number of cases in which there is an immediate response, apparent recovery, and acute recurrence of symptoms (Simons, 2009) (see Nursing Alert and Emergency box). Children with extremely sensitive food allergies should wear a medical identification bracelet and have an injectable epinephrine cartridge (EpiPen) readily available. (See Anaphylaxis, Chapter 42.) Any child with a history of food allergy or previous severe reaction to food should have a written emergency treatment plan and an EpiPen. Note that Benadryl and cetirizine are effective for cutaneous and nasal manifestations but not for airway manifestations (Keet, 2011).

Although the reason is unknown, many children "outgrow" their food allergies, especially to milk and eggs. Approximately 50% of all infants who are intolerant to cow's milk usually develop tolerance by 3 to 5 years of age (Sampson and Leung, 2011). More than half (60%) of infants have an IgE-mediated reaction to cow's milk, and 25% retain sensitivity until the second decade of life. Children who are allergic to more than one food may develop tolerance to each food at a different time. The most common allergens such as peanuts are outgrown less readily than other food allergens. Because of the tendency to lose the hypersensitivity, allergenic foods should be reintroduced into the diet after a period of abstinence (usually ≥1 year) to evaluate whether the food can safely be added to the diet. However, foods that are associated with severe anaphylactic reactions continue to present a lifelong risk and must be avoided.

BOX 41-1 COMMON ALLERGENIC FOODS AND SOURCES

Nuts*—Some chocolates, candy, baked goods, cherry soda (may be flavored with a nut extract), walnut oil
Eggs*—Mayonnaise, creamy salad dressing, baked goods, egg noodles, some cake icing, meringue, custard, pancakes, French toast, root beer
Wheat*—Almost all baked goods, wieners, bologna, pressed or chopped cold cuts, gravy, pasta, some canned soups
Legumes—Peanuts,* peanut butter or oil, beans, peas, lentils
Fish or shellfish*—Cod liver oil, pizza with anchovies, Caesar salad dressing, any food fried in same oil as fish
Soy*—Soy sauce, teriyaki or Worcestershire sauce, tofu, baked goods using soy flour or oil, soy nuts, soy infant formulas or milk, soybean paste, tuna packed in vegetable oil, many margarines
Chocolate—Cola beverages, cocoa, chocolate-flavored drinks
Milk—Ice cream, butter, margarine (if it contains dairy products), yogurt, cheese, pudding, baked goods, wieners, bologna, canned creamed soups, instant breakfast drinks, powdered milk drinks, milk chocolate
Buckwheat—Some cereals, pancakes
Pork, chicken—Bacon, wieners, sausage, pork fat, chicken broth
Strawberries, melon, pineapple—Gelatin, syrups
Corn—Popcorn, cereal, muffins, cornstarch, corn meal, corn bread, corn tortillas, corn syrup
Citrus fruits—Orange, lemon, lime, grapefruit; any of these in drinks, gelatin, juice, or medicines
Tomatoes—Juice, some vegetable soups, spaghetti, pizza sauce, catsup
Spices—Chili, pepper, vinegar, cinnamon

*Most common allergens.

EMERGENCY

*Emergency Management of Anaphylaxis**

Drug—Epinephrine 0.001 mg/kg up to maximum of 0.3 mg
Dose—EpiPen Jr (0.15 mg) intramuscularly (IM) for child weighing 8 to 25 kg (17.5-55 lbs)
EpiPen (0.3 mg) IM for child weighing 25 kg (55 lbs) or more
Observe for adverse reactions: tachycardia, hypertension, irritability, headaches, nausea, and tremors.

*Data from Keet C: Recognition and management of food-induced anaphylaxis, *Pediatr Clin North Am* 58(2):377-388, 2011; Sampson HA, Leung DYM: Adverse reactions to foods. In Kliegman RM, Stanton BF, St Geme JW, et al., editors: *Nelson textbook of pediatrics,* ed 19, Philadelphia, 2011, Saunders.

NURSING ALERT

Indications for the administration of *intramuscular* epinephrine in a child with a life-threatening anaphylactic reaction or one who is experiencing severe symptoms include any one of the following (Wang and Sampson, 2007):

- Itching sensation or tightness in throat; hoarseness
- "Barky" cough
- Difficulty swallowing; dyspnea
- Wheezing
- Cyanosis
- Respiratory arrest; mild dysrhythmia or mild hypotension
- Severe bradycardia, hypotension, or cardiac arrest; loss of consciousness

Diagnosis and Therapeutic Management

The diagnosis of food allergy is made based on a number of factors, including the occurrence of anaphylaxis or any combination of 37 symptoms listed in the NIAID guidelines within minutes to hours of ingesting food or if such symptoms have occurred after the ingestion of a specific food on one or more occasions. The gold standard is the double-blind, placebo-controlled food challenge; the skin prick test and serum IgE (sIgE) measurements may be used as an adjunct to diagnose food allergy but singly should not be used for the diagnosis. The atopy patch test, intradermal test, and sIgE test are not recommended for establishing a diagnosis. A single oral food challenge may be used in certain circumstances (Boyce, Assa'ad, Burks, et al., 2010). The management of food allergy consists of avoiding the specific food or ingredient that causes the manifestations. Because children with food allergies (usually two or more) are at risk for inadequate nutrient intake and growth failure, it is recommended that they have an annual nutritional assessment to prevent such problems.

CARE MANAGEMENT

Nursing care of children with potential food allergy consists of helping to collect vital health assessment data for the establishment of a diagnosis and helping with diagnostic tests. It is important for nurses to be informed about food allergy and provide parents, caregivers, and older children with accurate information regarding food allergy.

Educate parents, teachers, and day care workers regarding signs and symptoms of food allergy and reactions. People with food allergy should avoid unfamiliar foods and restaurants that do not disclose food ingredients. New labeling guidelines require that food additives such as spices and flavoring be labeled clearly on commercially sold, store-bought foods. Hidden ingredients in prepared foods are also potential sources of food allergy.

Children with a history of food allergy may spend a considerable amount of time in day care; therefore people working in day care centers and other children's settings need to be educated properly regarding recognition and management of severe anaphylactic reactions (see Critical Thinking Case Study).

Breastfeeding is now considered a primary strategy for avoiding atopy in families with known food allergies; however, there is no evidence that maternal avoidance (during pregnancy or lactation) of cow's milk protein or other dietary products known to cause food allergy prevents food allergy in children (AAP, 2009; Boyce, Assa'ad, Burks, et al., 2010). Researchers indicate that delaying the introduction of highly allergenic foods past 4 to 6 months of age may not be as protective for food allergy as previously believed (Greer, Sicherer, Burks, et al., 2008). Likewise studies have shown that soy formula does not prevent allergic disease in infants and children (AAP, 2009).*

CRITICAL THINKING CASE STUDY

Food Allergy Anaphylaxis

A group of nursing students is holding a health promotion fair at a local elementary school for first, second, and third graders. The nursing students have several booths set up in the school cafeteria. Three second-grade boys are horseplaying in front of one of the booths when one of the boys, Jason, an 8-year-old child, suddenly starts coughing and clutching his throat. The students also observe that he is developing red splotches on his face, neck, and throat and that he is scratching. Jason says, "I can't breathe!" The school nurse is nearby and comes over to see what's causing the commotion. One of the boys with Jason says, "We didn't mean any harm; we were just goofing around when we put peanuts in his trail mix." One of the student nurses says, "He's in obvious distress. What should we do?"

1. Evidence—Is there sufficient evidence to draw any conclusions at this time about Jason's condition?
2. Assumptions—Describe some underlying assumptions about the following:
   a. Clinical manifestations of food allergy
   b. The emergency treatment of a food allergy "reaction," or anaphylaxis
   c. Which one of the following interventions would have highest immediate priority?
      (1) Call Jason's parents and ask them to come pick him up from school.
      (2) Call Jason's family practitioner to obtain orders for medication.
      (3) Promptly administer an intramuscular dose of epinephrine.
      (4) Call 911 and wait for the emergency response personnel to arrive.
3. What implication for nursing care exists in this situation after an intervention in the previous question has been chosen and implemented?
4. Describe the potential results of taking a "Let's observe Jason for a few minutes before we do anything" stance in this scenario.
5. Is there evidence to support your immediate and secondary nursing interventions? Provide objective evidence to support your decisions for action.

Cow's Milk Allergy

Cow's milk allergy (CMA) is a multifaceted disorder representing adverse systemic and local GI reactions to cow's milk protein. Approximately 2.5% of infants develop cow's milk hypersensitivity, with 60% of these being IgE mediated. It is estimated that 50% of these children may outgrow the hypersensitivity by 3 to 4 years of age (Sampson and Leung, 2011). Some studies suggest that milk allergy may persist and some children may not be able to tolerate

*Additional information for parents of infants with food allergies is available from the American Academy of Allergy, Asthma and Immunology, 555 E. Wells St., Suite 1100, Milwaukee, WI 53202, 414-272-6071, www.aaaai.org. Additional helpful websites for information on food allergy include MedlinePlus (sponsored by U.S. National Library of Medicine and National Institutes of Health), www.nlm.nih.gov/medlineplus; Food Allergy and Anaphylaxis Network, 800-929-4040, www.foodallergy.org; and NIAID, www.niaid.nih.gov/Pages/default.aspx and www.allergicchild.com.

BOX 41-2 COMMON CLINICAL MANIFESTATIONS OF COW'S MILK ALLERGY

Gastrointestinal
- Diarrhea
- Vomiting
- Colic (controversial)
- Abdominal pain
- Nausea and vomiting
- Oral itching
- Constipation (controversial)
- Gastroesophageal reflux (controversial)
- Blood streaked mucous, loose stools (protein-induced allergic enterocolitis)

Respiratory
- Rhinitis
- Conjunctivitis
- Bronchitis
- Asthma
- Wheezing
- Sneezing
- Coughing
- Chronic nasal discharge
- Asthma exacerbation
- Laryngeal edema

Cutaneous
- Urticaria
- Atopic dermatitis

Systemic
- Anaphylaxis

Other Signs and Symptoms
- Eczema
- Excessive crying
- Pallor (from anemia secondary to chronic blood loss in gastrointestinal tract)

milk until they are 16 years of age (AAP, 2009). (This discussion centers on cow's milk protein contained in commercial infant formulas; whole milk is not recommended for infants younger than 12 months of age.) The allergy may be manifested within the first 4 months of life through a variety of signs and symptoms that may appear within 45 minutes of milk ingestion or after several days (Box 41-2). The diagnosis initially may be made from the history, although the history alone is not diagnostic. The timing and diversity of clinical manifestations vary greatly. For example, CMA may be manifested as colic (see Chapter 31), diarrhea, vomiting, GI bleeding, gastroesophageal reflux (GER), chronic constipation, or sleeplessness in an otherwise healthy infant.

Diagnostic Evaluation. A number of diagnostic tests may be performed, including stool analysis for blood, eosinophils, and leukocytes (both frank and occult bleeding can occur from the colitis); sIgE levels; skin-prick or scratch testing; and radioallergosorbent test (RAST) (measures IgE antibodies to specific allergens in serum by radioimmunoassay). Both skin testing and RAST may help identity the offending food, but the results are not always conclusive. No single diagnostic test is considered definitive for the diagnosis (AAP, 2009). In breastfed infants cow milk protein products should be eliminated (by the mother) to improve the diagnostic results (Kattan, Cocco, and Järvinen, 2011).

The most definitive diagnostic strategy is elimination of milk in the diet followed by challenge testing after improvement of symptoms. A clinical diagnosis is made when symptoms improve after removal of milk from the diet and two or more challenge tests produce symptoms (Ewing and Allen, 2005; Kattan, Cocco, and Järvinen, 2011). Challenge testing involves reintroducing small quantities of milk in the diet to detect resurgence of symptoms; at times it involves the use of a placebo so the parent is unaware of (or "blind" to) the timing of allergen ingestion. A double-blind, placebo-controlled food challenge is the gold standard for diagnosing food allergies such as CMA, yet it may not be used often for diagnosing CMA because of the expense, time involved, and risk for further exposure and anaphylactic reaction (Ewing and Allen, 2005). Careful observation of the child is required during a challenge test because of the possibility of anaphylactic reaction.

Therapeutic Management. Treatment of CMA is elimination of cow's milk–based formula and all other dairy products. For infants fed cow's milk–based formula, this primarily involves changing the formula to a casein hydrolysate milk formula (Pregestimil, Nutramigen, or Alimentum) in which the protein has been broken down into its amino acids through enzymatic hydrolysis. Although the AAP (2009) recommends the use of extensively hydrolyzed formulas for CMA, many practitioners may start a soy formula instead because of the expense of the hydrolyzed formulas. Approximately 50% of infants who are sensitive to cow's milk protein also demonstrate sensitivity to soy, but soy is less expensive than protein hydrolysate formula. Other choices for children who are intolerant to cow's milk–based formula are the amino acid–based formulas Neocate or EleCare, but their cost is a major consideration. Goat's milk (raw) is not an acceptable substitute because it cross-reacts with cow's milk protein, is deficient in folic acid, has a high sodium and protein content, and is unsuitable as the only source of calories. Some suggest that goat's milk infant formula may be a suitable substitute for cow's milk formula (Basnet, Schneider, Gazit, et al., 2010). Infants usually remain on the milk-free diet for 12 months, after which time small quantities of milk are reintroduced.

Children who have CMA may tolerate extensively heated cow's milk (Nowak-Wegrzyn, Bloom, Sicherer, et al., 2008). One study reports that these children became tolerant to uncooked milk products over time after consuming baked milk products (Kim, Nowak-Wegrzyn, Sicherer, et al., 2011).

CARE MANAGEMENT

The principal nursing objectives are identification of potential CMA and appropriate counseling of parents regarding substitute formulas. Parents often interpret GI symptoms such as spitting up and loose stools or fussiness as indications that the infant is allergic to cow's milk and switch the infant to a variety of formulas in an attempt to resolve the problem.

Parents need much reassurance regarding the needs of nonverbal infants with such an array of symptoms. Endless nights of lost sleep and a crying infant may promote feelings of parenting inadequacy and role conflict, thus aggravating the situation. Nurses can reassure parents that many of these symptoms are common and the reasons are often never found, yet the child does achieve appropriate growth and development. Report acute symptoms to the practitioner for further evaluation. Parents need reassurance that the infant will

receive complete nutrition from the new formula and will have no ill effects from the absence of cow's milk.

When solid foods are started, parents need guidance in avoiding milk product. Carefully reading all food labels helps avoid exposure to prepared foods containing milk products. Although labeled as nondairy, milk, cream, and butter substitutes may contain cow's milk protein (Kattan, Cocco, Järvinen, et al., 2011).

Lactose Intolerance

Lactose intolerance refers to at least four different entities that involve a deficiency of the enzyme lactase, which is needed for the hydrolysis or digestion of lactose in the small intestine; lactose is hydrolyzed into glucose and galactose. Congenital lactase deficiency occurs soon after birth after the newborn has consumed lactose-containing milk (human milk or commercial formula). This inborn error of metabolism involves the complete absence or severely reduced presence of lactase, is extremely rare, and requires a lifelong lactose-free or extremely reduced lactose diet.

Primary lactase deficiency, sometimes referred to as late-onset lactase deficiency, is the most common type of lactose intolerance and is manifested usually after 4 or 5 years of age, although the time of onset is variable. Ethnic groups with a high incidence of lactase deficiency include Asians, southern Europeans, Arabs, Israelis, and African-Americans; Scandinavians tend to have the lowest incidence. Lactose malabsorption manifests as lactose intolerance and is characterized by an imbalance between the ability for lactase to hydrolyze the ingested lactose and the amount of lactose ingested (Heyman and AAP Committee on Nutrition, 2006).

Secondary lactase deficiency may occur secondary to damage of the intestinal lumen, which decreases or destroys the enzyme lactase. Cystic fibrosis; sprue; celiac disease; kwashiorkor; and infections such as giardiasis, HIV, or rotavirus may cause a temporary or permanent lactose intolerance.

Developmental lactase deficiency refers to the relative lactase deficiency observed in preterm infants of less than 34 weeks of gestation (Heyman and AAP Committee on Nutrition, 2006).

The primary symptoms of lactose intolerance include abdominal pain, bloating, flatulence, and diarrhea after the ingestion of lactose. The onset of symptoms occurs within 30 minutes to several hours of lactose consumption. Lactose intolerance is often perceived as an allergy; and, in several studies with reports of acute GI symptoms ascribed to lactose intolerance, measurement of lactase activity is normal.

Lactose intolerance may be diagnosed on the basis of the history and improvement with a lactose-reduced diet. The breath hydrogen test is used to positively diagnose the condition. Breath samples in lactose-deficient individuals yield a higher percentage of hydrogen (≥20 parts per million [ppm] above baseline). In infants lactose malabsorption may be diagnosed by evaluating fecal pH and reducing substances; fecal pH in infants is usually lower than in older children, but an acidic pH may indicate malabsorption (Heyman and AAP Committee on Pediatrics, 2006).

Treatment of lactose intolerance is elimination of offending dairy products; however, some advocate decreasing amounts of dairy products rather than total elimination, especially in small children (Heyman and AAP Committee on Nutrition, 2006). In infants lactose-free or low-lactose formula offers no special advantages over lactose-containing formula except in those who are severely malnourished (Heyman and AAP Committee on Pediatrics, 2006).

One concern is that dairy avoidance in children and adolescents with lactose intolerance contributes to reduced bone mineral density and osteoporosis (AAP, 2009; Suchy, Brannon, Carpenter, et al., 2010). Evidence indicates that dietary lactose enhances calcium absorption and that lactose-free diets may negatively affect bone mineralization (Heyman and AAP Committee on Nutrition, 2006). It is recommended that individuals with lactose maldigestion who do not experience lactose intolerance symptoms continue to consume small amounts of dairy products with meals to prevent reduced bone mass density and subsequent osteoporosis. Some evidence indicates that probiotics (food preparations containing microorganisms such as *Lactobacillus,* which alter the GI microflora and thus are beneficial to the host) improve lactose intolerance when live cultures are fermented in dairy products (de Vrese and Schrezenmeir, 2008). The positive attributes of probiotics for those with lactose maldigestion include delayed GI transit (slower than milk), positive effects on intestinal and colonic microflora, and a reduction of maldigestion symptoms.

Most people are able to tolerate small amounts of lactose (≈1 cup of milk per day) even in the presence of deficient lactase activity (Heyman and AAP Committee on Nutrition, 2006; Suchy, Brannon, Carpenter, et al., 2010) and should be encouraged to continue their intake of dairy products in small amounts to obtain much-needed nutrients. Milk taken at meals may be better tolerated than when taken alone (see Family-Centered Care box). Pretreated milk (with microbial-derived lactase) is reported to be effective in improving lactose absorption. Because dairy products are a major source of calcium and vitamin D, supplementation of these nutrients is needed to prevent deficiency. Yogurt contains inactive lactase enzyme, which is activated by the temperature and pH of the duodenum; this lactase activity substitutes for the lack of endogenous lactase. Fresh, plain yogurt may be tolerated better than frozen or flavored yogurt; hard cheeses, lactase-treated dairy products, and lactase tablets taken with dairy products are also viable options. An important distinction between lactose intolerance and food allergy is that lactose intolerance does not manifest as an anaphylactic-type reaction.

CARE MANAGEMENT

Nursing care is similar to the interventions discussed for CMA in this chapter and includes explaining the dietary restrictions to the family; identifying alternate sources of calcium such as yogurt and calcium supplementation; explaining the importance of

FAMILY-CENTERED CARE

Controlling Symptoms of Lactose Intolerance

- In infants substitute lactose-free or soy-based formula for cow's milk–based formula or human milk (only after a diagnosis of congenital lactose deficiency or secondary lactase intolerance is made).
- Limit milk consumption to one to two glasses per day.
- Drink milk with other foods rather than alone.
- Eat hard cheese, cottage cheese, or yogurt instead of drinking milk.
- Use enzyme tablets (Lactaid, Lactrase, Dairy Ease) to metabolize the lactose in milk or supplement the lactase in the body (add tablets to milk or sprinkle on dairy products such as ice cream).
- Eat small amounts of dairy foods daily to help colonic bacteria adapt to ingested lactose.
- Include a probiotic (yogurt or cultured [fermented] milk) in meal or as a snack that has *Lactobacillus* or *Bifidobacterium* organisms.
- Take a calcium supplement if unable to consume any dairy products such as cheese.

supplementation; and discussing sources of lactose, especially hidden sources such as its use as a bulk agent in certain medications, and ways of controlling the symptoms (see Family-Centered Care box). Parents are advised to check with the pharmacist regarding this possibility when obtaining medication.

GASTROINTESTINAL DYSFUNCTION

The extensive surface area of the GI tract and its digestive function represent the major means of exchange between the human organism and the environment. Disorders that impair the functional integrity of the GI system have the potential to cause serious alterations in fluid and electrolyte balance. Disorders that involve GI losses of large amounts of fluid, absorption disorders, inflammatory disorders, and decreased or excessive water intake have the potential to cause fluid and electrolyte imbalance in infants and children.

Clinical observations often provide clues to specific GI problems (Box 41-3). In any disorder that involves GI losses of large amounts of fluid, dehydration poses a serious threat to life and demands immediate attention.

Dehydration

Dehydration is a common body fluid disturbance in infants and children and occurs whenever the total output of fluid exceeds the total intake, regardless of the cause. It may result from a number of diseases that cause insensible fluid losses through the skin and respiratory tract, through increased renal excretion, and through the GI tract. Although dehydration can result from impaired oral intake, it is often a result of abnormal losses such as those that occur in vomiting or diarrhea when oral intake only partially compensates for the abnormal losses. Other significant causes of dehydration include diabetic ketoacidosis and burns.

Types of Dehydration

The pathophysiology of dehydration is understood by recognizing that the distribution of water between the extracellular fluid (ECF) and intracellular fluid (ICF) spaces depends on active transport of potassium into and sodium out of cells by energy-requiring processes. Sodium is the chief solute in ECF and the primary determinant of ECF volume. It is considered a unique electrolyte in that water balance determines sodium concentration; when water is lost and sodium concentration becomes elevated, compensatory mechanisms in the kidney stop ADH secretion so water is retained. The thirst mechanism (not fully functional in infants) is also stimulated so water is replaced, thus increasing the total body water content and returning sodium to a normal level (Greenbaum, 2011). Potassium is found primarily inside the cell (intracellular), but small amounts are also found in ECF. Sodium depletion in diarrhea occurs in two ways: out of the body in stool and into the ICF compartment to replace potassium to maintain electrolyte equilibrium.

Dehydration is classified into three categories on the basis of osmolality and depends primarily on the serum sodium concentration: (1) isotonic, (2) hypotonic, and (3) hypertonic.

Isotonic (isosmotic or **isonatremic) dehydration,** the primary form of dehydration in children, occurs in conditions in which electrolyte and water deficits are present in approximately balanced proportions. Water and sodium are lost in approximately equal amounts. The observable fluid losses are not necessarily isotonic because losses from other avenues make adjustments so the sum of all losses, or the net loss, is isotonic. There is no osmotic force between the ICF and the ECF; thus the major loss is sustained from the ECF compartment. This significantly reduces the plasma volume and the circulating blood volume, which affects the skin, muscles, and kidneys. Shock is the greatest threat to life, and children with isotonic dehydration display symptoms characteristic of hypovolemic shock. Plasma sodium remains within normal limits, between 130 and 150 mEq/L.

Hypotonic (hyposmotic or **hyponatremic) dehydration** occurs when the electrolyte deficit exceeds the water deficit, leaving the

BOX 41-3 CLINICAL MANIFESTATIONS OF GASTROINTESTINAL DYSFUNCTION IN CHILDREN

Growth failure—Weight consistently below the third percentile, body mass index below the fifth percentile, or a decrease from established growth pattern

Spitting up or regurgitation—Passive transfer of gastric contents into the esophagus or mouth

Vomiting—Forceful ejection of gastric contents; involves a complex process under central nervous system control that causes salivation, pallor, sweating, and tachycardia; usually accompanied by nausea

- *Projectile vomiting*—Vomiting accompanied by vigorous peristaltic waves and typically associated with pyloric stenosis or pylorospasm

Nausea—Unpleasant sensation vaguely referred to the throat or abdomen with an inclination to vomit

Constipation—Delay or difficulty with the passage of stools that is present for 2 weeks or longer; associated with symptoms that may include blood-streaked stools and abdominal discomfort

Encopresis—Involuntary overflow of incontinent stool causing soiling or incontinence secondary to fecal retention or impaction

Diarrhea—Increase in the number of stools with increased water content as a result of alterations of water and electrolyte transport by the gastrointestinal (GI) tract; may be acute or chronic

Hypoactive, hyperactive, or absent bowel sounds—Evidence of intestinal motility problems that may be caused by inflammation or obstruction

Abdominal distention—Protuberant contour of the abdomen that may be caused by delayed gastric emptying, accumulation of gas or stool, inflammation, or obstruction

Abdominal pain—Pain associated with the abdomen that may be localized or diffuse, acute or chronic; often caused by inflammation, obstruction, or hemorrhage

Gastrointestinal bleeding—May be from an upper or lower GI source and may be acute or chronic

- *Hematemesis*—Vomiting of bright red or denatured blood that results from bleeding in the upper GI tract or from swallowed blood from the nose or oropharynx
- *Hematochezia*—Passage of bright red blood per rectum, usually indicating lower GI tract bleeding
- *Melena*—Passage of dark-colored, "tarry" stools resulting from denatured blood, suggesting upper GI tract bleeding or bleeding from the right colon

Jaundice—Yellow coloration of the skin and sclerae associated with liver dysfunction in infants and children over 4 weeks of age

Dysphagia—Difficulty swallowing caused by abnormalities in the neuromuscular function of the pharynx or upper esophageal sphincter or by disorders of the esophagus

Dysfunctional swallowing—Impaired swallowing caused by central nervous system defects or structural defects of the oral cavity, pharynx, or esophagus; can cause feeding problems or aspiration

Fever—Common manifestation of illness in children with GI disorders; usually associated with dehydration, infection, or inflammation

serum hypotonic. Because ICF is more concentrated than ECF in hypotonic dehydration, water moves from the ECF to the ICF to establish osmotic equilibrium. This movement further increases the ECF volume loss, and shock is a frequent finding. Because there is a greater proportional loss of ECF in hypotonic dehydration, the physical signs tend to be more severe with smaller fluid losses than with isotonic or hypertonic dehydration. Serum sodium concentration is less than 130 mEq/L.

Hypertonic (hyperosmotic or **hypernatremic) dehydration** results from water loss in excess of electrolyte loss and is usually caused by a proportionately larger loss of water or a larger intake of electrolytes. This type of dehydration is the most dangerous and requires more specific fluid therapy. Hypertonic dehydration may occur in infants who are given fluids by mouth that contain large amounts of solute or in children who receive high-protein nasogastric (NG) tube feedings that place an excessive solute load on the kidneys. In hypertonic dehydration fluid shifts from the lesser concentration of the ICF to the ECF. Plasma sodium concentration is greater than 150 mEq/L.

Because the ECF volume is proportionately larger, hypertonic dehydration consists of a greater degree of water loss for the same intensity of physical signs. Shock is less apparent. However, central nervous system (CNS) disturbances, including alterations in consciousness, poor ability to focus attention, lethargy, increased muscle tone with hyperreflexia, and hyperirritability to stimuli, are more likely to occur. CNS changes are serious and may result in permanent damage.

Degree of Dehydration

Diagnosis of the type and degree of dehydration is necessary to develop an effective plan of therapy. The degree of dehydration has been described as a percentage of body weight dehydrated: mild—less than 3% in older children or less than 5% in infants; moderate—5% to 10% in infants and 3% to 6% in older children; and severe—more than 10% in infants and more than 6% in older children (Greenbaum, 2011). Water constitutes only 60% to 70% of an infant's weight. However, adipose tissue contains little water and is highly variable in individual infants and children. A more accurate means of describing dehydration is to reflect acute loss (time frame of ≤48 hours) in milliliters per kilogram of body weight. For example, a loss of 50 mL/kg is considered to be a mild fluid loss, but a loss of 100 mL/kg produces severe dehydration. Weight is the most important determinant of the percent of total body fluid loss in infants and younger children. However, often the preillness weight is unknown. Other predictors of fluid loss include a changing level of consciousness (irritability to lethargy), altered response to stimuli, decreased skin elasticity and turgor, prolonged capillary refill (>2 sec), increased heart rate, and sunken eyes and fontanels. There is evidence that the clinical signs of abnormal capillary refill, abnormal skin turgor, and abnormal respiratory pattern are the most useful in predicting dehydration of 5% or more in children (Colletti, Brown, Sharieff, et al., 2010; Emond, 2009; Steiner, DeWalt, and Byerly, 2004).

Clinical signs provide clues to the extent of dehydration (Table 41-1). The earliest detectable sign usually is tachycardia followed by dry skin and mucous membranes, sunken fontanels, signs of circulatory failure (coolness and mottling of extremities), loss of skin elasticity, and prolonged capillary filling time (Table 41-2).

Compensatory mechanisms attempt to maintain fluid volume by adjusting to these losses. Interstitial fluid moves into the vascular compartment to maintain the blood volume in response to hemoconcentration and hypovolemia, and vasoconstriction of peripheral arterioles helps maintain pumping pressure. When fluid losses exceed the ability of the body to sustain blood volume and blood pressure, circulation is seriously compromised, and the blood pressure falls. This results in tissue hypoxia with accumulation of lactic acid, pyruvate, and other acid metabolites, which contribute to the development of metabolic acidosis.

TABLE 41-1 EVALUATING EXTENT OF DEHYDRATION

	LEVEL OF DEHYDRATION		
CLINICAL SIGNS	**MILD**	**MODERATE**	**SEVERE**
Weight loss—infants	3%-5%	6%-9%	≥10%
Weight loss—children	3%-4%	6%-8%	10%
Pulse	Normal	Slightly increased	Very increased
Respiratory rate	Normal	Slight tachypnea (rapid)	Hyperpnea (deep and rapid)
Blood pressure	Normal	Normal to orthostatic (>10 mm Hg change)	Orthostatic to shock
Behavior	Normal	Irritable, more thirsty	Hyperirritable to lethargic
Thirst	Slight	Moderate	Intense
Mucous membranes*	Normal	Dry	Parched
Tears	Present	Decreased	Absent, sunken eyes
Anterior fontanel	Normal	Normal to sunken	Sunken
External jugular vein	Visible when supine	Not visible except with supraclavicular pressure	Not visible even with supraclavicular pressure
Skin*	Capillary refill >2 sec	Slowed capillary refill (2-4 sec [decreased turgor])	Very delayed capillary refill (>4 sec) and tenting; skin cool, acrocyanotic or mottled
Urine specific gravity	>1.020	>1.020; oliguria	Oliguria or anuria

Data from Jospe N, Forbes G: Fluids and electrolytes—clinical aspects, *Pediatr Rev* 17(11):395–403, 1996; and Steiner MJ, DeWalt DA, Byerly JS: Is this child dehydrated? *JAMA* 291(22):2746–2754, 2004.
*These signs are less prominent in patients who have hypernatremia.

Renal compensation is impaired by reduced blood flow through the kidneys, and little urine is formed. Increased serum osmolality stimulates the secretion of antidiuretic hormone (ADH) to conserve fluid and initiates the renin-angiotensin mechanisms in the kidney, causing further vasoconstriction. Aldosterone is released to promote sodium retention and conserve water in the kidneys. If dehydration increases in severity, urine formation is greatly diminished, and metabolites and hydrogen ions that are normally excreted by this route are retained.

Shock, a common manifestation of severe depletion of ECF volume, is preceded by tachycardia and signs of poor perfusion and tissue oxygenation (by pulse oximeter readings). Peripheral circulation is poor as a result of reduced blood volume; therefore the skin is cool and mottled, with decreased capillary filling after blanching. Impaired kidney circulation often leads to oliguria and azotemia. Although low blood pressure may accompany other symptoms of shock, in infants and young children it is usually a late sign and may herald the onset of cardiovascular collapse.

Diagnostic Evaluation

To initiate a therapeutic plan, several factors must be determined:

- The degree of dehydration based on physical assessment
- The type of dehydration based on the pathophysiology of the specific illness responsible for the dehydrated state
- Specific physical signs other than general signs
- Initial plasma sodium concentrations
- Serum bicarbonate concentration
- Any associated electrolyte (especially serum potassium) and acid-base imbalances (as indicated)

Initial and regular ongoing evaluations assess the patient's progress toward equilibrium and the effectiveness of therapy.

In the examination of an infant or younger child, one of the most important determinants of the extent of dehydration is body weight because this can help to determine the percentage of total body fluid lost; however, because the preillness weight is often unknown, clinical manifestations must be evaluated. Important clinical manifestations include changing sensorium (irritability to lethargy), decreased response to stimuli, integumentary changes (decreased elasticity and turgor), prolonged capillary refill, increased heart rate, sunken eyes, and in infants sunken fontanels. Using multiple predictors increases the sensitivity of assessing the fluid deficit, and early studies have shown a reasonably high degree of agreement between experienced observers in assessment of the level of dehydration. Objective signs of dehydration are present at a fluid deficit of less than 5%.

Laboratory data are said to be useful only when results are significantly abnormal (Emond, 2009). Urine specific gravity, urine ketones, and urinary output during rehydration reportedly are unreliable assessments for determining dehydration in children (Steiner, Nager, and Wang, 2007). Shock, tachycardia, and very low blood pressure are common features of severe depletion of ECF volume (see Shock, Chapter 42).

Therapeutic Management

Medical management is directed at correcting the fluid loss or deficit and treating the underlying cause. When the child is alert, awake, and not in danger, correction of dehydration may be attempted with oral fluid administration. Mild cases of dehydration can be managed at home by this method. Several commercial rehydration fluids are available for use (Table 41-3). Oral rehydration management consists of replacement of fluid loss over 4 to 6 hours, replacement of continuing losses, and provision for maintenance fluid requirements. In general a mildly dehydrated child may be given 50 mL/kg of ORS, and a child with moderate dehydration may be given 100 mL/kg of ORS. A child with fluid losses from diarrhea may be given 10 mL/kg for each stool. Amounts and rates are determined from body weight and the severity of dehydration and are increased if rehydration is incomplete or if excess losses continue until the child is well hydrated and the basic problem is under control (Box 41-4).

Enhance the flavor of an ORS such as Pedialyte (unflavored) by adding 1 tsp of unsweetened powder Kool-Aid to each 60 to 90 mL of ORS. Older children may take a small Popsicle orally instead of fluids that require drinking. Many commercially available Popsicles are relatively inexpensive and contain small amounts of sucrose and approximately 40 to 50 mL of fluid. Frozen oral hydration may be accepted by some children when conventional ORS is rejected.

TABLE 41-2 CLINICAL MANIFESTATIONS OF DEHYDRATION

MANIFESTATION	ISOTONIC (LOSS OF WATER AND SODIUM)	HYPOTONIC (LOSS OF SODIUM IN EXCESS OF WATER)	HYPERTONIC (LOSS OF WATER IN EXCESS OF SODIUM)
Skin			
Color	Gray	Gray	Gray
Temperature	Cold	Cold	Cold or hot
Turgor	Poor	Very poor	Fair
Feel	Dry	Clammy	Thickened, doughy
Mucous membranes	Dry	Slightly moist	Parched
Tearing and salivation	Absent	Absent	Absent
Eyeball	Sunken	Sunken	Sunken
Fontanel	Sunken	Sunken	Sunken
Body temperature	Subnormal or elevated	Subnormal or elevated	Subnormal or elevated
Pulse	Rapid	Very rapid	Moderately rapid
Respirations	Rapid	Rapid	Rapid
Behavior	Irritable to lethargic	Lethargic or comatose; seizures	Marked lethargy with extreme hyperirritability on stimulation

TABLE 41-3 COMPOSITION OF SOME ORAL REHYDRATION SOLUTIONS

FORMULA	NA (mEq/L)	K (mEq /L)	CL (mEq /L)	BASE (mEq /L)	GLUCOSE (g/L)
Pedialyte (Abbott)*	45	20	35	30 (citrate)	25
Rehydralyte (Abbott)	75	20	65	30 (citrate)	25
Infalyte (Mead Johnson)	50	25	45	34 (citrate)	30
World Health Organization†	75§	30	65	10 (bicarbonate)	13.5

Cl, Chloride; *K,* potassium; *Na,* sodium.
*Note that many generic products are available with compositions identical to Pedialyte.
†Must be reconstituted with 1 L water.
§Reduced osmolarity 224 mmol/L formulation.

BOX 41-4 MODEL FOR REHYDRATION

- Rehydration solution should consist of 75 to 90 mEq/L of sodium (Na^+).
- Give 40 to 50 mL/kg of rehydration solution over 4 hours.
- Replacement and maintenance solution should consist of 40 to 60 mEq/L of Na^+.
- Reevaluate the need for further rehydration; initiate maintenance therapy using maintenance formulations, with daily volumes not to exceed 150 mL/kg/day.
- In children with diarrhea without significant dehydration, the maintenance phase may be initiated without the need for rehydration solution.
- If additional fluids are needed, use low-salt fluids such as breast milk or water.

Modified from Centers for Disease Control and Prevention: Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy, *MMWR Recommend Rep* 52(RR-16):1–16, 2003.

TABLE 41-4 DAILY MAINTENANCE FLUID REQUIREMENTS*

BODY WEIGHT (kg)	AMOUNT OF FLUID PER DAY
1-10	100 mL/kg
11-20	1000 mL plus 50 mL/kg for each kg >10 kg
>20	1500 mL plus 20 mL/kg for each kg >20 kg

*Not appropriate for neonatal use.

The child may not be thirsty even though dehydrated and may refuse oral fluids initially for fear of continued emesis (if occurring) or because of decreased strength, oral stomatitis, or thrush. In such children rehydration may proceed by administering 2 to 5 mL of ORS by a syringe or small medication cup every 2 to 3 minutes until the child is able to tolerate larger amounts; if the child has emesis, administering small amounts (5 to 10 mL) of ORS approximately every 5 minutes may help overcome fluid deficit, and the emesis often lessens over time. Evidence indicates that oral administration of ondansetron (Zofran) to children with acute gastroenteritis and vomiting reduces emesis and increases time to oral rehydration, thus preventing intravenous (IV) therapy (Carter and Fedorowicz, 2012). Oral rehydration therapy (ORT) is effective for treating mild or moderate dehydration in children, is less expensive, and involves fewer complications than therapy (AAP, 2009).

Parenteral Fluid Therapy. Parenteral fluid therapy is initiated whenever the child is unable to ingest sufficient amounts of fluid and electrolytes to (1) meet ongoing daily physiologic losses, (2) replace previous deficits, and (3) replace ongoing abnormal losses. Patients who usually require IV fluids are those with severe dehydration, with uncontrollable vomiting, who are unable to drink for any reason (e.g., extreme fatigue, coma), and with severe gastric distention.

Because dehydration constitutes a great threat to life, the first priority is the restoration of circulation by rapid expansion of the ECF volume to treat or prevent shock. IV administration of fluid begins immediately, although the exact nature of the dehydration and the serum electrolyte values may not be known initially. The solution selected is based on what is known regarding the probable type and cause of the dehydration. This usually involves an isotonic solution such as 0.9% sodium chloride or lactated Ringer's solution, both of which are close to the body's serum osmolality of 285 to 300 mOsm/kg and do not contain dextrose (which is contraindicated in the early treatment stages of diabetic ketoacidosis).

Parenteral rehydration therapy has three phases. The initial therapy is used to expand ECF volume quickly and improve circulatory and renal function. During initial therapy an isotonic solution is used at a rate of 20 mL/kg given as an IV bolus over 20 minutes and repeated as necessary after assessment of the child's response to therapy (Ford, 2009; Friedman, 2010). Subsequent therapy is used to replace deficits, meet maintenance water and electrolyte requirements, and catch up with ongoing losses. Table 41-4 lists daily maintenance fluid requirements for children. Water and sodium requirements for the deficit, maintenance, and ongoing losses are calculated at 8-hour intervals, taking into consideration the amount of fluids given with the initial boluses and the amount administered during the first 24-hour period. With improved circulation during this phase, water and electrolyte deficits can be evaluated, and acid-base status can be corrected either directly through the administration of fluids or indirectly through improved renal function. Potassium is withheld until kidney function is restored and assessed and circulation has improved.

The final phase of therapy allows the patient to return to normal and begin oral feedings, with a gradual correction of total body deficits. The potassium loss in ICF is replaced slowly by way of the ECF. The body fat and protein stores are replaced through diet. If the child is unable to eat or if feeding aggravates a chronic condition, IV maintenance fluids are provided.

Although the initial phase of fluid replacement is rapid in both isotonic and hypotonic dehydration, it is contraindicated in hypertonic dehydration because of the risk of water intoxication, especially in the brain cells, specifically the central pontine cells. Central pontine myelinolysis may occur with an overcorrection of fluid deficit and an overly rapid correction of serum sodium concentration. There is an apparent lag time for sodium to reach a steady state

when diffusing in and out of brain cells, but water diffuses almost instantaneously. Consequently rapid administration of fluid causes equally rapid diffusion of water into the dehydrated brain cells, causing marked cerebral edema. Because ECF volume is maintained relatively well in hypertonic as opposed to the other types of dehydration, shock is not a usual manifestation.

CARE MANAGEMENT

Nursing observation and intervention are essential for detection and therapeutic management of dehydration. A variety of circumstances cause fluid losses in infants and small children, and changes can take place quickly. An important nursing responsibility is observing for signs of dehydration. Nursing assessment should begin with observing general appearance and proceed to more specific observations. Conditions in which dehydration may develop quickly include diarrhea; vomiting; sweating; fever; disorders such as diabetic ketoacidosis, renal disease, and cardiac anomalies; administration of certain drugs (e.g., diuretics and steroids); and trauma (major surgery, burns, and other extensive injury).

Whether the child is at home, in the practitioner's office or clinic, or in the hospital, nursing assessment is an essential part of the nursing care plan. The assessment of suspected or potential fluid and electrolyte disturbance begins with the observation of general appearance. Ill children usually have drawn expressions, have dry mucous membranes and lips, and "look sick." Loss of appetite is one of the first behaviors observed in most childhood illnesses, and the infant's or child's activity level is diminished from baseline or usual activities. The cry of an ill infant is less vigorous, often whining, and higher pitched than usual. The child is irritable, seeks the parent's comfort and attention, and displays purposeless movements and inappropriate responses to people and familiar objects. In some cases he or she may not protest advances by the health care worker and procedures such as taking vital signs or starting an IV infusion. These are signs that the child truly feels bad and that the condition is serious and immediate intervention is necessary. As the child's illness and level of dehydration become more severe, irritability progresses to lethargy and even unconsciousness.

Assess capillary filling time by pinching the abdominal skin, chest, arm, or leg and estimating the time it takes for the blood to return. Capillary filling time in mild dehydration is less than 2 seconds, increasing to more than 4 seconds in severe dehydration. The technique is effective in children of all ages. However, it can be altered in the presence of heart failure, which affects circulation time, and hypertonic dehydration, in which fluid loss is primarily intracellular. Additional clinical signs observed in children with dehydration include cool mottled extremities, sunken eyes, tachypnea, and changes in sensorium.

When caring for the ill child, assess the vital signs as often as every 15 to 30 minutes and record fluid intake and output and body weight frequently during the initial phase of therapy. It is important to use the same scale each time the child is weighed and predetermine the weight of any equipment or devices that must remain attached during the weighing process, including elbow restraints, and any clothing the child might be wearing. Obtain routine weights at the same time each day using the same scales.

Accurate measurements of fluid intake and output are vital to the assessment of dehydration. This includes oral and parenteral intake and losses from urine, stools, vomiting, fistulas, NG suction, sweat, and wound drainage:

- *Urine*—Frequency, color, consistency, and volume (when weighing diapers, ≈1 g of wet diaper weight equals 1 mL of urine)
- *Stools*—Frequency, volume, and consistency
- *Vomitus*—Volume, frequency, and type
- *Sweating*—Can only be estimated from frequency of clothing and linen changes

In addition to fluid intake and output, the following observations help to assess dehydration:

- *Vital signs*—Temperature (normal, elevated, or lowered depending on degree of dehydration), pulse (tachycardia), respirations (hyperpnea), and blood pressure (hypotension)
- *Skin*—Color, temperature, turgor, presence or absence of edema, and capillary refill
- *Mucous membranes*—Moisture, color, and presence and consistency of secretions
- *Body weight*—Decreased in relation to degree of dehydration
- *Fontanel (infants)*—Sunken, soft, or normal
- *Sensory alterations*—Presence of thirst (only in older child)

It is important to measure and record all intake, oral and parenteral, and output from all sources, including urine, stool, emesis, drainage tubes, fistulas, and wounds from which appreciable amounts of fluid are lost. At home advise parents to observe the number of times and how much the child voids. A newborn may be expected to void at least once in the first 24 hours, 2 or 3 times in the second 24 hours of life, 3 or 4 times in the third and fourth days of life, and a minimum of 5 or 6 times by the fifth and sixth days; if intake is adequate, an infant 5 to 6 days old and older may be expected to have a minimum of six to eight voidings per day (AAP, 2009). Infants younger than 1 year of age may void every 1 to 2 hours; toddlers urinate approximately every 3 hours. As children get older they void less frequently. Instruct the parents to notify the nurse or clinician if the child appears to be voiding an insufficient amount or persistently losing fluid through vomiting or diarrhea.

For nursing interventions see discussion under specific disorders in this chapter.

DISORDERS OF MOTILITY

Diarrhea

Diarrhea is a symptom that results from disorders involving digestive, absorptive, and secretory functions. It is caused by abnormal intestinal water and electrolyte transport. Worldwide there are an estimated 1.7 billion episodes of diarrhea each year (WHO, 2013). Approximately 19% of all deaths in children living in developing countries are related to diarrhea and dehydration (Boschi-Pinto, Velebit, and Shibuya, 2008). Most children living in developed countries who have gastroenteritis have mild forms. However, in the United States approximately 200,000 children younger than 5 years of age are hospitalized, and approximately 200 children younger than 5 years die of diarrhea and dehydration each year (Malek, Curns, Holman, et al., 2006; Staat, 2006).

Diarrheal disturbances involve the stomach and intestines (gastroenteritis), the small intestine (enteritis), the colon (colitis), or the colon and intestines (enterocolitis). Diarrhea is classified as acute or chronic.

Acute diarrhea, a leading cause of illness in children younger than 5 years of age, is defined as a sudden increase in frequency and a change in consistency of stools, often caused by an infectious agent in the GI tract. It may be associated with upper respiratory or urinary tract infections, antibiotic therapy, or laxative use. Acute diarrhea is usually self-limited (<14 days' duration) and subsides without specific treatment if dehydration does not occur. Acute infectious diarrhea (infectious gastroenteritis) is caused by a variety of viral, bacterial, and parasitic pathogens (Table 41-5).

TABLE 41-5 INFECTIOUS CAUSES OF ACUTE DIARRHEA

ORGANISM	PATHOLOGY	CHARACTERISTICS	COMMENTS
Viral Agents			
Rotavirus Incubation: 48 hr Diagnosis: enzyme immunoassay (EIA) and latex agglutination assay	Fecal-oral transmission Seven groups (A-G): Most group A virus replicates in mature villous epithelial cells of small intestine; leads to (1) imbalance in ratio of intestinal fluid absorption to secretion, and (2) malabsorption of complex carbohydrates	Mild-to-moderate fever Vomiting followed by the onset of watery stools Fever and vomiting generally abate in approximately 2 days, but diarrhea persists 5-7 days Adult contacts in household may develop symptomatic infection	Most common cause of diarrhea in children <5 yr of age Infants 6-12 mo are most vulnerable Peak occurrences in winter months; important cause of hospital-acquired infections Affects all ages; usually milder in children >3 yr of age; immune-compromised children at greater risk for complications Virus can live on toys and hard surfaces (sinks, countertops) Vaccine available for infants
Noroviruses (formerly Norwalk-like) **Caliciviruses** Incubation: 12-48 hr Diagnosis: EIA, reverse-transcriptase polymerase chain reaction (RT-PCR)	Fecal-oral; contaminated food or water Pathology similar to rotavirus Affects villous epithelial cells of small intestine Leads to (1) imbalance in ratio of intestinal fluid absorption to secretion, and (2) malabsorption of complex carbohydrates	Abdominal cramps; nausea, vomiting, malaise, low-grade fever, watery diarrhea without blood; duration brief, 2-3 days; tends to resemble so-called food poisoning symptoms with nausea predominating	Affects all ages Multiple strains often named for location of outbreak (e.g., Norwalk, Sapporo, Snow Mountain, Montgomery) Common in closed populations such as day care and cruise ships
Bacterial Agents			
Escherichia coli Incubation: 3-4 days Variable, depending on strain Diagnosis: sorbitol MacConkey agar (SMAC agar) + for blood, but fecal leukocytes are absent or rare	Five *E. coli* strains produce diarrhea as a result of enterotoxin production, adherence, or invasion: enterotoxigenic-producing (ETEC), enteroaggregative (EAEC), Shiga toxin–producing (STEC), enteropathogenic (EPEC), and enteroinvasive *E. coli* (EIEC)	Watery diarrhea 1-2 days; then severe abdominal cramping and bloody diarrhea STEC can progress to hemolytic uremic syndrome (HUS) and postdiarrheal thrombotic thrombocytopenia (TTP); 50% require dialysis and 3%-5% die	Foodborne pathogen Traveler's diarrhea Highest incidence in summer Cause of nursery epidemics Symptomatic treatment Antibiotics may worsen course, but meta-analysis shows no harm or benefit from antibiotic therapy (AAP Committee on Infectious Diseases and Pickering, 2012) Antimotility agents and opioids should be avoided
***Salmonella* groups (nontyphoidal; gram-negative rods, nonencapsulated, nonsporulating)** Incubation 6-72 hr Diagnosis: gram-stained stool culture	Invasion of mucosa in small and large intestine; edema of lamina propria; focal acute inflammation with disruption of mucosa and microabscesses	Nausea, vomiting, colicky abdominal pain, bloody diarrhea, fever; symptoms variable: mild to severe May have headache, cerebral manifestations (e.g., drowsiness, confusion, meningismus, seizures) Infants may be afebrile and nontoxic May result in life-threatening septicemia and meningitis Nausea/vomiting typically short duration; diarrhea may persist as long as 2-3 wk Typically shed virus for average of 5 wk; cases reported up to 1 yr	Incidence highest in warm months: July to November Foodborne outbreaks common Usually transmitted person to person but may transmit via undercooked meats, poultry Poultry and poultry products cause about half the cases In children: pets (e.g., dogs, cats, hamsters, turtles) Communicable as long as organisms are excreted Antibiotics not recommended in uncomplicated cases Antimotility agents also not recommended—prolong transit time and carrier state Incidence decreasing over past 10 yr

TABLE 41-5 INFECTIOUS CAUSES OF ACUTE DIARRHEA—cont'd

ORGANISM	PATHOLOGY	CHARACTERISTICS	COMMENTS
Salmonella typhi Produces enteric fever—systemic syndrome Incubation: Usually 7-14 days but could be 3-30 days, depending on size of inoculum Diagnosis: positive blood cultures; also sometimes positive stool and urine Late stage: positive bone marrow culture	Bloodstream invasion; after ingestion organism attaches to microvilli of ileal brush borders, and bacteria invade intestinal epithelium via Peyer's patches; is then transported to intestinal lymph nodes and enters bloodstream via thoracic ducts; circulating organisms reach reticuloendothelial cells, causing bacteremia	Manifestations depend on age Abdominal pain; diarrhea; nausea, vomiting, high fever, lethargy Must be treated with antibiotics	Incidence is much lower in developed countries; United States has about 400 cases/yr 65% of U.S. cases acquired via international cases Ingestion of food/water contaminated with human feces is most common mode of transmission Congenital and intrapartum transmission can occur Three vaccines are available
***Shigella* species** Gram-negative organisms Nonmotile Anaerobic bacilli Incubation: 1-7 days Diagnosis: stool culture Loaded with polymorphonuclear leukocytes	Enterotoxins: invade epithelium with superficial mucosal ulcerations	Patients appear sick Symptoms begin with fever, fatigue, anorexia Crampy abdominal pain precedes watery or bloody diarrhea Symptoms usually subside in 5-10 days	Most cases in children younger than 9 yr with about one third of cases in children ages 1-4 wk Antibiotics shorten illness and lower mortality risk All patients are at risk for dehydration Acute symptoms may persist for 1 wk or more Antidiarrheal medications not recommended; may predispose to toxic megacolon
Yersinia enterocolitica Incubation period: dose dependent, 1-3 wk Diagnosis: stool culture serology; enzyme-linked immunosorbent assay (ELISA) Patients have leukocytosis; elevated sedimentation rate	Pathology poorly understood; possible production of enterotoxin	Mucoid diarrhea, sometimes bloody; abdominal pain suggestive of appendicitis; fever, vomiting	Seen more frequently in winter months Transmitted by pets and contaminated food, especially raw or poorly cooked meat; rarely person-to-person Antibiotics usually do not alter clinical course in uncomplicated cases; should be used in complicated infections and compromised hosts
Campylobacter jejuni* and *Campylobacter coli Microaerophilic, motile, gram-negative bacilli Incubation period: 1-7 days Ability to cause illness appears dose related Diagnosis by stool culture, sometimes in blood Commonly found in gastrointestinal (GI) tract of wild or domestic animals	Not fully understood; possibly (1) adherence to intestinal mucosa by toxin; (2) invasion of mucosa in terminal ileum and colon; (3) translocation, in which organisms penetrate mucosa and replicate in lamina propria	Fever, abdominal pain, diarrhea, can be bloody; vomiting Watery, profuse, foul-smelling diarrhea Clinically similar to *Salmonella* or *Shigella* Fecal-oral transmission	Most infections in humans relate to consumption of contaminated foods or water; undercooked meats, particularly chicken; unpasteurized milk Also acquired from contaminated household pets (e.g., dogs, cats, hamsters) Bimodal peaks in infants >1 yr and again at ages 15-29 mo Antibiotics do not prolong carriage of bacteria and may eliminate organism more quickly Erythromycin and azithromycin drugs of choice (5-7 days) Antimotility agents not recommended and tend to prolong symptoms
Vibrio cholerae Gram-negative, motile, curved bacillus living in bodies of salt water Incubation period: 1-3 days Diagnosis by stool culture	Enters via oral route in contaminated food or water; if survives acid stomach environment, travels to small intestine, adheres to mucosa, and produces toxin	Onset abrupt; vomiting, watery diarrhea without cramping or tenesmus Dehydration can occur quickly	More prevalent in developing countries Rehydration most important treatment Antibiotics can shorten diarrhea Despite continued efforts, still no vaccine

Continued

TABLE 41-5 INFECTIOUS CAUSES OF ACUTE DIARRHEA—cont'd

ORGANISM	PATHOLOGY	CHARACTERISTICS	COMMENTS
Clostridium difficile Gram-positive anaerobic bacillus Diagnosis by detecting *C. difficile* toxin in stool culture	Produces two important toxins (A and B) Toxin binds to enterocyte surface receptor, resulting in alteration of permeability, protein synthesis, and direct cytotoxicity	Most cases: mild, watery diarrhea lasting few days Some cases: prolonged diarrhea and illness May cause pseudomembranous colitis Some individuals are extremely ill with high fever, leukocytosis, hypoalbuminemia	Associated with alteration of normal intestinal flora by antibiotics More common in hospitalized persons Adults tend to have more severe symptoms than children Treatment with antibiotics in symptomatic patients; and metronidazole Resistant strains have developed Relapse common
Clostridium perfringens Incubation period: 8-24 hr; anaerobic, gram-positive, spore-producing bacilli	Toxins produced in intestine after ingestion of organism	Acute onset: watery diarrhea, crampy abdominal pain Fever, nausea and vomiting rare Duration of illness usually 24 hr	Transmitted by contaminated food products, most often meats and poultry Usually self-limiting and medical intervention not needed Oral rehydration usually sufficient Antibiotics serve no purpose and should not be used
Clostridium botulinum Incubation period: 12-26 hr (range, 6 hr to 8 days) Gram-positive, anaerobic, spore-producing bacilli Blood and stool culture should be obtained and transmitted to special laboratory (usually state health department) to detect toxin	Botulism caused by binding of toxin to neuromuscular junction	Clinical presentation related to age and strain of botulism Abdominal pain, cramping, and diarrhea Other strains: respiratory compromise, central nervous system symptoms	Transmitted in contaminated food products Can be acquired via wound infection Treatment involves supportive care and neutralization of toxin See Infant Botulism, Chapter 49
***Staphylococcus* (food poisoning)** Incubation period: generally short, 1-8 hr Gram-positive, nonmotile, aerobic, or facultative anaerobic bacteria Diagnosis by identifying organism in food, blood, pus, aspirate	Direct tissue invasion and production of toxin	Clinical presentation depends on site of entry In food poisoning: profuse diarrhea, nausea and vomiting Low-grade fever and hypothermia may occur	GI illness transmitted in inadequately cooked or refrigerated foods Self-limiting in GI illness Symptomatic treatment Antibiotics not recommended

Chronic diarrhea is defined as an increase in stool frequency and increased water content with a duration of more than 14 days. It is often caused by chronic conditions such as malabsorption syndromes, inflammatory bowel disease (IBD), immunodeficiency, food allergy, lactose intolerance, or chronic nonspecific diarrhea or as a result of inadequate management of acute diarrhea.

Intractable diarrhea of infancy is a syndrome that occurs in the first few months of life, persists for more than 2 weeks with no recognized pathogens, and is refractory to treatment. The most common cause is inadequately managed acute infectious diarrhea.

Chronic nonspecific diarrhea (CNSD), also known as irritable colon of childhood and toddlers' diarrhea, is a common cause of chronic diarrhea in children 6 to 54 months of age. These children have loose stools, often with undigested food particles, and diarrhea lasting more than 2 weeks. Children with CNSD grow normally and have no evidence of malnutrition, no blood in their stool, and no enteric infection. Dietary indiscretions and food sensitivities have been linked to chronic diarrhea. The excessive intake of juices and artificial sweeteners such as sorbitol, a substance found in many commercially prepared beverages and foods, may be a factor.

Etiology

Most pathogens that cause diarrhea are spread by the fecal-oral route through contaminated food or water or are from person to person where there is close contact (e.g., day care centers). Lack of clean water, crowding, poor hygiene, nutritional deficiency, and poor sanitation are major risk factors, especially for bacterial or parasitic pathogens. The increased frequency and severity of diarrheal disease in infants is also related to age-specific alterations in susceptibility to pathogens. For example, the immune systems of infants have not been exposed to many pathogens and have not acquired protective antibodies. Worldwide the most common causes of acute gastroenteritis are infectious agents, viruses, bacteria, and parasites. In developed nations viruses, primarily rotavirus, cause 70% to 80% of infectious diarrhea.

Rotavirus is the most important cause of serious gastroenteritis among children and a significant nosocomial (hospital-acquired) pathogen, accounting for 55,000 to 70,000 hospitalizations annually (AAP Committee on Infectious Diseases, 2012; CDC, 2009). However, population-based surveys in three U.S. counties indicate that hospitalizations among children younger than 36 months old

decreased by as much as 87% among 6 to 11 month olds, 96% among children ages 12 to 23 months, and 92% among those 24 to 35 months of age after introduction of the rotavirus vaccine in 2006 (Payne, Staat, Edwards, et al., 2011). Rotavirus disease is most severe in children 3 to 24 months of age. Children younger than 3 months of age have some protection from the disease because of maternally acquired antibodies. Approximately 25% of severe cases of rotavirus occur in older children.

Salmonella, Shigella, and *Campylobacter* organisms are the most frequently isolated bacterial pathogens. *Salmonella* has the highest occurrence in infants; *Giardia* and *Shigella* have the highest incidence among toddlers. *Shigella* infection is uncommon in the United States, accounting for fewer than 5% of diarrheal illnesses in infants and toddlers. *Campylobacter* infection has a bimodal presentation (highest in children younger than 12 months of age with a second rise in incidence at age 15 to 19 years). *Giardia* and *Cryptosporidium* organisms are parasites. *Giardia* infection represents 15% of nondysenteric illness in the United States; *Cryptosporidium* infection is often associated with outbreaks in young children in day care centers; an increase in infections has been seen in association with outdoor swimming (pools, lakes, splash fountains) in the summer and early fall (AAP Committee on Infectious Diseases, 2012). *Plesiomonas shigelloides* is frequently responsible for causing traveler's diarrhea. (See also Intestinal Parasitic Diseases, p. 1272.)

Antibiotic administration is frequently associated with diarrhea because antibiotics alter the normal intestinal flora, resulting in an overgrowth of other bacteria such as *Clostridium difficile.* National rates of *C. difficile* have more than doubled since 2000 (Richards, 2006), and it has become more virulent with a high rate of recurrence and treatment failure (Bakken, 2009; DuPont, 2011). Antibiotic-associated diarrhea can also be caused by *Salmonella* organisms, *Clostridium porringers* type A, and *Staphylococcus aureus* pathogens.

Pathophysiology

Invasion of the GI tract by pathogens results in increased intestinal secretion as a result of enterotoxins, cytotoxic mediators, or decreased intestinal absorption secondary to intestinal damage or inflammation. Enteric pathogens attach to the mucosal cells and form a cuplike pedestal on which the bacteria rest. The pathogenesis of the diarrhea depends on whether the organism remains attached to the cell surface, resulting in a secretory toxin (noninvasive, toxin-producing, noninflammatory type diarrhea) or penetrates the mucosa (systemic diarrhea). Noninflammatory diarrhea is the most common diarrheal illness, resulting from the action of enterotoxin that is released after attachment to the mucosa. The most serious and immediate physiologic disturbances associated with severe diarrheal disease are (1) dehydration, (2) acid-base imbalance with acidosis, and (3) shock that occurs when dehydration progresses to the point that circulatory status is seriously impaired.

Diagnostic Evaluation

Evaluation of a child with acute gastroenteritis begins with a careful history that seeks to discover the possible cause of diarrhea, assess the severity of symptoms and the risk of complications, and elicit information about current symptoms indicating other treatable illnesses that could be causing the diarrhea. The history should include questions about recent travel, exposure to untreated drinking or washing water sources, contact with animals or birds, day care center attendance, recent treatment with antibiotics, or recent diet changes. History questions should also explore the presence or absence of other symptoms such as fever and vomiting, frequency and character of stools (e.g., watery, bloody), urinary output, dietary habits, and recent food intake.

Extensive laboratory evaluation is not indicated in children who have uncomplicated diarrhea and no evidence of dehydration because most diarrheal illnesses are self-limiting. Laboratory tests are indicated for children who are severely dehydrated and receiving IV therapy. Watery, explosive stools suggest glucose intolerance; foul-smelling, greasy, bulky stools suggest fat malabsorption. Diarrhea that develops after the introduction of cow's milk, fruits, or cereal may be related to enzyme deficiency or protein intolerance. Neutrophils or red blood cells in the stool indicate bacterial gastroenteritis or IBD. The presence of eosinophils suggests protein intolerance or parasitic infection. Stool cultures should be performed only when blood, mucus, or polymorphonuclear leukocytes are present in the stool; when symptoms are severe; when there is a history of travel to a developing country; and when a specific pathogen is suspected. Gross or occult blood may indicate pathogens such as *Shigella*, *Campylobacter*, or hemorrhagic *Escherichia coli* strains. An enzyme-linked immunosorbent assay (ELISA) may be used to confirm the presence of rotavirus or *Giardia* organisms. If there is a history of recent antibiotic use, the stool should be tested for *C. difficile* toxin. When bacterial and viral culture results are negative and diarrhea persists for more than a few days, stools should be examined for ova and parasites. A stool specimen with a pH of less than 6.0 and the presence of reducing substances may indicate carbohydrate malabsorption or secondary lactase deficiency. Stool electrolyte measurements may help identify children with secretory diarrhea.

The serum bicarbonate (CO_2) may be useful when combined with other clinical signs. In the presence of metabolic acidosis an anion gap may be helpful to distinguish between types of metabolic imbalance. Obtain a complete blood count (CBC), serum electrolytes, creatinine, and blood urea nitrogen (BUN) in the child who has moderate-to-severe dehydration or who requires hospitalization. The hemoglobin, hematocrit, creatinine, and BUN levels are usually elevated in acute diarrhea and should normalize with rehydration.

Therapeutic Management

The major goals in the management of acute diarrhea include (1) assessment of fluid and electrolyte imbalance, (2) rehydration, (3) maintenance fluid therapy, and (4) reintroduction of an adequate diet. Infants and children with acute diarrhea and dehydration should be treated first with oral rehydration therapy (ORT). ORT is one of the major worldwide health care advances. It is more effective, safer, less painful, and less costly than IV rehydration. The AAP, WHO, and CDC recommend ORT as the treatment of choice for most cases of dehydration caused by diarrhea (CDC, 2003) (see Box 41-4). Oral rehydration solutions (ORSs) enhance and promote the resorption of sodium and water; studies indicate that these solutions greatly reduce vomiting, volume loss from diarrhea, and the duration of the illness. ORSs, including reduced-osmolarity ORS, are available in the United States as commercially prepared solutions and are successful in treating the majority of infants with dehydration. Guidelines for rehydration recommended by the AAP are included in Table 41-6.

After rehydration ORS may be used during maintenance fluid therapy by alternating the solution with a low-sodium fluid such as

TABLE 41-6 TREATMENT OF ACUTE DIARRHEA

DEGREE OF DEHYDRATION	SIGNS AND SYMPTOMS	REHYDRATION THERAPY*	REPLACEMENT OF STOOL LOSSES	MAINTENANCE THERAPY
Minimal	Increased thirst Slightly dry buccal mucous membranes	ORS, 50 mL/kg over 4 hr ORS, give 5-10 mL every 2-3 minutes	<10 kg: 60-120 mL per vomiting or diarrheal episode >10 kg:120-140 mL ORS per episode of vomiting or diarrhea	Breastfeeding, if established, should continue; give regular infant formula if tolerated. If lactose intolerance suspected, give undiluted lactose-free formula (or half-strength lactose-containing formula for brief period only); infants and children who receive solid food should continue their usual diet.
Mild to Moderate	Loss of skin turgor, dry buccal mucous membranes, sunken eyes, sunken fontanel	ORS, 100 mL/kg within 4 hr	Same as for Minimal	
Severe	Signs of moderate dehydration plus one of following: rapid, thready pulse; cyanosis; rapid breathing; lethargy; or coma	IV fluids (Ringer's lactate; 0.9 NS), 20 mL/kg bolus over 30 minutes and repeat until pulse and state of consciousness return to normal; then maintenance fluids with dextrose and 0.45 NS; add K+ after renal function adequate; give 50-100 mL/kg or ORS	Same as for Minimal	

Modified from Centers for Disease Control and Prevention: Managing acute gastroenteritis among children: oral rehydration, maintenance, and nutritional therapy, *MMWR Recommend Rep* 52(RR-16):1–16, 2003.
IV, Intravenous; *NS,* normal saline; *ORS,* oral rehydration solution.
*If no signs of dehydration are present, rehydration therapy is not necessary. Proceed with maintenance therapy and replacement of stool losses.

breast milk or commercial infant formula. In older children ORS can be given, and a regular diet continued. Ongoing stool losses should be replaced on a 1:1 basis with ORS. If the stool volume is not known, approximately 10 mL/kg (4 to 8 oz) of ORS should be given for each diarrheal stool.

The WHO and UNICEF (United Nations Children's Fund) recommend the addition of zinc to ORS for the treatment of diarrheal disease in children (Granado-Villar, Cunill-de Sautu, and Granados, 2012). Zinc supplementation has been shown to decrease the frequency of stools in acute gastroenteritis (Atia and Buchman, 2009). Liquids such as sports drinks, tea, juices, or carbonated beverages are not appropriate for ORT in small children.

Solutions for oral hydration are useful in most cases of dehydration, and vomiting is not a contraindication. A child who is vomiting should be given an ORS at frequent intervals and in small amounts. For young children the caregiver may give the fluid with a spoon or small syringe in 5- to 10-mL increments every 1 to 5 minutes. An ORS may also be given via NG or gastrostomy tube infusion. Infants without clinical signs of dehydration do not need ORT. However, they should receive the same fluids recommended for infants with signs of dehydration in the maintenance phase and for ongoing stool losses. The use of probiotics in tandem with rehydration therapy reduces the duration and stool frequency in acute infectious diarrhea (Allen, Martinez, Gregorio, et al., 2010).

Early reintroduction of nutrients is desirable and is gaining more widespread acceptance. Continued feeding or early reintroduction of a normal diet has no adverse effects and actually lessens the severity and duration of the illness and improves weight gain compared with the gradual reintroduction of foods (AAP, 2009; Bhutta, 2011). Infants who are breastfeeding should continue to do so, and ORS should be used to replace ongoing losses in these infants. Formula-fed infants should resume their formula; if it is not tolerated, a lactose-free formula may be used for a few days. In older children a regular diet, including milk, generally can be offered after rehydration has been achieved. In toddlers there is no contraindication to continuing soft or pureed foods. A diet of easily digestible foods such as cereals, cooked vegetables, and meats is adequate for older children.

! NURSING ALERT

Diarrhea is not managed by encouraging intake of clear fluids by mouth such as fruit juices, carbonated soft drinks, and gelatin. These fluids usually have a high carbohydrate content, a very low electrolyte content, and a high osmolality. Caffeinated soda is avoided because caffeine is a mild diuretic and may lead to increased loss of water and sodium. Chicken or beef broth is not given because it contains excessive sodium and inadequate carbohydrate. A BRAT diet (bananas, rice, applesauce, and toast or tea) is contraindicated for children and especially for infants with acute diarrhea because it has little nutritional value (low in energy and protein), is high in carbohydrates, and is low in electrolytes (AAP, 2009).

In cases of severe dehydration and shock, IV fluids are initiated whenever the child is unable to ingest sufficient amounts of fluid and electrolytes to (1) meet ongoing daily physiologic losses, (2) replace previous deficits, and (3) replace ongoing abnormal losses. Patients who usually require IV fluids are those with severe dehydration, with uncontrollable vomiting, who are unable to drink for any reason (e.g., extreme fatigue, coma), and with severe gastric distention.

The IV solution for fluid replacement is selected based on what is known regarding the probable type and cause of the dehydration—usually a saline solution (0.9 normal saline [NS] or lactated Ringer's solution for rapid volume replacement (see Parenteral Fluid Therapy, p. 1258).

After the severe effects of dehydration are under control, specific diagnostic and therapeutic measures are begun to detect and treat the cause of the diarrhea. The use of antibiotic therapy in children with acute gastroenteritis is controversial. Antibiotics may shorten the course of some diarrheal illnesses (e.g., those caused by *Shigella* organisms). However, most bacterial diarrheas are self-limiting, and the diarrhea often resolves before the causative organism can be determined. Antibiotics may prolong the carrier period for bacteria such as *Salmonella* spp. However, they may be considered in patients with immunosuppression, severe symptoms, or persistent disease and in patients who have had transplantation. Antimotility drugs such as loperamide are not recommended in children, and antiemetic drugs such as the phenothiazines are not recommended because of their side effects. Because of the self-limiting nature of vomiting and its tendency to improve when dehydration is corrected, historically the use of antiemetic agents has not been recommended; however, ondansetron has few side effects and may be administered if vomiting persists and interferes with ORT (Bhutta, 2011).

The treatment of relapsing *Clostridium difficile* with antibiotics has met partial success, but relapses are common. Recently a novel therapy has been used widely in adults (Mellow and Kanatzar, 2011) and on a limited basis in children to colonize the gut with donor fecal bacteria in order to stop diarrhea associated with *C. difficile*. The fecal bacteriotherapy resulted in a resolution of symptoms within 36 hours of treatment (Russell, Kaplan, Ferraro, et al., 2010).

Prevention. Two rotavirus vaccines are now available for children. Human-bovine reassortant rotavirus vaccine (RotaTeq), which became available in 2006, and live-attenuated human rotavirus vaccine (Rotarix) may be used to prevent this infectious diarrheal disease. Infants should receive three doses of RotaTeq oral vaccine at 2, 4, and 6 months of age. Two doses of Rotarix induce protective immunity and may be administered at 2 and 4 months of age (AAP Committee on Infectious Diseases and Pickering, 2012) (see Chapter 31, Immunizations). Population-based studies show a reduction of diarrhea-associated hospitalizations by as much as 87% to 96% in the years after rotavirus vaccination (Payne, Staat, Edwards, et al., 2011). Breastfeeding during the first 6 months of life has been found to have a protective effect against rotavirus infection (Plenge-Bönig, Soto-Ramirez, Karmaus, et al., 2010).

CARE MANAGEMENT

The management of most cases of acute diarrhea takes place in the home with education of the caregiver. Caregivers are taught to monitor for signs of dehydration (especially the number of wet diapers or voidings) and the amount of fluids taken by mouth and to assess the frequency and amount of stool losses. Education relating to ORT, including the administration of maintenance fluids and replacement of ongoing losses, is important (see Critical Thinking Case Study). ORS should be administered in small quantities at frequent intervals. Vomiting is not a contraindication to ORT unless it is severe. Information concerning the introduction of a normal diet is essential. Parents need to know that a slightly higher stool output initially occurs with continuation of a normal diet and with ongoing replacement of stool losses. The benefits of a better nutritional outcome with fewer complications and a shorter duration of illness outweigh the potential increase in stool frequency. Parents' concerns should be addressed to ensure adherence to the treatment plan.

If the child with acute diarrhea and dehydration is hospitalized, an accurate weight must be obtained, and fluid intake and output carefully monitored. The child may be placed on parenteral fluid therapy with nothing by mouth (NPO) for 12 to 48 hours, but the trend is to start small amounts of oral fluids to tolerance unless there are other illness factors that preclude ORT. Monitoring the IV infusion is an important nursing function. The nurse must ensure that the correct fluid and electrolyte concentration is infused, the flow rate is adjusted to deliver the desired volume in a given time, and the IV site is maintained.

Accurate measurement of output is essential to determine whether renal blood flow is sufficient to permit the addition of potassium to the IV fluids. The nurse is responsible for examination of stools and collection of specimens for laboratory examination (see Collection of Specimens, Chapter 39). Care should be taken when obtaining and transporting stools to prevent possible spread of infection. Stool specimens should be transported to the laboratory in appropriate containers and media.

Diarrheal stools are highly irritating to the perianal skin, and extra care is needed to protect the skin of the diaper region from excoriation (see Diaper Dermatitis, Chapter 47). Taking the temperature rectally is usually avoided because it stimulates

CRITICAL THINKING CASE STUDY

Diarrhea

A mother brings her 8-month-old infant, Mary, to the primary care clinic. The mother reports that Mary has had a "cold" for about 2 days and this morning she began to vomit and has had diarrhea for the past 8 hours. The mother states that Mary is still breastfeeding but that she is not taking as much milk as usual and she is having 3 times as many stools as usual (the stools are watery in consistency). When the nurse practitioner examines Mary, she notes that her temperature is 38° C (100.4° F), her pulse and blood pressure are in the normal range, her mucous membranes are moist, and she has tears when she cries. The nurse practitioner also notes that Mary's weight has not changed from what it was when she was seen in the clinic 2 weeks ago for her well-child visit.

1. Evidence—Is there sufficient evidence for the nurse practitioner to draw any conclusions for her initial plan of management?
2. Assumptions—Describe some underlying assumptions about the following:
   a. Clinical manifestations of various levels of dehydration
   b. Management of acute diarrhea
   c. Breastfeeding and the management of acute diarrhea
   d. Use of antidiarrheal medications for acute diarrhea
3. Which nursing interventions should the nurse practitioner implement at this time?
4. Does the evidence support the nurse practitioner's conclusion?

the bowel, increasing the passage of stool and causing mucosal irritation.

Support for the child and family involves the same care and consideration given to all hospitalized children (see Chapter 38). Parents are kept informed of the child's progress and instructed in the use of frequent and proper hand washing and the disposal of soiled diapers, clothes, and bed linens. Everyone caring for the child must be aware of "clean" and "dirty" areas, especially in the hospital, where the sink in the child's room is used for many purposes. Soiled diapers and linens should be discarded in receptacles close to the bedside.

Prevention. The best intervention for diarrhea is prevention. The fecal-oral route spreads most infections, and parents need information about preventive measures such as personal hygiene, protection of the water supply from contamination, and careful food preparation.

! NURSING ALERT

To reduce the risk of bacteria transmitted via food, encourage parents to:

- Quickly freeze or refrigerate all ground meat and other perishable foods.
- Never thaw food on the counter or let it sit out of the refrigerator for more than 2 hours.
- Wash hands, utensils, and work areas with hot, soapy water after contact with raw meat to keep bacteria from spreading.
- Check ground meat with a fork to make certain that no pink is showing before taking a bite.
- Cook all dishes made with ground meat until brown or gray inside or to an internal temperature of 71° C (160° F).
- Use soap or a weak chlorine bleach solution to wash all fruits and vegetables that are unable to be peeled.

Meticulous attention to perianal hygiene, disposal of soiled diapers, proper hand washing, and isolation of infected people also minimize the transmission of infection (see Infection Control, Chapter 39).

Parents need information about preventing diarrhea while traveling. They are cautioned against giving their children adult medications that are used to prevent traveler's diarrhea. Until vaccines or other prophylactic measures are proved to be safe for children, the best measure during travel to areas where water may be contaminated is to allow children to drink only bottled water and carbonated beverages. Tap water, ice, unpasteurized dairy products, raw vegetables, unpeeled fruits, meats, and seafood should also be avoided.

Constipation

Constipation is an alteration in the frequency, consistency, or ease of passing stool. It is defined as a decrease in bowel movement frequency or trouble defecating for more than 2 weeks (Philichi, 2008). It is an alteration in the frequency, consistency, or ease of passing stool. Parents often define constipation as passing less than three stools per week. It may also be defined as painful bowel movements, which are often blood streaked or include the retention of stool, with or without soiling, even with a stool frequency of more than three stools per week (Loening-Baucke and Pashankar, 2006). However, the frequency of bowel movements is not considered a diagnostic criterion because it varies widely among children. Having extremely long intervals between defecation is **obstipation.** Constipation with fecal soiling is **encopresis.**

Constipation may arise secondary to a variety of organic disorders or in association with a wide range of systemic disorders. Structural disorders of the intestine such as strictures, ectopic anus, and Hirschsprung disease (HD), may be associated with constipation. Systemic disorders associated with constipation include hypothyroidism, hypercalcemia resulting from hyperparathyroidism or vitamin D excess, and chronic lead poisoning. Constipation may be associated with use of drugs such as antacids, diuretics, antiepileptics, antihistamines, opioids, and iron supplementation. Spinal cord lesions may be associated with loss of rectal tone and sensation. Affected children are prone to chronic fecal retention and overflow incontinence.

The majority of children have idiopathic or functional constipation because no underlying cause can be identified. Chronic constipation may occur as a result of environmental or psychosocial factors or a combination of both. Transient illness, stool withholding and avoidance secondary to painful or negative experiences with stooling, and dietary intake with decreased fluid and fiber all play a role in the etiology of constipation.

Newborn Period

Normally newborn infants pass a first meconium stool within 24 to 36 hours of birth. Any infant who does not do so should be assessed for evidence of intestinal atresia or stenosis, HD, hypothyroidism, meconium plug, or meconium ileus. Meconium plug is caused by meconium that has reduced water content and is usually evacuated after digital examination but may require irrigations with a hypertonic solution or contrast medium.

Meconium ileus, the initial manifestation of cystic fibrosis, is the luminal obstruction of the distal small intestine by abnormal meconium. Treatment is the same as for a meconium plug; early surgical intervention may be needed to evacuate the small intestine.

Infancy

The onset of constipation frequently occurs during infancy and may result from organic causes such as HD, hypothyroidism, and strictures. It is important to differentiate these conditions from functional constipation. Constipation in infancy is often related to dietary practices. It is less common in breastfed infants, who have softer stools than bottle-fed infants. Breastfed infants may also have decreased stools because of more complete digestion of breast milk with little residue. When constipation occurs with a change from human milk or modified cow's milk to whole cow's milk (12 months old and older), simple measures such as adding or increasing the amount of cereal, vegetables, and fruit in the infant's diet usually correct the problem. When a bottle-fed infant passes a hard stool that results in an anal fissure, stool-withholding behaviors may develop in response to pain on defecation (see Critical Thinking Case Study).

Childhood

Most constipation in early childhood is attributable to environmental changes or normal development when a child begins to attain control over bodily functions. A child who has experienced discomfort during bowel movements may deliberately try to withhold stool. Over time the rectum accommodates to the accumulation of stool, and the urge to defecate passes. When the bowel contents ultimately are evacuated, the accumulated feces are passed with pain, thus reinforcing the desire to withhold stool.

Constipation in school-age children may represent an ongoing problem or a first-time event. The onset of constipation at this age is often the result of environmental changes, stresses, and changes in toileting patterns. A common cause of new-onset constipation at school entry is fear of using the school bathrooms, which are noted

CRITICAL THINKING CASE STUDY

Constipation

Harry, an 8-month-old infant, is seen by the pediatric nurse practitioner for his well-child visit. Harry's mother states that he usually has one hard stool every 4 or 5 days, which causes discomfort when the stool is passed. He has also had one episode of diarrhea and two episodes of ribbonlike stools. Abdominal distention and vomiting have not accompanied the constipation, and Harry's growth has been appropriate for his age. Currently his diet consists of formula only. Harry's mother reports that the infrequent passage of hard stools began approximately 6 weeks ago when she stopped breastfeeding.

1. Evidence—Is there sufficient evidence for the nurse practitioner to draw any conclusions about the management of Harry's problem?
2. Assumptions—Describe some underlying assumptions about the following:
   a. Causes of constipation in infants
   b. Factors associated with functional constipation in infants
   c. Management of functional constipation in infants
3. Which interventions should the nurse practitioner implement at this time?
4. Does the evidence support these interventions?

for their lack of privacy. Early and hurried departure for school immediately after breakfast may also impede bathroom use.

The management of simple constipation consists of a plan to promote regular bowel movements. Often this is as simple as changing the diet to provide more fiber and fluids, eliminating foods known to be constipating, and establishing a bowel routine that allows for regular passage of stool. An increase in dietary fiber is recommended as a treatment for constipation in the healthy child. The amount of fiber for children of different ages varies by various authorities, but the formula of "age + 5 g" daily intake of fiber is recommended for children 3 years old and older (Kranz, Brauchla, Slavin et al., 2012). The DRI average intake (AI) for children 4 to 8 years old is 25 g of fiber daily. AI dietary fiber intake recommendations for children 9 to 13 years (boys) are 31 g/day and 26 g/day for girls of the same age and up to age 18 years. For boys ages 14 to 18 years the AI for fiber intake is 38 g/day.

Stool-softening agents such as docusate or lactulose may also be helpful. Polyethylene glycol (PEG) 3350 without electrolytes (Miralax) is a chemically inert polymer that has been introduced as a new laxative in recent years. It is usually tolerated well by children because it can be mixed in a beverage of choice. If other symptoms such as vomiting, abdominal distention, or pain and evidence of growth failure are associated with the constipation, the condition should be investigated further.

CARE MANAGEMENT

Constipation tends to be self-perpetuating. A child who has difficulty or discomfort when attempting to evacuate the bowels has a tendency to retain the bowel contents, and this may initiate a vicious cycle. Nursing assessment begins with an accurate history of bowel habits; diet; events associated with the onset of constipation; drugs or other substances that the child may be taking; and the consistency, color, frequency, and other characteristics of the stool. If there is no evidence of a pathologic condition, the major task is to educate the parents regarding normal stool patterns and participate in the education and treatment of the child.

TABLE 41-7 FIBER CONTENT OF SELECT FOODS

FOOD	SERVING SIZE	GRAMS OF FIBER
Apple, raw, with skin	1 apple	3.3
Bananas, ripe, raw		3.1
Beans, baked, canned	1 cup	10.4
Beans, pinto, mature seeds*	1 cup	15.4
Beets*	1 cup	3.4
Blackberries, raw	1 cup	7.6
Blueberries, raw	1 cup	3.5
Bread, mixed grain (includes whole grain)	1 slice	1.6
Broccoli*	1 cup	5.1
Brussel sprouts*	1 cup	4.1
Carrots*	1 cup	4.7
Cereals, ready-to-eat, General Mills, Cheerios	1 cup	3.6
Cereals, ready-to-eat, General Mills, Raisin nut bran	1 cup	5.1
Cereals, ready-to-eat, Kellogg's All Bran, original	½ cup	8.8
Cereals, ready-to-eat, Kellogg's Raisin Bran	1 cup	7.3
Collards*	1 cup	5.3
Dates, daglet noor	1 cup	14.2
Lentils, mature seeds*	1 cup	15.6
Lima beans, large, mature*	1 cup	13.2
Oat bran, cooked	1 cup	5.7
Oranges, raw	1 orange	3.1
Pears, raw	1 pear	5.1
Peas, green, frozen*	1 cup	8.8
Raisins, seedless	1 cup	5.4
Spinach*	1 cup	4.3
Vegetables, mixed, frozen*	1 cup	8.0
Wheat flour, whole grain	1 cup	14.6
Wheat flour, white, all-purpose, enriched	1 cup	3.5

Modified from USDA National Nutrient Database for Standard Reference, Release 17, Fiber, total dietary content of selected foods per common measure, sorted alphabetically, http://www.nal.usda.gov/fnic/foodcomp/Data/SR17/wtrank/sr17a291.pdf.
*Cooked, boiled, drained, no salt.

Dietary modifications are essential in preventing constipation. Lactulose (1 to 3 mL/kg/day) and glycerin suppositories are safe and effective in infants, whereas the addition of other ingredients to formula is not recommended (Rowan-Legg and Canadian Paediatric Society, 2011). During childhood the diet should contain increased amounts of fiber and fluid. Parents benefit from guidance in selecting foods that facilitate bowel movements (Table 41-7). They need reassurance concerning the benign nature of the

condition. It is also important to discuss their attitudes and expectations regarding toilet habits.

When constipation persists despite dietary intervention, more aggressive management may be necessary. It is important to differentiate an acute episode of constipation from chronic functional constipation, which can result from chronic stool-withholding behavior. As the rectal vault becomes distended over time, further complications such as fecal impaction and encopresis may develop (see Chapter 34).

Hirschsprung Disease

HD is a congenital anomaly that results in mechanical obstruction from inadequate motility of part of the intestine. It accounts for about one fourth of all cases of neonatal intestinal obstruction. The incidence is 1 in 5000 live births. It is 4 times more common in males than in females and follows a familial pattern in a small number of cases. Mutations in the *RET* protooncogene have been found in 17% to 38% of children with short-segment HD and in 70% to 80% of those with long-segment involvement (Dasgupta and Langer, 2004). In more than 80% of cases the aganglionosis is restricted to the internal sphincter, rectum, and a few centimeters of the sigmoid colon and is termed *short-segment disease* (Theocharatos and Kenny, 2008).

Pathophysiology

The pathology of HD relates to the absence of ganglion cells in the affected areas of the intestine, resulting in a loss of the rectosphincteric reflex and an abnormal microenvironment of the cells of the affected intestine (Theocharatos and Kenny, 2008). The term *congenital aganglionic megacolon* describes the primary defect, which is the absence of ganglion cells in the myenteric plexus of Auerbach and the submucosal plexus of Meissner (Fig. 41-1).

The absence of ganglion cells in the affected bowel results in a lack of enteric nervous system stimulation, which decreases the ability of the internal sphincter to relax. Unopposed sympathetic stimulation of the intestine results in increased intestinal tone. In addition to the contraction of the abnormal bowel and the resulting lack of peristalsis, there is a loss of the rectosphincteric reflex. Normally, when a stool bolus enters the rectum, the internal sphincter relaxes, and the stool is evacuated. In HD the internal sphincter does not relax. In most cases the aganglionic segment includes the rectum and some portion of the distal colon. However, the entire colon or part of the small intestine may be involved (long-segment disease). Occasionally skip segments or total intestinal aganglionosis may occur.

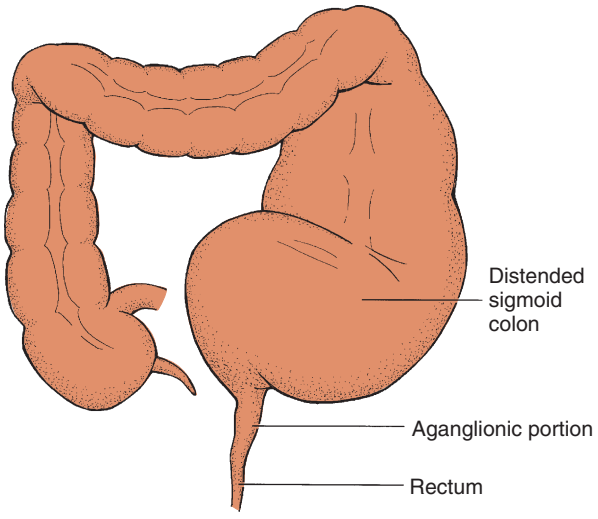

FIG 41-1 Hirschsprung disease.

Diagnostic Evaluation

Most children with HD are diagnosed in the first few months of life. Clinical manifestations vary according to the age when symptoms are recognized and the presence of complications, such as enterocolitis (Box 41-5). A neonate usually is seen with distended abdomen, feeding intolerance with bilious vomiting, and delay in the passage of meconium. Typically 95% of normal term infants pass meconium in the first 24 hours of life, but fewer than 10% of infants with HD do so. In older children a careful history is helpful. Radiographs, an unprepped contrast enema, and anorectal manometric examinations assist in the differential diagnosis, which is confirmed by a full-thickness rectal biopsy demonstrating the absence of ganglion cells in the myenteric and submucosal plexuses.

Therapeutic Management

The majority of children with HD require surgery rather than medical therapy with frequent enemas (Levitt, Martin, Olesevich, et al., 2009). After the child is stabilized with fluid and electrolyte replacement if needed, surgery is performed with a high rate of success. Surgical management consists primarily of the removal of the aganglionic portion of the bowel to relieve obstruction, restore normal motility, and preserve the function of the external anal sphincter. The majority of children with HD require one of the following operative procedures: a Soave transanal pull-through procedure, the Swenson procedure, or the Duhamel procedure (Gourlay, 2013). With earlier diagnosis the proximal bowel may not be extremely distended, thus allowing for a primary pull-through or one-stage procedure and eliminating the need for a temporary colostomy. Simpler operations such as an anorectal myomectomy may be indicated in very short–segment disease.

BOX 41-5 CLINICAL MANIFESTATIONS OF HIRSCHSPRUNG DISEASE

Newborn Period
- Failure to pass meconium within 24 to 48 hours after birth
- Refusal to feed
- Bilious vomiting
- Abdominal distention

Infancy
- Growth failure
- Constipation
- Abdominal distention
- Episodes of diarrhea and vomiting
- Signs of enterocolitis
- Explosive, watery diarrhea
- Fever
- Appears significantly ill

Childhood (Symptoms Appear More Chronic)
- Constipation
- Ribbonlike, foul-smelling stools
- Abdominal distention
- Visible peristalsis
- Easily palpable fecal mass
- Undernourished, anemic appearance

Prognosis. After the pull-through procedure, anal stricture and incontinence may occur and require further therapy, including dilations or bowel retraining therapy. Constipation and fecal incontinence are chronic problems in a small proportion of patients after surgical correction for HD (Fiorino and Liacouras, 2011). As these children grow older, this can significantly affect their quality of life (Mills, Konkin, Milner, et al., 2008).

CARE MANAGEMENT

The nursing concerns depend on the child's age and the type of treatment. If the disorder is diagnosed during the neonatal period, the main objectives are to (1) help the parents adjust to a congenital defect in their child, (2) foster infant-parent bonding, (3) prepare them for the medical-surgical intervention, and (4) assist them in colostomy care after discharge (as applicable).

Preoperative Care. The child's preoperative care depends on age and clinical condition. A child who is malnourished may not be able to withstand surgery until his or her physical status improves. Often this involves symptomatic treatment with enemas; a low-fiber, high-calorie, and high-protein diet; and in severe situations the use of total parenteral nutrition (TPN).

Physical preoperative preparation includes the same measures that are common to any surgery (see Surgical Procedures, Chapter 39). In newborns whose bowels are relatively sterile, no additional preparation may be necessary. However, in other children preparation for the pull-through procedure involves emptying the bowels with saline enemas and decreasing bacterial flora with oral or systemic antibiotics and colonic irrigations using antibiotic solution. Enterocolitis is the most serious complication of HD. Emergency preoperative care includes frequent monitoring of vital signs and blood pressure for signs of shock; monitoring fluid and electrolyte replacements and plasma or other blood derivatives; and observing for symptoms of bowel perforation such as fever, increasing abdominal distention, vomiting, increased tenderness, irritability, dyspnea, and cyanosis.

The child's age dictates the type and extent of psychologic preparation. When a colostomy is performed, the child who is of preschool age is told about the procedure in concrete terms with the use of visual aids (see Chapter 39). It is important to time explanations appropriately to prevent the anxiety and confusion that could result from too much information. It is also important to stress to parents and older children that the colostomy for HD is temporary unless so much bowel is involved that a permanent ileostomy must be performed. In most instances the extent of bowel resection is known before surgery, although the nurse should be aware of cases when doubt exists concerning repair. The nurse should remember that, although a temporary colostomy is favorable in terms of future health and adjustment, it requires additional surgery, which may be stressful to parents and children.

Postoperative Care. Postoperative care is the same as that for any child or infant with abdominal surgery (see Surgical Procedures, Chapter 39). When a colostomy is part of the corrective procedure, skin and stomal care is a major nursing task (see Ostomies, Chapter 39). To prevent contamination of an infant's abdominal wound with urine, the diaper should be placed below the dressing.

Discharge Care. After surgery parents need instruction concerning colostomy care (as applicable) and establishment of a bowel training program (age appropriate). Even a preschooler can be included in the care by handing articles to the parent, rolling up the colostomy pouch after it is emptied, or applying barrier preparations to the surrounding skin. Although the diagnosis of HD is less frequent in school-age children and adolescents, children this age can often be involved in colostomy care to the point of total responsibility.

An enterostomal therapy nurse can provide expert assistance in planning home care. If families require financial assistance and psychologic support, referral to a social worker, home health care agency, or community health nurse provides continuity of care.

Vomiting

Vomiting is the forceful ejection of gastric contents through the mouth. It is a well-defined, complex, coordinated process that is under CNS control and is often accompanied by nausea and retching. Vomiting may be divided into two categories: nonbilious and bilious. Some small intestinal reflux is common in all vomiting. In nonbilious vomiting the majority of bile drains into the more distal portions of the intestine. If an obstruction is present, nonbilious vomiting suggests a more proximal obstruction. Bilious vomiting implies a disorder of motility or distal physical blockage. Causes of nonbilious vomiting include infectious, inflammatory, metabolic or endocrinologic, neurologic, and psychologic causes and obstructive lesions such as pyloric stenosis. Causes of bilious vomiting include intestinal atresia and stenosis, malrotation with or without volvulus, ileus, intussusception, intestinal duplication, mass lesions, incarcerated inguinal hernia, and appendicitis. Vomiting may also be associated with other processes, including acute infectious diseases, increased intracranial pressure, toxic ingestion, food intolerance and allergies, mechanical obstruction of the GI tract, metabolic disorders, and psychogenic problems. Vomiting is common in childhood, is usually self-limiting, and requires no specific treatment. However, complications may occur, including acute fluid volume loss (dehydration) and electrolyte disturbances, malnutrition, aspiration, and Mallory-Weiss syndrome (small tears in the distal esophageal mucosa).

Vomiting is a well-recognized response to psychologic stress. During stress adrenaline levels rise and may stimulate the chemoreceptor trigger zone. Nausea and vomiting are likely a protective mechanism to remove toxins from the system. Vomiting may follow GI infection or toxic ingestion, or it can be a learned behavioral response.

Cyclic vomiting syndrome is a rare disorder characterized by bouts of vomiting that can last from hours to several days (McRonald and Fleisher, 2005). The cause of this syndrome is unknown (Bullard and Page, 2005).

Therapeutic Management

Management is directed toward detection and treatment of the cause of the vomiting and prevention of complications from the loss of fluid. Fluids are administered in the same manner and in an electrolyte composition similar to those administered for diarrhea. Although most children respond to these measures, antiemetic drugs may be needed. Antiemetics such as ondansetron (Zofran) and trimethobenzamide (Tigan) block receptors in the chemoreceptor trigger zone; others such as metoclopramide (Reglan) enhance gastroduodenal peristalsis; still others such as promethazine (Phenergan) compete for H_1-receptor sites. For children who are prone to motion sickness, it is helpful to administer an appropriate dose of dimenhydrinate (Dramamine) before a trip.

CARE MANAGEMENT

The major focus of nursing care is observing and reporting vomiting behavior and associated symptoms and implementing measures to

reduce the vomiting. Accurate assessment of the type of vomiting, the appearance of the vomitus, and the child's behavior in association with the vomiting helps to establish a diagnosis.

Nursing interventions are determined by the cause of the vomiting. When it is a manifestation of improper feeding methods, establishing proper techniques through teaching and example usually corrects the situation. If vomiting is believed to be an indication of obstruction, food is usually withheld or special feeding techniques are implemented. In situations in which vomiting is related to concurrent infection, dietary indiscretion, or emotional factors, efforts are directed toward maintaining hydration or preventing dehydration.

The thirst mechanism is the most sensitive guide to fluid needs, and *ad libitum* administration of an oral rehydration solution to an alert child restores water and electrolytes satisfactorily. It is important to include carbohydrate to spare body protein and avoid ketosis resulting from exhaustion of glycogen stores. Small, frequent feedings of fluids or foods are preferred. After vomiting has stopped, more liberal amounts of fluids are offered followed by gradual resumption of the regular diet.

The vomiting infant or child is positioned on the side or semireclining to prevent aspiration and observed for evidence of dehydration. It is important to emphasize the need for the child to brush the teeth or rinse the mouth after vomiting to dilute hydrochloric acid that comes in contact with the teeth. A flavored mouthwash or toothbrushing freshens the mouth. Careful monitoring of fluid and electrolyte status is necessary to prevent an electrolyte disturbance.

Gastroesophageal Reflux

GER is defined as the transfer of gastric contents into the esophagus. This phenomenon is physiologic, occurring throughout the day, most frequently after meals and at night; therefore it is important to differentiate GER from gastroesophageal reflux disease (GERD). GERD represents symptoms or tissue damage that result from GER. Approximately 50% of infants younger than 2 months old are reported to have GER (Suwandhi, Ton, and Schwarz, 2006). This "physiologic" GER usually resolves spontaneously by 1 year of age (Blanco, Davenport, and Kane, 2012).

Certain conditions predispose children to a high prevalence of GERD, including neurologic impairment, hiatal hernia, repaired esophageal atresia (EA), and morbid obesity (Suwandhi, Ton, and Schwarz, 2006). *Sandifer syndrome* is an uncommon condition, usually occurring in young children and characterized by repetitive stretching and arching of the head and neck that can be mistaken for a seizure (Blanco, Davenport, and Kane, 2012). This maneuver likely represents a physiologic neuromuscular response attempting to prevent acid refluxate from reaching the upper portion of the esophagus (Cavataio and Guandalini, 2005).

Infants who are prone to develop GER include preterm infants and those with bronchopulmonary dysplasia. Children who have had tracheoesophageal or EA repairs, extracorporeal membrane oxygenation (ECMO), neurologic disorders, scoliosis, asthma, cystic fibrosis, cerebral palsy, or other neuromuscular conditions are also prone to developing GER. The clinical manifestations of GER are listed in Box 41-6.

Pathophysiology

Although the pathogenesis of GER is multifactorial, its primary causative mechanism likely involves inappropriate transient relaxation of the lower esophageal sphincter (LES) (Suwandhi, Ton, and Schwarz, 2006). Factors that increase abdominal pressure such as coughing and sneezing, scoliosis, and overeating may contribute to GERD. Esophageal symptoms are caused by inflammation from the acid in the gastric refluxate, but *reactive airway disease (RAD)* may result from stimulation of airway reflexes by the acid refluxate.

Diagnostic Evaluation

The history and physical examination are usually sufficiently reliable to help establish the diagnosis of GER, but many experts suggest that a combination of tests is required for a definitive diagnosis (Blanco, Davenport, and Kane, 2012). The upper GI series is helpful in evaluating the presence of anatomic abnormalities (e.g., pyloric stenosis, malrotation, annular pancreas, hiatal hernia, esophageal stricture). The 24-hour intraesophageal pH monitoring study is the gold standard in the diagnosis of GER (Blanco, Davenport, and Kane, 2012; Suwandhi, Ton, and Schwarz, 2006). Endoscopy with biopsy may be helpful to assess the presence and severity of esophagitis, strictures, and Barrett esophagus and to exclude other disorders such as Crohn's disease (CD). Scintigraphy (gastroesophageal) detects radioactive substances in the esophagus after a feeding of the compound and assesses gastric emptying. It can differentiate between aspiration of gastric contents from reflux versus aspiration from poor oropharyngeal muscle coordination. A modified barium swallow study with video fluoroscopy may also be used as a diagnostic tool for this condition.

Therapeutic Management

Therapeutic management of GER depends on its severity. No therapy is needed for the infant who is growing and has no respiratory complications. Avoidance of certain foods that exacerbate acid reflux (e.g., caffeine, citrus, tomatoes, alcohol, peppermint, spicy or fried foods), lifestyle modifications in older children (e.g., weight control if indicated; small, more frequent meals; smoking cessation), and feeding maneuvers in infants (e.g., thickened feedings) can improve mild GER symptoms. Thickened feedings do not improve

BOX 41-6 CLINICAL MANIFESTATIONS OF GASTROESOPHAGEAL REFLUX

Infants

- Spitting up, regurgitation, vomiting (may be forceful)
- Excessive crying, irritability, arching of the back with neck extension, stiffening
- May be "silent" (no clinical signs observed)
- Weight loss, failure to grow (thrive)
- Respiratory problems (cough, wheeze, stridor, gagging, choking with feedings)
- Hematemesis
- Feeding refusal
- Apnea or ALTE

Children

- Heartburn
- Dyspepsia
- Abdominal pain
- Noncardiac chest pain
- Chronic cough
- Dysphagia
- Nocturnal bronchospasm and asthma
- Recurrent pneumonia, pneumonitis

ALTE, Apparent life-threatening event.

pH scores on 24-hour intraesophageal monitoring but may decrease the number of vomiting episodes. Feedings thickened with 1 tsp to 1 Tbsp of rice cereal per ounce of formula may be recommended. This may benefit infants who are underweight as a result of GERD. NG feedings may be necessary for infants with severe reflux and growth failure until surgery can be performed. Elevating the head of the bed 30 degrees or placing the infant in an infant seat elevated 30 degrees for 1 hour after feedings may decrease GER. Prone positioning of infants also decreases episodes of GER but is recommended only with extreme caution when the risk of GERD complications exceeds the risk of sudden infant death syndrome (Cavataio and Guandalini, 2005). The AAP Task Force on Sudden Infant Death Syndrome (2011) recommends supine positioning for sleep (see Chapter 31). If the prone position is used, parents need to be cautioned to avoid soft bedding. If cow's milk protein sensitivity is suspected, a brief trial of extensively hydrolyzed formula may alleviate reflux symptoms; however, changes in formula should occur under medical supervision. A weight loss program may be necessary for children with GERD symptoms that occur as a result of obesity.

Pharmacologic therapy may be used to treat infants and children with GERD. Both H_2-receptor antagonists (H_2-RAs) (cimetidine [Tagamet], ranitidine [Zantac], or famotidine [Pepcid]) and proton pump inhibitors (PPIs) (esomeprazole [Nexium], lansoprazole [Prevacid], omeprazole [Prilosec], pantoprazole [Protonix], and rabeprazole [Aciphex]) reduce gastric hydrochloric acid secretion and may stimulate some increase in LES tone. Use of available prokinetic drugs (e.g., bethanechol [Urecholine] and metoclopramide) remains controversial. Published clinical practice guidelines for the management of GER in infants and children recommend the use of PPIs over H_2RAs for relieving symptoms and healing esophagitis (Vandenplas, Rudolph, Di Lorenzo, et al., 2009).

Surgical management of GER is reserved for children with severe complications such as recurrent aspiration pneumonia, apnea, severe esophagitis, or FTT and for children who have failed to respond to medical therapy. The Nissen fundoplication (Fig. 41-2) is the most common surgical procedure, which is commonly performed laparoscopically with outcomes of decreased time to feedings, better cosmetic results, less pain, and fewer complications (Kane, 2009). This surgery involves passage of the gastric fundus behind the esophagus to encircle the distal esophagus. Long-term complications from fundoplication include breakdown of the wrap, small bowel obstruction, gas-bloat syndrome, infection, retching, and dumping syndrome.

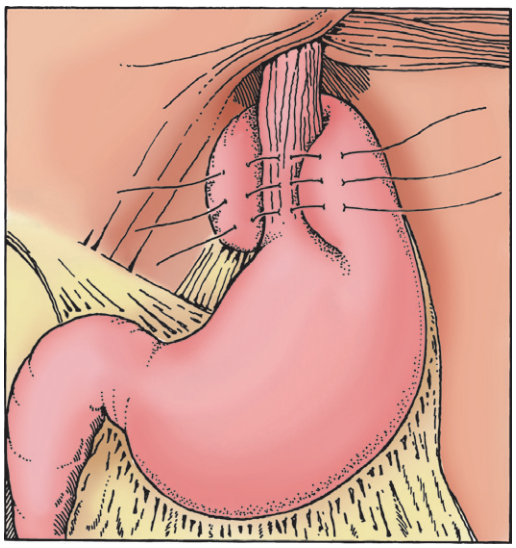

FIG 41-2 Nissen fundoplication sutures passing through esophageal musculature. (Redrawn from Campbell A, Ferrara B: *AORN J* 57:671–679, 1993.)

CARE MANAGEMENT

Nursing care is directed at (1) identifying children with symptoms suggestive of GER; (2) educating parents regarding home care, including feeding, positioning, and medications when indicated; and (3) caring for the child undergoing surgical intervention. For the majority of infants parental reassurance of the benign nature of the condition and its relationship to physiologic maturity is the most important intervention. To help parents cope with the inconvenience of dealing with a child who spits up or regurgitates frequently, simple tips such as using bibs and protective clothes during feeding and prone positioning when holding the infant after feeding are beneficial.

It is important to educate and reassure parents about positioning. In the past recommendations encouraged upright positioning during sleeping for both infants and older children. The supine position for sleeping continues to be recommended by the AAP Task Force on Sudden Infant Death Syndrome (2011). Parents should not place infants on their sides as an alternative to fully supine sleeping, and avoiding soft bedding and soft objects in the bed is important. Infant sleep positioners have been associated with 13 infant deaths since 1997 and should not be used to position infants on their sides for GER (Lawrence, Gantt, Samuels-Reid, et al., 2012). Rescheduling of the family's routine may be required to accommodate more frequent feeding times. If parents thicken formula with cereal, they should also enlarge the nipple opening for easier sucking. Usually breastfeeding may continue, and the mother may provide more frequent feeding times or express the milk for thickening with rice cereal. Parents should avoid feeding the child spicy foods or any foods that they find aggravate symptoms in general and avoid caffeine, chocolate, tobacco smoke, and alcohol when breastfeeding. Other practical advice includes advising the parents to avoid vigorous play after feedings and feeding just before bedtime.

When regurgitation is severe and growth is restricted, continuous NG tube or gastrostomy feedings may be considered; these feedings decrease the amount of emesis and provide constant buffering of gastric acid. Special preparation of caregivers is required when this type of nutritional therapy is indicated.

The nurse can support the family by providing information about all aspects of treatment. Parents often require specific information about the medications given for GER. PPIs are most effective when administered 30 minutes before breakfast so the peak plasma concentrations occur with mealtime. If they are given twice a day, the second best time for administration is 30 minutes before the evening meal. Parents need to be reassured because it takes several days of administration to achieve a steady state of acid suppression. They may not see the results that they expect right away. A number of new formulations available in PPIs allow for more efficient administration. Some preparations are available in dissolvable pills. Powder and granule preparations are available as well. Many pharmacies compound the medication in a liquid form for administration.

Postoperative nursing care after the Nissen fundoplication is similar to that for other types of laparoscopic or open abdominal surgery.

INTESTINAL PARASITIC DISEASES

Intestinal parasitic diseases, including helminths (worms) and protozoa, constitute the most frequent infections in the world. In the United States the incidence of intestinal parasitic disease, especially giardiasis, has increased among young children who attend day care centers. Young children are especially at risk because of typical hand-mouth activity and uncontrolled fecal activity.

Intestinal parasitic diseases in humans are caused by various infecting organisms. This discussion is limited to the two most common parasitic infections among children in the United States: giardiasis and pinworms. Table 41-8 describes the outstanding features of selected helminths that belong to the family of nematodes.

General Nursing Care Management

Nursing responsibilities related to intestinal parasitic infections involve helping to identify the parasite, treat the infection, and prevent initial infection or reinfection. Identification of the organism is accomplished by laboratory examination of substances containing the worm, its larvae, or ova. Most are identified by examining fecal smears from the stools of persons suspected of harboring the parasite. Fresh specimens are best for revealing parasites or larvae; therefore collected specimens should be taken directly to the laboratory for examination. If this is not feasible, the specimen is placed in a container with a preservative. Parents need clear instructions on obtaining an adequate sample and the number of samples required (see Stool Specimens, Chapter 39). In most parasitic infections examination of other family members, especially children, may be carried out to identify those who are similarly affected.

Once the diagnosis is confirmed and appropriate treatment is planned, parents need further explanation and reinforcement. Compliance in terms of drug therapy and other measures such as thorough hand washing is essential for eradication of the parasite. The family needs to understand the nature of transmission and that in some cases the medication must be repeated in 2 weeks to 1 month to kill organisms hatched since initial treatment.

TABLE 41-8 SELECTED INTESTINAL PARASITES

CLINICAL MANIFESTATIONS	COMMENTS
Ascariasis—*Ascaris lumbricoides* (Common Roundworm)	
Light infections: asymptomatic	Transferred to mouth by way of contaminated food, fingers, or toys
Heavy infections: anorexia, irritability, nervousness, enlarged abdomen, weight loss, fever, intestinal colic	Largest of the intestinal helminths
Severe infections: intestinal obstruction, appendicitis, perforation of intestine with peritonitis, obstructive jaundice, lung involvement—pneumonitis	Affects principally young children 1-4 yr of age
	Prevalent in warm climates
Hookworm Disease—*Necator americanus*	
Light infections in well-nourished individuals: no problems	Transmitted by discharging eggs on the soil, which are picked up, causing infection from direct skin contact with contaminated soil
Heavier infections: mild-to-severe anemia, malnutrition	Wearing shoes is recommended, although children playing in contaminated soil expose many skin surfaces
May be itching and burning followed by erythema and a papular eruption in areas to which the organism migrates	
Strongyloidiasis—*Strongyloides stercoralis* (Threadworm)	
Light infection: asymptomatic	Transmission is same as for hookworm (direct contact with human skin), except that autoinfection (organism can complete its life cycle in humans) is common
Heavy infection: respiratory signs and symptoms; abdominal pain, distention; nausea and vomiting; diarrhea—large, pale stools, often with mucus	Older children and adults affected more often than young children
	Severe infections may lead to severe nutritional deficiency
Threat to life in children with weakened immunologic defenses	Prevalent in warm climates
Elevated eosinophils may be the only manifestation	
Visceral Larva Migrans—*Toxocara canis* (Dogs); Intestinal Toxocariasis—*Toxocara cati* (Cats)	
Depends on reactivity of infected individual	Transmitted by ingestion of or contact with soil containing eggs from feces of infected dog or cat
May be asymptomatic except for eosinophilia	Dogs and cats should be kept away from areas where children play; sandboxes are especially common transmission areas
Specific diagnosis difficult	More prevalent in hot, humid environments where eggs remain in soil
	Periodic deworming of diagnosed dogs and cats
	Control of dog and cat population
	Continued education and laws to prevent indiscriminate canine and feline defecation
Trichuriasis—*Trichuris trichiura* (Whipworm)	
Light infections: asymptomatic	Transmitted from contaminated soil or vegetables grown in soil where eggs are present
Heavy infections: abdominal pain and distention, diarrhea	Most frequent in warm, moist climates
	Occurs most often in undernourished children living in unsanitary conditions

The nurse's most important function is preventive education of children and families regarding hygiene and health habits. Thorough hand washing before eating or handling food and after using the toilet is the most important precautionary method.

Giardiasis

Giardiasis is caused by the protozoan *Giardia lamblia* (also called *Giardia intestinalis, Giardia duodenalis,* and *Lamblia intestinalis*). It is the most common intestinal parasitic pathogen in the United States. Child care centers and institutions providing care for persons with developmental disabilities are common sites for urban giardiasis, and children may pass cysts for months. Giardiasis should also be considered in those with a history of recent travel to an endemic area (Shields, Gleim, and Beach, 2008; Yoder and Beach, 2010).

The potential for transmission is great because the cysts (i.e., the nonmotile stage of the protozoa) can survive in the environment for months. Chief modes of transmission are person to person; contaminated water, especially in mountain lakes and streams and swimming or wading pools frequented by diapered infants (who have the condition); food; and animals, especially puppies. In children person-to-person transmission is the most likely cause and is commonly seen in day care centers and institutions where staff or family become infected. Recent studies indicate swimming pool filters and interactive water fountains to be sites of contamination (Eisenstein, Bodager, and Ginzl, 2008; Shields, Gleim, and Beach, 2008).

Although individuals infected with giardiasis may be asymptomatic, common symptoms include abdominal cramps and diarrhea (Box 41-7).

Diagnosis of giardiasis may be made by microscopic examination of stool specimens or duodenal fluid or identification of *G. lamblia* antigens in these specimens by techniques such as enzyme immunoassay (EIA). Because the *Giardia* organisms live in the upper intestine and are excreted in a highly variable pattern, repeated microscopic examination of stool specimens may be required to identify *trophozoites* (active parasites) or cysts. Duodenal specimens are obtained by direct aspiration, biopsy, or the *string* test. In the string test the child swallows a gelatin capsule with a nylon string attached. Several hours later the string is withdrawn, and the contents are sent for laboratory analysis. With the availability of EIA techniques to identify *Giardia* antigens in stool specimens, other tests are being used less often.

BOX 41-7 CLINICAL MANIFESTATIONS OF GIARDIASIS

- Infants and young children:
  - Diarrhea
  - Vomiting
  - Anorexia
  - Growth failure
- Children older than 5 years of age:
  - Abdominal cramps
  - Intermittent loose stools
  - Constipation
  - Stools may be malodorous, watery, pale, and greasy
- Most infections resolve spontaneously in 4 to 6 weeks
- Rarely chronic form occurs:
  - Intermittent loose, foul-smelling stools
  - Possibility of abdominal bloating, flatulence, sulfur-tasting belches, epigastric pain, vomiting, headache, and weight loss

Therapeutic Management

The drugs of choice for treatment of giardiasis are metronidazole (Flagyl), tinidazole (Tindamax), and nitazoxanide (Alinia). Tinidazole is said to have an 80% to 100% cure rate after a single dose and has fewer side effects than metronidazole (AAP Committee on Infectious Diseases and Pickering, 2012). Metronidazole and tinidazole have a metallic taste and GI side effects, including nausea and vomiting; nitazoxanide has no bitter taste and should be taken with food to avoid GI symptoms. Albendazole is also used to treat the disease and reportedly has fewer side effects than metronidazole (AAP Committee on Infectious Diseases and Pickering, 2012).

CARE MANAGEMENT

The most important nursing considerations are preventing giardiasis and educating parents, child care center staff, and those who are entrusted with the daily care of small children. Attention to meticulous sanitary practices, especially during diaper changes, is essential (Fig. 41-3). Nurses can play an important role in educating parents of small children and day care staff regarding appropriate sanitation practices. In addition, young children who are infected or who have diarrhea should be discouraged from swimming in community or private pools until they are infection free. Lakes and streams may contain high numbers of *Giardia* spore cysts, which can be swallowed in the water. Discourage children from swimming in stagnant bodies of water or water where children who are known to be infected are swimming when there is a high chance of swallowing water. *Giardia* organisms are said to be resistant to chlorine (Eisenstein, Bodager, and Ginzl, 2008). Parents are encouraged to take small children to the restroom frequently when swimming, to avoid

FIG 41-3 Prevention of giardiasis, especially in day care centers, requires sanitary practices during diaper changes such as discarding paper diapers in a covered receptacle, changing paper covers on the diaper-changing surface, and having facilities for hand washing nearby. NOTE: Soiled cloth diapers and clothing should be stored in a plastic bag for transport home.

letting children in diapers in swimming areas, and to change diapers away from the water source (see also CDC information on recreational water illnesses [www.cdc.gov/healthywater/swimming]). After children are infected, family education regarding drug administration is essential.

Enterobiasis (Pinworms)

Enterobiasis, or pinworms, caused by the nematode *Enterobius vermicularis,* is the most common helminthic infection in the United States. It is universally present in temperate climatic zones and may infect more than 30% of all children at any one time. Crowded conditions such as in classrooms and day care centers favor transmission.

Infection begins when the eggs are ingested or inhaled (they float in the air). The eggs hatch in the upper intestine and then mature and migrate through the intestine. After mating adult females migrate out the anus and lay eggs. The movement of the worms on skin and mucous membrane surfaces causes intense itching. As the child scratches, eggs are deposited on the hands and underneath the fingernails. The typical hand-to-mouth activity of youngsters makes them especially prone to reinfection. Pinworm eggs persist in the indoor environment for 2 to 3 weeks, contaminating anything they contact such as toilet seats, doorknobs, bed linen, underwear, and food. Except for the intense rectal itching associated with pinworms, the clinical manifestations are nonspecific (Box 41-8).

Diagnostic Evaluation

Diagnosis is most commonly made from the tape test (see Care Management). Repeated tests to collect eggs may be necessary; and, if there is a possibility that other family members may be infected, a tape test should be performed on them.

Therapeutic Management

The drugs available for treatment of pinworms include mebendazole (Vermox), pyrantel pamoate (Pin-Rid, Antiminth), and albendazole. The drug of choice is mebendazole, which is safe, effective, and convenient with few side effects; however, it is not recommended for children younger than 2 years of age. If pyrvinium pamoate is prescribed, advise parents that the drug stains stool, vomitus, and clothing or skin with which it comes in contact bright red; it is available without prescription and should not be used in children under 2 years without consulting the primary practitioner. Because pinworms are transmitted easily, all household members should be treated. The dose of antiparasitic medication should be repeated in 2 weeks to completely eradicate the parasite and prevent reinfection.

BOX 41-8 CLINICAL MANIFESTATIONS OF PINWORMS

- Intense perianal itching (principal symptom); evidence of itching in young children includes the following:
  - General irritability
  - Restlessness
  - Poor sleep
  - Bed-wetting
  - Distractibility
  - Short attention span
- Perianal dermatitis and excoriation secondary to itching
- If worms migrate, possible vaginal (vulvovaginitis) and urethral infection

CARE MANAGEMENT

Nursing care is directed at identifying the parasite, eradicating the organism, and preventing reinfection. Parents need clear, detailed instructions for the *tape test*. A loop of transparent (not "frosted" or "magic") tape, sticky side out, is placed around the end of a tongue depressor, which is then firmly pressed against the child's perianal area. A convenient, commercially prepared tape is also available for this purpose. Pinworm specimens are collected in the morning as soon as the child awakens and *before* he or she has a bowel movement or bathes. The procedure may need to be performed on 3 or more consecutive days before eggs are collected. Parents are instructed to place the tongue blade in a glass jar or loosely in a plastic bag so it can be brought in for microscopic examination. For specimens collected in the hospital, practitioner's office, or clinic, the tape is placed smoothly on a glass slide, sticky side down, for examination.

Adherence to the drug regimen is usually excellent because the duration of treatment is typically only one dose. However, the family is reminded of the need to take a second dose in 2 weeks to ensure eradication of the eggs.

To prevent reinfection washing all clothes and bed linens in hot water and vacuuming the house may be recommended. However, there is little documentation about the effectiveness of these measures because pinworms survive on many surfaces. Helpful suggestions include hand washing after toileting and before eating, keeping the child's fingernails short to minimize the chance of ova collecting under the nails, dressing children in one-piece sleeping outfits, and daily showering rather than tub bathing. Families should be informed that recurrence is common. Repeated infections should be treated in the same manner as the first one.

INFLAMMATORY DISORDERS

Acute Appendicitis

Appendicitis, inflammation of the vermiform appendix (blind sac at the end of the cecum), is the most common cause of emergency abdominal surgery in childhood. In the United States, 60,000 to 80,000 cases are diagnosed each year. The peak incidence is between the ages of 12 and 18 years of age, with boys and girls equally affected before puberty; more cases occur in the fall and winter. Classically the first symptom of appendicitis is periumbilical pain followed by nausea, right lower quadrant pain, and later vomiting with fever; however, more than 50% of children may have an atypical presentation (Aiken and Oldham, 2011). Perforation of the appendix can occur within approximately 48 hours of the initial complaint of pain. At the time of initial presentation, about one third of all cases involve an already perforated appendix. Complications from appendiceal perforation include major abscess, phlegmon, enterocutaneous fistula, peritonitis, and partial bowel obstruction. A phlegmon is an acute suppurative inflammation of subcutaneous connective tissue that spreads.

Etiology

The cause of appendicitis is obstruction of the lumen of the appendix, usually by hardened fecal material *(fecalith).* Swollen lymphoid tissue, frequently occurring after a viral infection, can also obstruct the appendix. Another rare cause of obstruction is a parasite such as *Enterobius vermicularis,* or pinworms, which can obstruct the appendiceal lumen.

Pathophysiology

With acute obstruction the outflow of mucus secretions is blocked; pressure builds within the lumen, resulting in compression of blood vessels. The resulting ischemia is followed by ulceration of the epithelial lining and bacterial invasion. Subsequent necrosis causes perforation or rupture with fecal and bacterial contamination of the peritoneal cavity. The resulting inflammation spreads rapidly throughout the abdomen *(peritonitis),* especially in young children who are unable to localize infection. Progressive peritoneal inflammation results in functional intestinal obstruction of the small bowel *(ileus)* because intense GI reflexes severely inhibit bowel motility. Because the peritoneum represents a major portion of total body surface, the loss of ECF to the peritoneal cavity leads to electrolyte imbalance and hypovolemic shock.

Diagnostic Evaluation

Diagnosis is not always straightforward. Fever, vomiting, abdominal pain, and an elevated white blood cell (WBC) count are associated with appendicitis but are also seen in IBD, pelvic inflammatory disease, gastroenteritis, urinary tract infection, right lower lobe pneumonia, mesenteric adenitis, Meckel diverticulum, and intussusception. Prolonged symptoms and delayed diagnosis often occur in younger children, in whom the risk of perforation is greatest because of their inability to verbalize their complaints.

The diagnosis is based primarily on the history and physical examination (Box 41-9). Pain, the cardinal feature, initially is generalized (usually periumbilical); however, it usually descends to the lower right quadrant. The most intense site of pain may be at McBurney point, located at a point midway between the anterior superior iliac crest and the umbilicus. Rebound tenderness is not a reliable sign and is extremely painful to the child. Referred pain, elicited by light percussion around the perimeter of the abdomen, indicates peritoneal irritation. Movement such as riding over bumps in an automobile or stretcher aggravates the pain. In addition to pain, significant clinical manifestations include fever, a change in behavior, anorexia, and vomiting.

Laboratory studies usually include a CBC, urinalysis (to rule out a urinary tract infection), and in adolescent females serum human chorionic gonadotropin (to rule out an ectopic pregnancy). A WBC count greater than 10,000/mm^3 and an elevated C-reactive protein (CRP) are common but not necessarily specific for appendicitis. An elevated percentage of bands (often referred to as *a shift to the left*) may indicate an inflammatory process. CRP is an acute-phase reactant that rises within 12 hours of the onset of infection.

BOX 41-9 CLINICAL MANIFESTATIONS OF APPENDICITIS

- Right lower quadrant abdominal pain
- Fever
- Rigid abdomen
- Decreased or absent bowel sounds
- Vomiting (typically follows onset of pain)
- Constipation or diarrhea may be present
- Anorexia
- Tachycardia; rapid, shallow breathing
- Pallor
- Lethargy
- Irritability
- Stooped posture (guarding)

Computed tomography (CT) has become the imaging technique of choice, although ultrasonography may also be helpful in diagnosing appendicitis. Ultrasonography is preferred by many because of the decreased radiation exposure in comparison to CT scan (Pepper, Stanfill, and Pearl, 2012). A CT scan result is considered positive in the presence of enlarged appendiceal diameter; appendiceal wall thickening; and periappendiceal inflammatory changes, including fat streaks, phlegmon, and fluid collection (Aiken and Oldham, 2011; Vissers and Lennarz, 2010).

! NURSING ALERT

In addition to fever, signs of peritonitis include sudden relief from pain after perforation; a subsequent increase in pain (usually diffuse and accompanied by rigid guarding of the abdomen); progressive abdominal distention; tachycardia; rapid, shallow breathing; pallor; chills; and irritability.

Therapeutic Management

Treatment of appendicitis before perforation includes rehydration, antibiotics, and surgical removal of the appendix (appendectomy). Laparoscopic surgery is now commonly used to treat nonperforated acute appendicitis (Aiken and Oldham, 2011); however, this approach may also be used for perforated cases by some surgeons. Recovery is rapid, and if no complications occur the hospital stay is short. A one-time dose of antibiotics may be administered intravenously before surgery.

Ruptured Appendix. Management of the child diagnosed with peritonitis caused by a ruptured appendix often begins before surgery with IV administration of fluid and electrolytes, systemic antibiotics, and NG decompression. Postoperative management includes IV fluids, continued administration of antibiotics, and NG suction for abdominal decompression until intestinal activity returns. Sometimes surgeons close the wound after irrigation of the peritoneal cavity. At other times the wound is left open (delayed closure) to prevent wound infection. A Penrose drain may be used to permit transperitoneal drainage.

Prognosis. Complications are uncommon after a simple appendectomy. The mortality rate for perforating appendicitis has improved from nearly certain death a century ago to 0.3% or less at present (Aiken and Oldham, 2011). Early recognition of the illness is essential to prevent complications.

CARE MANAGEMENT

Because abdominal pain is the most common childhood complaint with appendicitis, it is important to assess the severity of pain (see Pain Assessment, Chapter 30). One of the most reliable estimates is the degree of change in behavior. Younger, nonverbal children assume a rigid, motionless, side-lying posture with the knees flexed on the abdomen, and there is decreased range of motion of the right hip. Older children may exhibit all of these behaviors while complaining of abdominal pain. They can always indicate a point at which the pain is worse than at any other location.

! NURSING ALERT

Whenever appendicitis is suspected, be aware of the danger of administering laxatives or enemas or applying heat to the area. Such measures stimulate bowel motility and increase the risk of perforation.

Postoperative Care. Postoperative care for the nonperforated appendix is the same as for most abdominal procedures. Care of the child with a ruptured appendix and peritonitis involves more complex care, and the course of recovery is considerably longer. The child is maintained on IV fluids, NPO, and the NG tube is kept on low continuous gastric decompression until there is evidence of intestinal activity. Listening for bowel sounds and observing for other signs of bowel activity (e.g., passage of flatus or stool) are part of the routine assessment. Management of IV therapy is the same as for any child receiving fluids and parenteral antibiotics. A drain may be placed in the wound during surgery, and frequent dressing changes with meticulous skin care are essential to prevent excoriation of the area surrounding the surgical site. Wound care includes irrigation with antibacterial solution or saline. Montgomery straps or a wound binder may be used when the wound is left open after surgery to facilitate dressing changes and prevent frequent placement and removal of tape on sensitive skin.

Management of pain from the incision and repeated dressing changes and irrigations are an essential part of the child's care. Psychologic care of the child and parents is similar to that used in other emergency situations (see Emergency Admission, Chapter 38). Parents and older children need to express their feelings and concerns regarding the events surrounding the illness and hospitalization. The nurse can provide education and psychosocial support to promote adequate coping and alleviate anxiety for both the child and the family (see Nursing Care Plan).

Meckel Diverticulum

Meckel diverticulum is a remnant of the fetal omphalomesenteric duct, which connects the yolk sac with the primitive midgut during fetal life (Olson, Kim, and Donnelly, 2009). Normally the structure is obliterated by the seventh to eighth week of gestation, when the placenta replaces the yolk sac as the source of nutrition for the fetus. Failure of obliteration may result in an omphalomesenteric fistula (a fibrous band connecting the small intestine to the umbilicus), known as *Meckel diverticulum*.

Meckel diverticulum is a true diverticulum because it arises from the antimesenteric border of the small intestine and includes all layers of the intestinal wall. The position of the diverticulum varies, but it is usually found within 40 to 50 cm (16 to 20 inches) of the ileocecal valve.

Meckel diverticulum is the most common congenital malformation of the GI tract and is present in 2% to 4% of the population, with more frequent occurrence in boys than girls (Menezes, Tareen, Saeed, et al., 2008; Pepper, Stanfill, and Pearl, 2012). Often it exists without ever causing symptoms.

Pathophysiology

Bleeding, obstruction, or inflammation causes the symptomatic complications of Meckel diverticulum. Gastric mucosa is the most common ectopic tissue found. Bleeding, which is the most common problem in children, is caused by peptic ulceration or perforation because of the unbuffered acidic secretion. Several mechanisms may cause obstruction (Olson, Kim, and Donnelly, 2009). Intussusception may be led by Meckel diverticulum. Obstruction may also be caused by entanglement of the small intestine around a fibrous cord, trapping of a loop of intestine under the band, incarceration within a hernia sac, or volvulus of the intestinal segment containing the diverticulum. Diverticulitis occurs when peptic ulceration or obstruction leads to inflammation.

BOX 41-10 CLINICAL MANIFESTATIONS OF MECKEL DIVERTICULUM

Abdominal Pain
- Similar to appendicitis
- May be vague and recurrent

Bloody Stools*
- Painless
- Bright or dark red with mucus ("currant jelly" stool)
- In infants bleeding may be accompanied by pain

Sometimes
- Severe anemia
- Shock

*Often an initial sign.

Diagnostic Evaluation

Diagnosis is usually based on the history, physical examination, and radiographic studies. Meckel diverticulum is often a diagnostic challenge. Radionucleotide scintigraphy (Meckel scan) is most often used but is less reliable in the presence of bleeding (Menezes, Tareen, Saeed, et al., 2008). CT scan, wireless capsule endoscopy, and mesenteric angiography may be used to investigate complications of Meckel diverticulum (Thurley, Halliday, Somers, et al., 2009). Laboratory studies are usually part of the general workup to rule out any bleeding disorder and evaluate the severity of the anemia.

The most common clinical presentation in children includes painless rectal bleeding, abdominal pain, or signs of intestinal obstruction (Box 41-10). Bleeding, which may be mild or profuse, often appears as dark red or "currant jelly" stools; it may be significant enough to cause hypotension.

Therapeutic Management

The standard treatment is surgical removal of the diverticulum. When severe hemorrhage increases the surgical risk, interventions to correct hypovolemic shock such as blood replacement, IV fluids, and oxygen may be necessary. Antibiotics may be used before surgery to control infection. If intestinal obstruction has occurred, appropriate preoperative measures are used to reverse electrolyte imbalances and prevent abdominal distention.

Prognosis. If this condition is diagnosed and treated early, full recovery is likely. The mortality rate of untreated Meckel diverticulum ranges from 2.5% to 15%. Complications of untreated Meckel diverticulum include GI hemorrhage and bowel obstruction.

CARE MANAGEMENT

Nursing care is the same as for any child undergoing abdominal surgery (see Chapter 38). When intestinal bleeding is present, specific preoperative considerations include frequent monitoring of vital signs, including blood pressure; recording the approximate amount of blood lost in stools; and reassuring the child and parents of the surgical success. Pain management is essential to preoperative and postoperative care of the child with this condition.

After surgery the child requires IV fluids and an NG tube for decompression and evacuation of gastric secretions; laparoscopic surgery may avoid the necessity for an NG tube. Signs of return of normal bowel function should be monitored in the postoperative

NURSING CARE PLAN

The Child with Appendicitis

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALE
Acute Pain related to inflamed appendix (tissue trauma) **Child's or Family's Defining Characteristics *(Subjective and Objective Data)*** Crying Guarding abdomen Limited movement Withdrawal Refusal to eat or drink Fever Increased pulse	The child will have no pain, or pain will be reduced to a level acceptable to child.	Allow child to choose position most comfortable (usually legs flexed). Provide small pillow or stuffed animal for abdomen. Administer analgesia on ATC basis in the first 24 hours after surgery. Teach child (as age appropriate) use of PCA pump	To promote the most comfortable position To splint the abdomen To provide pain relief To minimize breakthrough pain
Risk for Infection related to possibility of rupture before surgery and open wound after surgery (if open procedure is performed) **Child's or Family's Defining Characteristics *(Subjective and Objective Data)*** Abdominal pain Fever Rebound tenderness Nausea and vomiting Anorexia Increased WBC count Fluid around the appendix visualized on ultrasound imaging	Child will be free of signs and symptoms of peritonitis. Signs of peritonitis will be recognized early.	Monitor wound status and integrity and type of dressing (e.g., dressing dry, intact; saline or antiseptic solution irrigation or soaks [wet-to-dry] required for open wound]); specify interval for dressing change Monitor vital signs, including temperature, pulse oximeter, and blood pressure at least every 4 hours in stable child and more often in child with rupture Monitor bowel function, including bowel sounds, passage of flatus Monitor wound drain(s) in relation to proper function, amount, and character of drainage (specify time interval) Encourage early ambulation after surgery with assistance after administration of analgesia Sit in bedside chair at least twice a day For child on lengthy bed rest, place antiembolism devices For child with NG tube, monitor status of NG and suction apparatus to ensure proper function and skin care where anchored Administer antibiotics as prescribed Ensure adequacy and function of IV fluid infusion Provide dietary instructions for foods that provide sufficient calories and protein for growth (once able to eat)	To detect infection and plan interventions To prevent infection at surgical site To promote tissue healing To detect fever or hemodynamic instability and plan necessary intervention To evaluate bowel status and function after surgery To evaluate wound status and healing To decrease accumulation of flatus and abdominal distention and promote early return of proper bowel function To improve circulation, decrease flatus, and promote bowel function To prevent DVT To prevent nausea and vomiting; to promote drainage of GI secretions and acid To prevent wound infection To promote appropriate fluid intake To support an appropriate diet that can increase wound healing
Risk for Deficient Fluid Volume related to decreased fluid intake and fluid losses secondary to loss of appetite, vomiting **Child's or Family's Defining Characteristics *(Subjective and Objective Data)*** Dry mucous membranes Loss of skin turgor Sunken eyes, sunken fontanel Rapid thready pulse, rapid breathing Lethargy	Child will receive sufficient fluids to replace losses. Child will exhibit signs of adequate hydration (specify).	Maintain NPO status as prescribed For child with uncomplicated appendectomy (nonperforation), encourage intake of small amounts of ice chips and progress to clear fluids as prescribed Maintain integrity of infusion site for IV fluids Administer IV fluids and electrolytes as prescribed Monitor fluid intake and output	To minimize fluid losses through vomiting and minimize abdominal distention To promote fluid intake and bowel function To infuse fluids and electrolytes To replace fluid losses To assess hydration status and renal function

TABLE 41-9 CLINICAL MANIFESTATIONS OF INFLAMMATORY BOWEL DISEASES

CHARACTERISTICS	ULCERATIVE COLITIS	CROHN DISEASE
Rectal bleeding	Common	Uncommon
Diarrhea	Often severe	Moderate to severe
Pain	Less frequent	Common
Anorexia	Mild or moderate	May be severe
Weight loss	Moderate	May be severe
Growth delay	Usually mild	May be severe
Anal and perianal lesions	Rare	Common
Fistulas and strictures	Rare	Common
Rashes	Mild	Mild
Joint pain	Mild to moderate	Mild to moderate

period. Because the onset of illness is usually rapid, psychologic support is important as in other acute conditions such as appendicitis. It is important to remember that rectal bleeding is usually traumatic to both the child and the parents and may significantly affect their emotional reaction to hospitalization and surgery.

Inflammatory Bowel Disease

Inflammatory bowel disease (IBD) is a term used to refer to two major forms of chronic intestinal inflammation: Crohn disease (CD) and ulcerative colitis (UC). CD and UC have similar epidemiologic, immunologic, and clinical features, but they are distinct disorders (Table 41-9).

In addition to GI symptoms, both CD and UC are characterized by extraintestinal and systemic inflammatory responses. Exacerbations and remissions without complete resolution are also characteristics of IBD. Growth failure, which is particularly common in CD, is an important problem unique to the pediatric population. CD is also more disabling, has more serious complications and is often less amenable to medical and surgical treatment than is UC. Because UC is confined to the colon, theoretically it may be cured by a colectomy.

The prevalence of IBD is between 12 and 40 per 100,000 people, with 25% of these individuals being diagnosed before 20 years of age (Wong, Clark, Garnett, et al., 2009). Over the past 30 years the incidence of CD has risen, but the incidence of UC in children has remained stable. Children 6 to 17 years of age with CD appear to have a more complicated disease course compared with that of 0- to 5-year-old children (Gupta, Bostrom, Kirschner, et al., 2008).

Etiology

Despite decades of research, the etiology of IBD is not completely understood, and there is no known cure. There is evidence to indicate a multifactorial etiology. Research is focused on theories of defective immunoregulation of the inflammatory response to bacteria or viruses in the GI tract in individuals with a genetic predisposition (Silbermintz and Markowitz, 2006). In CD the chronic immune process is characterized by a T–helper 1 cytokine profile; in UC the response is more humoral and mediated by T–helper 2 cells (Silbermintz and Markowitz, 2006).

Development of IBD has a genetic influence. Several IBD susceptibility genes have now been identified through family and twin studies. Family-based genetic studies have linked chromosome 6 in UC and the *NOD2* gene in CD (Sauer and Kugathasan, 2010).

Pathophysiology of Ulcerative Colitis

The inflammation found with UC is limited to the colon and rectum, with the distal colon and rectum the most severely affected. Inflammation affects the mucosa and submucosa and involves continuous segments along the length of the bowel with varying degrees of ulceration, bleeding, and edema. Thickening of the bowel wall and fibrosis are unusual, but long-standing disease can result in shortening of the colon and strictures. Extraintestinal manifestations are less common in UC than in CD. Toxic megacolon is the most dangerous form of severe colitis.

Pathophysiology of Crohn Disease

The chronic inflammatory process of CD involves any part of the GI tract from the mouth to the anus but most often affects the

terminal ileum. The disease involves all layers of the bowel wall (transmural) in a discontinuous fashion, meaning that between areas of intact mucosa there are areas of affected mucosa (skip lesions). The inflammation may result in ulcerations; fibrosis; adhesions; stiffening of the bowel wall; stricture formation; and fistulas to other loops of bowel, bladder, vagina, or skin.

Diagnostic Evaluation

The diagnosis of UC and CD comes from the history, physical examination, laboratory evaluation, and other diagnostic procedures. Laboratory tests include a CBC to evaluate anemia and an erythrocyte sedimentation rate (ESR) or CRP to assess the systemic reaction to the inflammatory process. Levels of total protein, albumin, iron, zinc, magnesium, vitamin B_{12}, and fat-soluble vitamins may be low in children with CD. Stools are examined for blood, leukocytes, and infectious organisms. A serologic panel is often used in combination with clinical findings to diagnose IBD and differentiate between CD and UC. Observational studies on the use of blood tests to detect perinuclear antineutrophilic cytoplasmic antibodies (pANCA) and anti–*Saccharomyces cerevisiae* antibodies (ASCA) showed that the combination is specific but not sensitive for diagnosing UC (Reese, Constantinides, Simillis, et al., 2006).

In patients with CD an upper GI series with small-bowel follow-through assists in assessing the existence, location, and extent of disease. Upper endoscopy and colonoscopy with biopsies are an integral part of diagnosing IBD (Langan, Gotsch, Krafczyk, et al., 2007). Endoscopy allows direct visualization of the surface of the GI tract so the extent of inflammation and narrowing can be evaluated. CT and ultrasonography also may be used to identify bowel wall inflammation, intraabdominal abscesses, and fistulas. CD lesions may pierce the walls of the small intestine and colon, creating tracts called *fistulas* between the intestine and adjacent structures such as the bladder, anus, vagina, or skin.

Therapeutic Management

The natural history of the disease continues to be unpredictable and characterized by recurrent flare-ups that can severely impair patients' physical and social functioning (Vernier-Massouille, Balde, Salleron, et al., 2008). The goals of therapy are to (1) control the inflammatory process to reduce or eliminate the symptoms, (2) obtain long-term remission, (3) promote normal growth and development, and (4) allow as normal a lifestyle as possible. Treatment is individualized and managed according to the type and the severity of the disease, its location, and the response to therapy.

Medical Treatment. The goal of any treatment regimen is first to induce remission of acute symptoms and then to maintain remission over time. 5-Aminosalicylates (5-ASAs) are effective in the induction and maintenance of remission in mild-to-moderate UC. Mesalamine, olsalazine, and balsalazide are now preferred over sulfasalazine because of reduced side effects (headache, nausea, vomiting, neutropenia, and oligospermia). Suppository and enema preparations of mesalamine are used to treat left-sided colitis. These drugs decrease inflammation by inhibiting prostaglandin synthesis. 5-ASAs can be used to induce remission in mild CD. Corticosteroids such as prednisone and prednisolone are indicated in induction therapy in children with moderate-to-severe UC and CD. These drugs inhibit the production of adhesion molecules, cytokines, and leukotrienes. Although they reduce the acute symptoms of IBD, they have side effects that relate to long-term use, including growth suppression (adrenal suppression), weight gain, and decreased bone density. High doses of IV corticosteroids may be administered in acute episodes and tapered according to clinical response. Budesonide, a synthetic corticosteroid, is designed for controlled release in the ileum and indicated for ileal and right-sided colitis; budesonide has fewer side effects than prednisone and prednisolone (Silbermintz and Markowitz, 2006). Rectal steroid therapy (enemas and foam-based preparations) are available for both induction and maintenance therapy in left-sided colitis.

Immunomodulators such as azathioprine and its metabolite 6-mercaptopurine (6-MP) are used to induce and maintain remission in children with IBD who are steroid resistant or steroid dependent and to treat chronic draining fistulas. They block the synthesis of purine, thus inhibiting the ability of deoxyribonucleic acid (DNA) and ribonucleic acid (RNA) to hinder lymphocyte function, especially that of T-cells. Side effects include infection, pancreatitis, hepatitis, bone marrow toxicity, arthralgia, and malignancy. Methotrexate is also useful in inducing and maintaining remission in CD patients unresponsive to standard therapies. Cyclosporine and tacrolimus have both been effective in inducing remission in severe steroid-dependent UC. 6-MP or azathioprine is then used to maintain remission. Patients taking immunomodulating medications require regular monitoring of their CBC and differential to assess for changes that reflect suppression of the immune system because many of the side effects can be prevented or managed by dose reduction or discontinuation of medication.

Antibiotics such as metronidazole and ciprofloxacin may be used as an adjunctive therapy to treat complications such as perianal disease or small-bowel bacterial overgrowth in CD. Side effects of these drugs are peripheral neuropathy, nausea, and a metallic taste.

Biologic therapies act to regulate inflammatory and antiinflammatory cytokines. With the emergence of the biologic agents, specifically the use of antitumor necrosis factor (TNF-α) agents such as adalimumab and infliximab, progress has been made in targeting specific pathogenetic mechanisms and achieving a more prolonged clinical response (Bradley and Oliva-Hemker, 2012; Hyams and Markowitz, 2005; Ricart, García-Bosch, Ordás, et al., 2008). TNF-α is believed to influence active inflammation.

Nutritional Support. Nutritional support is important in the treatment of patients with IBD. Growth failure is a common serious complication, especially in CD. It is characterized by weight loss, alteration in body composition, restricted height, and delayed sexual maturation. Malnutrition causes the growth failure, and its etiology is multifactorial. Malnutrition occurs as a result of inadequate dietary intake, excessive GI losses, malabsorption, drug-nutrient interaction, and increased nutritional requirements. Inadequate dietary intake occurs with anorexia and episodes of increased disease activity. Excessive loss of nutrients (protein, blood, electrolytes, and minerals) occurs secondary to intestinal inflammation and diarrhea. Carbohydrate, lactose, fat, vitamin, and mineral malabsorption and vitamin B_{12} and folic acid deficiencies occur with disease episodes, with drug administration, and when the terminal ileum is resected. Finally nutritional requirements are increased with inflammation, fever, fistulas, and periods of rapid growth (e.g., adolescence).

The goals of nutritional support include (1) correction of nutrient deficits and replacement of ongoing losses, (2) provision of adequate energy and protein for healing, and (3) provision of adequate nutrients to promote normal growth. Nutritional support includes both enteral and parenteral nutrition (PN). A well-balanced, high-protein, high-calorie diet is recommended for children whose symptoms do not prohibit an adequate oral intake. There is little evidence that avoiding specific foods influences the severity of the disease. Supplementation with multivitamins, iron, and folic acid is recommended.

Special enteral formulas given either by mouth or continuous NG infusion (often at night) may be required. Elemental formulas are completely absorbed in the small intestine with almost no residue. A diet consisting only of elemental formula not only improves nutritional status but also induces disease remission, either without steroids or with a diminished dosage of steroids required. An elemental diet is a safe and potentially effective primary therapy for patients with CD. Unfortunately remission is not sustained when NG feedings are discontinued unless maintenance medications are added to the treatment regimen.

TPN has also improved nutritional status in patients with IBD. Short-term remissions have been achieved after TPN, although complete bowel rest has not reduced inflammation or added to the benefits of improved nutrition by TPN. Nutritional support is less likely to induce a remission in UC than in CD. However, improvement of nutritional status is important in preventing deterioration of the patient's health status and preparing the patient for surgery.

Surgical Treatment. Surgery is indicated for UC when medical and nutritional therapies fail to prevent complications. Surgical options include a subtotal colectomy and ileostomy that leaves a rectal stump as a blind pouch. A reservoir pouch is created in the configuration of a J or S to help improve continence after surgery. An ileoanal pull-through preserves the normal pathway for defecation. *Pouchitis,* an inflammation of the surgically created pouch, is the most common late complication of this procedure and had been reported to occur in up to 50% of cases. In many cases UC can be cured with a total colectomy.

Surgery may be required in children with CD when complications cannot be controlled by medical and nutritional therapy. Segmental intestinal resections are performed for small-bowel obstructions, strictures, or fistulas. Partial colonic resection is not curative, and the disease often recurs.

Prognosis. IBD is a chronic disease. Relatively long periods of quiescent disease may follow exacerbations. The outcome is influenced by the regions and severity of involvement and appropriate therapeutic management. Malnutrition, growth failure, and bleeding are serious complications. The overall prognosis for UC is good.

The development of colorectal cancer (CRC) is a long-term complication of IBD. In UC the cumulative incidence of CRC is 2.5% after 20 years, increasing to 10.8% after 30 years (Rutter, Saunders, Wilkinson, et al., 2006). Surveillance colonoscopy with multiple biopsies should begin approximately 10 years after diagnosis of UC or Crohn's colitis and continue every 1 to 2 years (Rubin and Kavitt, 2006). Removal of the diseased colon prevents development of CRC. However, in CD surgical removal of the affected colon does not prevent cancer from developing elsewhere in the GI tract.

CARE MANAGEMENT

The nursing considerations in the management of patients with IBD extend beyond the immediate period of hospitalization. These interventions involve continued guidance of families in terms of (1) managing diet; (2) coping with factors that increase stress and emotional lability; (3) adjusting to a disease of remissions and exacerbations; and (4) when indicated, preparing the child and parents for the possibility of diversionary bowel surgery.

Because nutritional support is an essential part of therapy, encouraging the anorexic child to consume enough food is often a challenge. Successful interventions include involving the child in meal planning; encouraging small, frequent meals or snacks rather than three large meals a day; serving meals around medication schedules when diarrhea, mouth pain, and intestinal spasm are controlled; and preparing high-protein, high-calorie foods such as eggnog, milkshakes, cream soups, puddings, or custard (if lactose is tolerated). (See Feeding the Sick Child, Chapter 39.) Using bran or a high-fiber diet for active IBD is questionable. Bran, even in small amounts, has been shown to worsen the condition. Occasionally the occurrence of *aphthous stomatitis* further complicates adherence to dietary management. Mouth care before eating and the selection of bland foods help relieve the discomfort of mouth sores.

When NG feedings or TPN is indicated, nurses play an important role in explaining the purpose and expected outcomes of this therapy. The nurse should acknowledge the anxieties of the child and family members and give them adequate time to demonstrate the skills necessary to continue the therapy at home if needed (see Critical Thinking Case Study).

The importance of continued drug therapy despite remission of symptoms must be stressed to the child and family members. Failure to adhere to the pharmacologic regimen can result in exacerbation of the disease (see Compliance, Chapter 39). Unfortunately exacerbation of IBD can occur even if the child and family are compliant with the treatment regimen, and it is difficult for the child and family to cope.

Family Support. The nurse should attend to the emotional components of the disease and assess any sources of stress. Frequently she or he can help children adjust to problems of growth restriction, delayed sexual maturation, dietary restrictions, feelings of being "different" or "sickly," inability to compete with peers, and necessary absence from school during exacerbations of the illness (see Impact of the Child's Chronic Illness, Chapter 36).

If a permanent colectomy-ileostomy is required, the nurse can teach the child and family how to care for the ileostomy. The nurse

CRITICAL THINKING CASE STUDY

Inflammatory Bowel Disease

Susan, a 13-year-old girl, was admitted to the hospital because of bloody diarrhea, abdominal pain, and weight loss. After a thorough evaluation, including laboratory tests, radiographic studies, and gastrointestinal endoscopy procedures, the diagnosis of Crohn disease (CD) was made. Medical treatment, including corticosteroid drugs and nutritional support, was implemented during this hospitalization.

Susan has improved considerably and is to be discharged home this week. Enteral formula administered by continuous nighttime gastrostomy infusion will be continued at home, and both Susan and her family are eager to learn how to perform these feedings. You are the nurse who is responsible for Susan's discharge planning.

1. Evidence—Are there sufficient data to formulate any specific interventions for discharge?
2. Assumptions—Describe some underlying assumptions about the following:
   a. The goals of nutritional support for children with CD
   b. Teaching required by an adolescent or family member who is administering gastrostomy tube feedings at home
   c. Psychosocial issues related to CD
3. What are the priorities for discharge planning at this time?
4. Does the evidence support your conclusion?

can also emphasize the positive aspects of the surgery, particularly accelerated growth and sexual development, permanent recovery, the eliminated risk of colonic cancer in UC, and the normality of life despite bowel diversion. Introducing the child and parents to other ostomy patients, especially those who are the same age, can be effective in fostering eventual acceptance. Whenever possible continent ostomies should be offered as options to the child, although they are not performed in all centers in the United States.

Because of the chronic and often lifelong nature of the disease, families benefit from the educational services provided by organizations such as the Crohn's and Colitis Foundation of America (CCFA).* If diversionary bowel surgery is indicated, the United Ostomy Associations of America (UOAA)† and the Wound, Ostomy and Continence Nurses Society‡ are available to assist with ileostomy care and provide important psychologic support through their self-help groups. Adolescents often benefit by participating in peer-support groups, which are sponsored by the CCFA.

Peptic Ulcer Disease

Peptic ulcers may be classified as acute or chronic, and peptic ulcer disease (PUD) is a chronic condition that affects the stomach or duodenum. Ulcers are described as gastric or duodenal and as primary or secondary. A gastric ulcer involves the mucosa of the stomach; a duodenal ulcer involves the pylorus or duodenum. Most primary ulcers occur in the absence of a predisposing factor and tend to be chronic, occurring more frequently in the duodenum. Secondary or *stress ulcers* result from the stress of a severe underlying disease or injury (e.g., severe burns, sepsis, increased intracranial pressure, severe trauma, multisystem organ failure) and are more frequently acute and gastric.

About 1.7% of children in general pediatric practices have PUD, and the disease represents about 3.4% per 10,000 of pediatric hospital admissions. Primary ulcers are more common in children older than 6 years, and stress ulcers are more common in infants younger than 6 months. Except for very young children, the incidence is 2 to 3 times greater in boys than in girls.

Etiology

The exact cause of PUD is unknown, although infectious, genetic, and environmental factors are important. There is an increased familial incidence, and the disease is increased in people with blood group O.

There is a significant relationship between the bacterium *Helicobacter pylori* and ulcers. *H. pylori* is a microaerophilic, gram-negative, slow-growing, spiral-shaped, and flagellated bacterium known to colonize the gastric mucosa in about half of the population of the world (Sung, Kuipers, and El-Serag, 2009). *H. pylori* synthesizes the enzyme urease, which hydrolyses urea to form ammonia and carbon dioxide. Ammonia then absorbs acid to form ammonium, thus raising the gastric pH. *H. pylori* may cause ulcers by weakening the gastric mucosal barrier and allowing acid to damage the mucosa. It is believed that it is acquired via the fecal-oral route, and this hypothesis is supported by finding viable *H. pylori* in feces.

In addition to ulcerogenic drugs, both alcohol and smoking contribute to ulcer formation. There is no conclusive evidence to implicate particular foods such as caffeine-containing beverages or spicy foods, but polyunsaturated fats and fiber may play a role in ulcer formation. Psychologic factors may play a role in the development of PUD, and stressful life events, dependency, passiveness, and hostility have all been implicated as contributing factors.

Pathophysiology

Most likely the pathology is caused by an imbalance between the destructive (cytotoxic) factors and defensive (cytoprotective) factors in the GI tract. The toxic mechanisms include acid, pepsin, medications such as aspirin and nonsteroidal antiinflammatory drugs (NSAIDs), bile acids, and infection with *H. pylori.* The defensive factors include the mucus layer, local bicarbonate secretion, epithelial cell renewal, and mucosal blood flow. Prostaglandins play a role in mucosal defense because they stimulate both mucus and alkali secretion. The primary mechanism that prevents the development of peptic ulcer is the secretion of mucus by the epithelial and mucous glands throughout the stomach. The thick mucus layer acts to diffuse acid from the lumen to the gastric mucosal surface, thus protecting the gastric epithelium. The stomach and the duodenum produce bicarbonate, decreasing acidity on the epithelial cells and thereby minimizing the effects of the low pH. When abnormalities in the protective barrier exist, the mucosa is vulnerable to damage by acid and pepsin. Exogenous factors such as aspirin and NSAIDs cause gastric ulcers by inhibition of prostaglandin synthesis.

Zollinger-Ellison syndrome may occur in children who have multiple, large, or recurrent ulcers. This syndrome is characterized by hypersecretion of gastric acid, intractable ulcer disease, and intestinal malabsorption caused by a gastrin-secreting tumor of the pancreas.

Diagnostic Evaluation

Diagnosis is based on the history of symptoms, physical examination, and diagnostic testing. The focus is on symptoms such as epigastric abdominal pain, nocturnal pain, oral regurgitation, heartburn, weight loss, hematemesis, and melena (Box 41-11). History should include questions relating to the use of potentially causative substances such as NSAIDs, corticosteroids, alcohol, and tobacco. Frequently a history of epigastric and periumbilical pain accompanies PUD. However, children often find it difficult to describe the location of their pain and often indicate the location by moving their hand in circular movement all around the stomach area. Asking the child to take one finger and point to the area where it hurts the most often helps to identify the location of the pain. Pain may also be elicited during the examination with palpation. Laboratory studies may include a CBC to detect anemia, stool analysis for occult blood, liver function tests (LFTs), ESR, or CRP to evaluate IBD; amylase and lipase to evaluate pancreatitis; and gastric acid measurements to identify hypersecretion. A lactose breath test may be performed to detect lactose intolerance.

Radiographic studies such as an upper GI series may be performed to evaluate obstruction or malrotation. An endoscopy of the esophagus, stomach, and duodenum is the most reliable procedure to diagnose PUD. A biopsy can determine the presence of *H. pylori.* A blood test can also identify the presence of the antigen to this organism. The ^{13}C-urea breath test measures bacterial

BOX 41-11 CHARACTERISTICS OF PEPTIC ULCER

Neonates
- Usually gastric and secondary to stress or critical illness
- Commonly has a history of preterm birth, respiratory distress, sepsis, hypoglycemia, or an intraventricular hemorrhage
- Perforation may be first sign of an ulcer
- Hematemesis, feeding difficulty, crying episodes, or melena

Infants to 3-Year-Old Children
- Most likely to have a secondary ulcer located equally in the stomach or duodenum
- Primary ulcers less common and usually located in stomach
- Likely to occur in relation to illness, surgery, or trauma
- Hematemesis, melena, or perforation

2- to 6-Year-Old Children
- Primary or secondary ulcers
- Located equally in stomach and duodenum
- Perforation more likely in secondary ulcers
- Periumbilical pain, poor eating, vomiting, irritability, nighttime waking, hematemesis, melena

Children 6 Years and Older
- Usually primary and most often duodenal
- More typical of adult type
- Chance of recurrence greater
- Often associated with *Helicobacter pylori*
- Epigastric or vague abdominal pain
- Possibly nighttime waking, hematemesis, melena, and anemia

colonization in the gastric mucosa. This test may be used to screen for *H. pylori* in adults and children. Polyclonal and monoclonal stool antigen tests are an accurate, noninvasive method for both the initial diagnosis of *H. pylori* and the confirmation of its eradication after treatment (Gisbert, de la Morena, and Abraira, 2006). In children, however, an initial upper endoscopy is recommended to evaluate and confirm H. pylori disease (Blanchard and Czinn, 2011).

Therapeutic Management

The major goals of therapy for children with PUD are to relieve discomfort, promote healing, prevent complications, and prevent recurrence. Management is primarily medical and consists of administration of medications to treat the infection and reduce or neutralize gastric acid secretion.

- Antacids are beneficial medications to neutralize gastric acid.
- Histamine (H2) receptor antagonists (antisecretory drugs) act to suppress gastric acid production. Cimetidine (Tagamet), ranitidine (Zantac), and famotidine (Pepcid) are examples of these medications. These medications have few side effects, although cimetidine has multiple drug interactions and therefore should be used with caution.
- PPIs such as omeprazole and lansoprazole act to inhibit the hydrogen ion pump in the parietal cells, thus blocking the production of acid. These agents have been shown to be effective in children and adolescents but not in infants (van der Pol, Smits, van Wijk, et al., 2011). Long-term side effects are not fully known but may include decreased bone density with long-term use because of reduced gastric absorption of calcium and hypergastrinemia of unknown significance (Hassall, Owen, Kerr, et al., 2011). With short-term use these agents appear to be well tolerated and have infrequent side effects (e.g., headache, diarrhea, nausea and vomiting).
- Mucosal protective agents such as sucralfate and bismuth-containing preparations may be prescribed for PUD. Sucralfate is an aluminum-containing agent that forms a protective barrier over ulcerated mucosa to protect against acid and pepsin. Sucralfate is available in both pill and liquid forms. Because sucralfate blocks the absorption of other medications, it should be given separately from them.
- Bismuth compounds are sometimes prescribed for the relief of ulcers, but they are used less frequently than PPIs. Although these compounds inhibit the growth of microorganisms, the mechanism of their activity is poorly understood. In combination with antibiotics, bismuth is effective against *H. pylori.* Although concern has been expressed about the use of bismuth salts in children because of potential side effects, none of these side effects has been reported when these compounds have been used in the treatment of *H. pylori* infection.

Triple-drug therapy is the standard first-line treatment regimen for *H. pylori* (O'Connor, Gisbert, and O'Morain, 2009). Combination therapy has demonstrated 90% effectiveness in eradication of *H. pylori* compared with antibiotic monotherapy. Examples of drug combinations used in triple therapy are (1) bismuth, clarithromycin, and metronidazole; (2) lansoprazole, amoxicillin, and clarithromycin; and (3) metronidazole, clarithromycin, and omeprazole. Recently, however, there has been an increase in resistance to metronidazole and clarithromycin, with resulting treatment failure, and a 10- to 14-day course of bismuth-based quadruple therapy has been proposed (Luther, Chey, and Saad, 2011). The benefits on the use of probiotics as an adjunct to treatment remain unclear, with conflicting literature on their effect on eradication and minimizing side effects (O'Connor, Gisbert, and O'Morain, 2009).

Common side effects of medications include diarrhea and nausea and vomiting. In addition to medications, children with PUD should have a nutritious diet and avoid caffeine. Warn adolescents about gastric irritation associated with alcohol use and smoking.

Children with an acute ulcer who have developed complications such as significant hemorrhage require emergency care. The administration of IV fluids, blood, or plasma depends on the amount of blood loss. Replacement with whole blood or packed cells may be necessary for significant loss.

Surgical intervention may be required for complications such as hemorrhage, perforation, or gastric outlet obstruction. Ligation of the source of bleeding or closure of a perforation is performed. A vagotomy and pyloroplasty may be indicated in children with recurring ulcers despite aggressive medical treatment.

Prognosis. The long-term prognosis for PUD is variable. Many ulcers are successfully treated with medical therapy; however, primary duodenal peptic ulcers often recur. Complications such as GI bleeding can occur and extend into adult life. The effect of maintenance drug therapy on long-term morbidity remains to be established with further studies.

CARE MANAGEMENT

The primary nursing goal is to promote healing of the ulcer through compliance with the medication regimen. If an analgesic-antipyretic

is needed, acetaminophen, not aspirin or NSAIDs, is used. Critically ill neonates, infants, and children in intensive care units (ICUs) should receive H_2 blockers to prevent stress ulcers.

MEDICATION ALERT

Critically ill children receiving IV H_2 blockers should have their gastric pH values checked at frequent intervals.

For nonhospitalized children with chronic illnesses, consider the role stress plays. In children many ulcers occur secondary to other conditions, and the nurse should be aware of family and environmental conditions that may aggravate or precipitate ulcers. Children may benefit from psychologic counseling and from learning how to cope constructively with stress.

HEPATIC DISORDERS

Acute Hepatitis

Etiology

Hepatitis is an acute or chronic inflammation of the liver that can result from several different causes. One cause is infection. Many types of hepatitis are caused by viruses such as the hepatitis viruses, Epstein-Barr virus (EBV), cytomegalovirus (CMV), and HIV. Other causes of hepatitis are nonviral (abscess, amebiasis), autoimmune, metabolic, chemical, neoplastic, anatomic (choledochal duct cyst and biliary atresia [BA]), hemodynamic (shock, congestive heart failure), and idiopathic (sclerosing cholangitis and Reye syndrome). The following six viruses cause 90% of cases of viral hepatitis (Table 41-10):

1. Hepatitis A virus (HAV)
2. Hepatitis B virus (HBV)
3. Hepatitis C virus (HCV)
4. Hepatitis D virus (HDV)
5. Hepatitis E virus (HEV)
6. Hepatitis G virus (HGV)

Hepatitis A. Hepatitis A incidence in the United States has declined 92%, from 12 cases per 100,000 population in 1995 to one case per 100,000 population in 2007, the lowest rate ever recorded. Declines were greatest among children and in states where routine vaccination of children was recommended beginning in 1999 (Daniels, Grytdal, Wasley, et al., 2009). The virus is spread directly or indirectly by the fecal-oral route by ingestion of contaminated foods, direct exposure to infected fecal material, or close contact with an infected person. The virus is particularly prevalent in developing countries with poor living conditions, inadequate sanitation, crowding, and poor personal hygiene practices. The spread of HAV has been associated with improper food handling and high-risk areas such as households with infected persons, residential centers for people with disabilities, and day care centers. The average incubation period is about 4 weeks, with a range of 15 to 50 days. Fecal shedding of the virus can occur for 2 to 3 weeks before and for 1 week after the onset of jaundice. During this time, although the individual is asymptomatic, the virus is most likely to be transmitted. Infants with HAV infection are likely to be asymptomatic *(anicteric hepatitis).* Children often have diarrhea, and their symptoms are frequently attributed to gastroenteritis. Only one in 12 young children develops jaundice. Most adults develop clinical signs with *icteric hepatitis.* The prognosis of HAV infection is usually good, and complications are rare.

Hepatitis B. Hepatitis B can be an acute or chronic infection, ranging from an asymptomatic, limited infection to fatal, fulminant (rapid and severe) hepatitis. There are no environmental or animal reservoirs for HBV. Humans are the main source of infections. HBV may be transmitted parenterally, percutaneously, or transmucosally. Hepatitis B surface antigen (HBsAg) has been found in all body fluids, including feces, bile, breast milk, sweat, tears, vaginal secretions, and urine; but only blood, semen, and saliva have been found to contain infectious HBV particles. HBV infection from human bites has been documented, but transmission from feces has not. HBV has been acquired after blood transfusion, but the likelihood of this has been reduced through blood product screening procedures. Adults whose occupations are associated with considerable exposure to blood or blood products such as health care workers are at an increased risk of contracting HBV.

Most HBV infection in children is acquired perinatally. Transmission from mother to infant during the perinatal period (e.g., blood exposure during delivery) results in chronic infection in 70% to 90% of infants if the mother is positive for HBsAg and HBeAg (AAP Committee on Infectious Diseases and Pickering, 2012). Perinatal infection occurs during the birthing process when the infant comes in contact with maternal body fluids, most likely blood. It is still not known if the virus enters infants via mucosal membranes, the intestinal tract, or skin abrasions. HBsAg has been detected in breast milk, but it is not clear whether HBV infection is transmitted through ingested breast milk or from swallowed maternal blood from injured nipples (Tran, 2009). Infants and children who are not infected during the perinatal period remain at high risk for acquiring person-to-person transmission from their mothers during the first 5 years of life.

Hepatitis B virus infection occurs in children and adolescents in specific high-risk groups, which are (1) individuals with hemophilia or other disorders who have received multiple transfusions, (2) children and adolescents involved in IV drug abuse, (3) institutionalized children, (4) preschool children in endemic areas, and (5) individuals engaged in heterosexual activity or sexual activity with homosexual men. The incubation period for HBV infection ranges from 45 to 160 days with an average of 120 days (AAP Committee on Infectious Diseases and Pickering, 2012). HBV infection can cause a carrier state and lead to chronic hepatitis with eventual cirrhosis or hepatocellular carcinoma in adulthood.

Hepatitis C. Hepatitis C virus is transmitted parenterally through exposure to blood and blood products from HCV-infected people (AAP Committee on Infectious Diseases and Pickering, 2012). The most common risk factors associated with HCV acquisition are injections, drug use, having received a blood product before 1992 (e.g., hemophilia), and having multiple sex partners. Recent improvements in donor screening and inactivation procedures for blood products such as the factor concentrates used for patients with hemophilia have significantly reduced the risk of transmission through blood products. The mechanism of nonparenteral or nonpercutaneous transmission of HCV is uncertain. Sexual transmission among monogamous couples and among family contacts is rare. Maternal co-infection with HIV has been associated with increased risk of perinatal transmission of HCV and may depend on the HCV genotype and the serum titer of maternal HCV-RNA. All persons with HCV antibody or HCV-RNA in their blood are considered to be infectious (AAP Committee on Infectious Diseases and Pickering, 2012).

TABLE 41-10 COMPARISON OF TYPES A, B, AND C HEPATITIS

CHARACTERISTICS	TYPE A	TYPE B	TYPE C
Incubation period	15-50 days; average 25-30 days	30-180 days; average 50 days	2 weeks-6 months; average, 6-7 weeks
Period of communicability	Believed to be latter half of incubation period to first week after onset of clinical illness	Variable Virus in blood or other body fluids during late incubation period and acute stage of disease; may persist in carrier state for years to lifetime	Begins before onset of symptoms May persist in carrier state for years
Mode of transmission	Principal route—fecal-oral Rarely—parenteral	Principal route—parenteral Less frequent route—oral, sexual, any body fluid Perinatal transfer—transplacental blood (last trimester); at delivery; or during breastfeeding, especially if mother has cracked nipples	Principal route—parenteral Nonparenteral spread possible
Clinical features			
Onset	Usually rapid, acute	More insidious	Usually insidious
Fever	Common and early	Less frequent	Less frequent
Anorexia	Common	Mild to moderate	Mild to moderate
Nausea and vomiting	Common	Sometimes present	Mild to moderate
Rash	Rare	Common	Sometimes present
Arthralgia	Rare	Common	Rare
Pruritus	Rare	Sometimes present	Sometimes present
Jaundice	Present (however, many cases anicteric)	Present	Present
Immunity	Present after one attack; no crossover to type B or C	Present after one attack; no crossover to type A or C	Present after one attack; no crossover to type A or B
Carrier state	No	Yes	Yes
Chronic infection	No	Yes	Yes
Prophylaxis			
IG	Passive immunity Successful, especially in early incubation period and preexposure prophylaxis	Passive immunity Inconsistent benefits; probably of no use	Not currently recommended by CDC
HAV vaccine	Two inactivated vaccines approved for children ages 12 months to 18 years: Havrix and Vaqta; given in a two-dose schedule (6-12 months between doses); TWINRIX contains both HAV and HBV (for patients 18 years old and older)		
HBV immunoglobulin (HBIG)	No benefit	Passive immunity	No benefit
HBV vaccine	No benefit	Postexposure protection possible if given immediately after definite exposure Provides active immunity Universal vaccination recommended for all newborns (see also Chapter 31)	No benefit
Mortality rate	0.1%-0.2%	0.5%-2% in uncomplicated cases; may be higher in complicated cases	1%-2% in uncomplicated cases; may be higher in complicated cases

CDC, Centers for Disease Control and Prevention; *HAV,* hepatitis A virus; *HBIG,* hepatitis B immunoglobulin; *HBV,* hepatitis B virus; *IG,* immunoglobulin.

The clinical course varies. The incubation period for HCV ranges from 14 to 180 days with an average of 45 days. The natural history of the disease in children is not well defined. Some children may be asymptomatic, but hepatitis C can become a chronic condition and can cause cirrhosis and hepatocellular carcinoma. About 60% to 70% of individuals infected with HCV develop chronic disease. Infection with HCV is the leading reason for liver transplantation in the United States (AAP Committee on Infectious Diseases and Pickering, 2012).

Hepatitis D. Hepatitis D occurs in children already infected with HBV. HDV is a defective RNA virus that requires the helper function of HBV. The incubation period is from 2 to 8 weeks. Both acute and chronic forms of hepatitis D tend to be more severe than hepatitis B and can lead to cirrhosis. HDV infection occurs mostly in drug abusers, individuals with hemophilia, and people immigrating from endemic areas.

Hepatitis E. Hepatitis E is enterically transmitted non-A, non-B hepatitis. Transmission may occur through the fecal-oral route or from contaminated water. The incubation period is 2 to 9 weeks. This illness is uncommon in children, does not cause chronic liver disease, is not a chronic condition, and has no carrier state. However, it can be a devastating disease among pregnant women, with an unusually high case-fatality rate (10%) (AAP Committee on Infectious Diseases and Pickering, 2012).

Hepatitis G. Hepatitis G virus is a bloodborne virus that may also be transmitted by organ transplantation. High-risk groups include transfusion recipients, IV drug users, and individuals infected with HCV. Individuals with the virus are often asymptomatic, and most infections are chronic. The incubation period is unknown.

Pathophysiology

Pathologic changes occur primarily in the parenchymal cells of the liver and result in variable degrees of swelling; infiltration of liver cells by mononuclear cells; and subsequent degeneration, necrosis, and fibrosis. Structural changes within the hepatocyte account for altered liver functions such as impaired bile excretion, elevated transaminase levels, and decreased albumin synthesis. The disorder may be self-limiting with regeneration of liver cells without scarring, leading to a complete recovery. However, some forms of hepatitis do not result in complete return of liver function. These include fulminant hepatitis, which is characterized by a severe, acute course with massive destruction of the liver tissue causing liver failure and high mortality within 1 to 2 weeks; and subacute or chronic active hepatitis, which is characterized by progressive liver destruction, uncertain regeneration, scarring, and potential cirrhosis.

The progression of liver disease is characterized according to histopathology by Ludwig's classification of four stages: (1) stage 1 is characterized by mononuclear inflammatory cells surrounding small bile ducts; (2) in stage 2 there is proliferation of small bile ductules; (3) stage 3 is characterized by fibrosis or scarring; and (4) stage 4 is cirrhosis (Angulo and Lindor, 2010).

Clinical Manifestations

The clinical manifestations and course of uncomplicated acute viral hepatitis are similar for most of the hepatitis viruses. Usually the prodromal, or anicteric, phase (absence of jaundice) lasts 5 to 7 days. Anorexia, malaise, lethargy, and easy fatigability are the most common symptoms. Fever may be present, especially in adolescents. Nausea, vomiting, and epigastric or right upper quadrant abdominal pain or tenderness may occur. Arthralgia and skin rashes may occur and are more likely in children with hepatitis B than those with hepatitis A. The transaminases rather than bilirubin are often elevated in acute hepatitis, and hepatomegaly may be present. Some mild cases of acute viral hepatitis do not cause symptoms or can be mistaken for influenza.

In young children most of the prodromal symptoms disappear with the onset of jaundice, or the icteric phase. However, many children with acute viral hepatitis never develop jaundice. If jaundice occurs, it is often accompanied by dark urine and pale stools. Pruritus may accompany jaundice and can be bothersome for children.

Children with chronic active hepatitis may be asymptomatic but more commonly have nonspecific symptoms of malaise, fatigue, lethargy, weight loss, or vague abdominal pain. Hepatomegaly may be present, and the transaminases are often very high, with mild-to-severe hyperbilirubinemia (conjugated [direct]).

Fulminant hepatitis is primarily caused by HBV or HCV. Many children with fulminant hepatitis develop characteristic clinical symptoms and rapidly develop manifestations of liver failure, including encephalopathy, coagulation defects, ascites, deepening jaundice, and an increasing WBC count. Changes in mental status or personality indicate impending liver failure. Although children with acute hepatitis may have hepatomegaly, a rapid decrease in the size of the liver (indicating loss of tissue caused by necrosis) is a serious sign of fulminant hepatitis. Complications of fulminant hepatitis include GI bleeding, sepsis, renal failure, and disseminated coagulopathy.

Diagnostic Evaluation

Diagnosis is based on the history; physical examination; and serologic markers for hepatitis A, B, and C. No LFT is specific for hepatitis, but serum aspartate (AST) and serum aminotransferase (ALT) levels are markedly elevated. Serum bilirubin levels peak 5 to 10 days after clinical jaundice appears. Histologic evidence from liver biopsy may be required to establish the diagnosis and assess the severity of the liver disease. Serologic markers indicate the antibodies or antigens formed in response to the specific virus and confirm the diagnosis. Serum immunologic tests are not available to detect HAV antigen, but there are two HAV antibody tests: anti-HAV immunoglobulin G (IgG) and immunoglobulin M (IgM). Anti-HAV antibodies are present at the onset of the disease and persist for life. A positive anti-HAV antibody test result indicates acute infection, immunity from past infection, passive antibody acquisition (e.g., from transfusion, serum immunoglobulin infusion), or immunization. To diagnose an acute or recent HAV infection, a positive anti-HAV IgM test result that is present with the onset of the disease and that persists for only 2 or 3 days is required.

Diagnosis of hepatitis B is confirmed by the detection of various hepatitis virus antigens and the antibodies that are produced in response to the infection. These antibodies and antigens and their significance include the following:

- *HBsAg*—HBsAg (found on the surface of the virus), indicating ongoing infection or carrier state
- *Anti-HBs*—Antibody to surface antigen HbsAg, indicating resolving or past infection
- *HBcAg*—Hepatitis B core antigen (found on the inner core of the virus), detected only in the liver
- *Anti-HBc*—Antibody to core antigen HbcAg, indicating ongoing or past infection
- *HBeAg*—Hepatitis Be antigen (another component of the HBV core), indicating active infection

Anti-HBe—Antibody to HBeAg, indicating resolving or past infection

IgM anti-HBc—IgM antibody to core antigen

Tests are available for detection of all the HBV antigens and antibodies except HBcAg. HBsAg is detectable during acute infection. The presence of HBsAg indicates that the individual has been infected with the hepatitis virus. If the infection is self-limiting, HBsAg disappears in most patients before serum anti-HBs can be detected (termed the *window phase of infection)*. IgM anti-HBc is highly specific in establishing the diagnosis of acute infection and during the window phase in older children and adults. However, IgM anti-HBc usually is not present in perinatal HBV infection (AAP Committee on Infectious Diseases and Pickering, 2012). Neonatal infection is most likely to occur in infants born to mothers who are HBeAg positive. In contrast, hepatitis B is much less likely to occur in infants whose mothers are HbsAg positive but HBeAg negative and who have antibodies to HBeAg.

Clinical improvement is usually associated with a decrease in or disappearance of these antigens followed by the appearance of their antibodies. For example, anti-HBc of the IgM class often occurs early in the disease followed by a rise in anti-HBc of the IgG class. Because the antibodies persist indefinitely, they are used to identify the carrier state (individuals with HBV who have no clinical disease but are able to transmit the organism). People with chronic HBV infection have circulating HBsAg and anti-HBc, and on rare occasions anti-HBsAg is present. Both anti-HBs and anti-HBc are detected in people with resolved infection, but anti-HBs alone is present in individuals who have been immunized with the HBV vaccine.

Hepatitis C virus RNA is the earliest serologic marker for HCV. HCV-RNA can be detected during the incubation period before symptoms of HCV disease are expressed. A positive HCV-RNA result indicates active infection, and persistence of HCV-RNA indicates chronic infection. A negative test result correlates with resolution of the disease. HCV-RNA is also used to determine patient response to antiviral therapy for HCV.

The history of all patients should include questions to seek evidence of (1) contact with a person known to have hepatitis, especially a family member; (2) unsafe sanitation practices such as contaminated drinking water; (3) ingestion of certain foods such as clams or oysters (especially from polluted water); (4) multiple blood transfusions; (5) ingestion of hepatotoxic drugs such as salicylates, sulfonamides, antineoplastic agents, acetaminophen, and anticonvulsants; and (6) parenteral administration of illicit drugs or sexual contact with a person who uses these drugs.

Therapeutic Management

Treatment options for viral hepatitis are limited in children and adolescents. The goals of management include early detection, prevention of further viral replication, support and monitoring of the disease, recognition of chronic liver disease, and prevention of spread of the disease. Special high-protein, high-carbohydrate, low-fat diets are generally not of value. The use of corticosteroids alone or with immunosuppressive drugs is not advocated in the treatment of chronic viral hepatitis. However, steroids have been used to treat chronic autoimmune hepatitis. Hospitalization is required in the event of coagulopathy or fulminant hepatitis. Human interferon-α has been used in the treatment of chronic hepatitis B and C in adults and is being used to treat these infections in children. Therapy for hepatitis depends on the severity of inflammation and the cause of the disorder.

A number of antiviral medications are being used currently to treat HBV and HCV (Degertekin and Lok, 2009; Yazigi and Balistreri, 2011). Telbivudine is more potent than lamivudine but is associated with a high rate of antiviral resistance compared with entecavir or tenofovir. Combined therapy with lamivudine and adefovir reduces the rate of antiviral resistance compared with lamivudine monotherapy. Interferon-α-2b (IFN-α-2b) has both immunomodulatory and antiviral effects but has drawbacks of subcutaneous administration; a 24-week treatment; and side effects of retinal changes, marrow suppression, and autoimmune disorders (Yazigi and Balistreri, 2011). Individualizing dose and duration of pegylated interferon-α (PEG-IFN-α) and oral ribavirin according to on-treatment virologic response may improve sustained virologic response rates in children with HCV (Mack, Gonzalez-Peralta, Gupta, et al., 2012). Several specifically targeted antiviral therapies, notably protease and polymerase inhibitors, are promising but must be used in combination with PEG-IFN-α and ribavirin; recently these have been approved only for use in adults. These agents have multiple side effects, and patients require regular monitoring and support. Many products are under current investigation in clinical trials, largely with adult patients.

Prevention. Proper hand washing and Standard Precautions prevent the spread of viral hepatitis. Prophylactic use of standard immunoglobulin is effective in preventing hepatitis A in situations of preexposure (e.g., anticipated travel to areas where HAV is prevalent) or within 2 weeks of exposure.

Hepatitis B immunoglobulin (HBIG) is effective in preventing HBV infection after 1-time exposures such as accidental needle punctures or other contact of contaminated material with mucous membranes and should be given to newborns whose mothers are HbsAg positive. It is prepared from plasma that contains high titers of antibodies against HBV. HBIG should be given within 72 hours of exposure.

Vaccines have been developed to prevent HAV and HBV infection (see Table 41-10). HBV vaccination is recommended for all newborns and for high-risk groups. HAV vaccination is recommended for infants starting at 12 months of age. (See Immunizations, Chapter 31.) In addition, the AAP (AAP Committee on Infectious Diseases and Pickering, 2012) recommends universal immunization of all adolescents with the HBV vaccine. Because HDV cannot be transmitted in the absence of HBV infection, it is possible to prevent HDV infection by preventing HBV infection. Routine serologic testing for anti-HCV of children born to women previously identified as being infected with HCV is also recommended (AAP Committee on Infectious Diseases and Pickering, 2012).

Prognosis. The prognosis for children with hepatitis varies and depends on the type of virus and the child's age and immunocompetence. Hepatitis A and E are usually mild, brief illnesses with no carrier state. Hepatitis B can cause a wide spectrum of acute and chronic illness. Infants are more likely than older children to develop chronic hepatitis. Hepatocellular carcinoma during adulthood is a potentially fatal complication of chronic HBV infection. Hepatitis C frequently becomes chronic, and cirrhosis may develop in these children; however, a small percentage of children go into spontaneous remission; approximately 25% of children infected develop chronic hepatitis C and cirrhosis, liver failure, and possibly hepatocellular carcinoma (Yazigi and Balistreri, 2011). Limited data concerning hepatitis G suggest that the rate of progression to cirrhosis with this virus may be very low. The highest mortality occurs in hepatitis D. Viral hepatitis causes approximately 50% of the cases of fulminant hepatic failure. The mechanism by which

fulminant hepatic failure occurs is not well understood, and survival varies.

CARE MANAGEMENT

Nursing care depends largely on the severity of the hepatitis, the medical treatment, and factors influencing the control and transmission of the disease. Because children with mild viral hepatitis are frequently cared for at home, it is often the nurse's responsibility to explain any medical therapies and infection control measures. When further assistance is needed for parents to comply with instructions, a community health nursing referral is necessary.

Encourage a well-balanced diet and a schedule of rest and activity adjusted to the child's condition. Because the child with HAV is not infectious within 1 week after the onset of jaundice, he or she may feel well enough to resume school shortly thereafter. Caution parents about administering any medication to the child because normal doses of many drugs may become dangerous because of the inability of the liver to detoxify and excrete them.

Standard Precautions should be followed when children are hospitalized. However, these children are not usually isolated in a separate room unless they are fecally incontinent or their toys and other personal items are likely to become contaminated with feces. Discourage children from sharing their toys.

Hand washing is the single most effective measure in prevention and control of hepatitis in any setting. Parents and children need an explanation of the usual ways in which HAV (fecal-oral route) and HBV (parenteral route) are spread. Parents should also be aware of the recommendation for universal vaccination against HBV for newborns and adolescents (see Chapter 31).

The nurse has the responsibility of helping young people with HBV infection who have a known or suspected history of illicit drug use realize the associated dangers of drug abuse, stressing the parenteral mode of transmission of hepatitis, and encouraging them to seek counseling through a drug program.

Cirrhosis

Cirrhosis occurs at the end stage of many chronic liver diseases, including BA and chronic hepatitis. It can also result from infectious, autoimmune, or toxic factors and from chronic diseases such as hemophilia and cystic fibrosis. A cirrhotic liver is irreversibly damaged.

Clinical manifestations of cirrhosis include jaundice, poor growth, anorexia, muscle weakness, and lethargy. Ascites, edema, GI bleeding, anemia, and abdominal pain may be present in children with impaired intrahepatic blood flow. Pulmonary function may be impaired because of pressure against the diaphragm caused by hepatosplenomegaly and ascites. Dyspnea and cyanosis may occur, especially on exertion. Intrapulmonary arteriovenous shunts may develop, which can also cause hypoxemia. Spider angiomas and prominent blood vessels on the upper torso are often present.

Therapeutic Management

There is no successful treatment to arrest the progression of cirrhosis. The goals of management include monitoring liver function and managing specific complications such as esophageal varices and malnutrition. Assessment of the child's degree of liver dysfunction is important so the child can be evaluated for transplantation at the appropriate time.

Liver transplantation has improved the prognosis substantially for many children with cirrhosis. The combination of new immunosuppressive medications and new surgical techniques has resulted in 83% to 91% 1-year survival rates in many large hospital centers and 5-year survival rates of 82% to 83% (Kamath and Olthoff, 2010). The policy governing the allocation of livers for transplantation by the United Network for Organ Sharing allows patients with acute fulminant liver failure plus those with failed liver grafts and the sickest pediatric patients to be placed at the top of the network transplantation lists. Although this change has benefited many pediatric patients, the shortage of available donors for children continues to dictate transplantation decisions, and many children continue to die while waiting for a suitable donor.

Nutritional support is an important therapy for children with cirrhosis and malnutrition. Supplements of fat-soluble vitamins are often required, and mineral supplements may be indicated. In some instances aggressive nutritional support in the form of continuous tube feedings or PN may be necessary.

Esophageal and gastric varices are life-threatening complications of portal hypertension. Acute hemorrhage is managed with IV fluids, blood products, vasopressin, and gastric lavage. Balloon tamponade with a Sengstaken-Blakemore tube may be indicated. Endoscopic sclerotherapy and endoscopic banding ligation are also effective therapies for esophageal and gastric varices.

Ascites can be managed by sodium restriction and diuretics. Severe ascites with respiratory compromise can be managed with administration of albumin or by paracentesis.

Although the full mechanism of hepatic encephalopathy is unknown, failure of the damaged liver to remove endogenous toxins such as ammonia plays a role. Treatment is directed at limiting the ammonia formation and absorption that occur in the bowel, especially with the drugs neomycin and lactulose. Because ammonia is formed in the bowel by the action of bacteria on ingested protein, neomycin reduces the number of intestinal bacteria so less ammonia is produced. The fermentation of lactulose by colonic bacteria produces short-chain fatty acids, which lower the colonic pH, thereby inhibiting bacterial metabolism. This decreases the formation of ammonia from bacterial metabolism of protein.

Prognosis. The success of liver transplantation has revolutionized the approach to liver cirrhosis. Liver failure and cirrhosis are indications for transplantation. Retransplantation occurs in 10% to 30% of recipients because of primary nonfunction or hepatic artery thrombosis; rejection of the transplanted graft is seen in approximately 60% of children who have a liver transplant (Kamath and Olthoff, 2010). About 20% of infants who undergo portoenterostomy survive into adulthood with their native liver; more than half of patients undergoing portoenterostomy normalize their bilirubin within 6 months, and 5-year survival rates after portoenterostomy (with native liver) are reported to be about 60% (Pakarinen and Rintala, 2011). Careful monitoring of the child's condition and quality of life is necessary to evaluate the need for and timing of transplantation (see Family-Centered Care box).

CARE MANAGEMENT

Several factors influence nursing care of the child with cirrhosis, including the cause of the cirrhosis, the severity of complications, and the prognosis. The prognosis is often poor unless successful liver transplantation occurs. Therefore nursing care of the child is similar to that for any child with a life-threatening illness (see Chapter 36). Hospitalization is required when complications such as hemorrhage, severe malnutrition, or hepatic failure occur. Nursing assessments are directed at monitoring the child's condition, and interventions

FAMILY-CENTERED CARE

End-Stage Liver Disease

In many cases the child and family must cope with an uncertain progression of the disease. The only hope for long-term survival may be liver transplantation. Transplantation can be very successful, but the waiting period may be long, and many more children are in need of organs than there are donors. The procedure is very expensive and performed only at designated medical centers that are often far from the family's home. The nurse should recognize the unique stresses of coping with end-stage liver disease and waiting for transplantation and help the family cope with these stressors. The assistance of social workers and support from other parents can be very beneficial.

are aimed at treatment of specific complications. If liver transplantation is an option, the family needs support and assistance to cope.

Biliary Atresia

Biliary atresia, or extrahepatic biliary atresia (EHBA), is a progressive inflammatory process that causes both intrahepatic and extrahepatic bile duct fibrosis, resulting in eventual ductal obstruction. The incidence of BA is approximately one in 10,000 to 15,000 live births (A-Kader and Balistreri, 2011; Kelly and Davenport, 2007). Associated malformations include polysplenia, intestinal atresia, and malrotation of the intestine. If untreated, BA usually leads to cirrhosis, liver failure, and death in the first 2 years of life.

Etiology and Pathophysiology

The exact cause of BA is unknown, although immune mechanisms or viral injury may be responsible for the progressive process that results in complete obliteration of the bile ducts. BA is not seen in fetuses or stillborn or newborn infants. This suggests that BA is acquired late in gestation or in the perinatal period and is manifested a few weeks after birth. The majority of cases of BA (85%) have a complete obliteration of the extrahepatic biliary tree at or above the porta hepatitis (A-Kader and Balistreri, 2011).

Jaundice, manifesting with yellow discoloration of the skin or sclerae, is the most common early symptom of BA. Jaundice, indicating cholestasis (the accumulation of compounds that cannot be excreted because of occlusion or obstruction of the biliary tree), can be visible at a total serum bilirubin concentration as low as 5 mg/dL. An abnormal direct bilirubin has been designated as greater than 1 mg/dL if the total bilirubin is less than 5 mg/dL or a value of direct bilirubin that represents more than 20% of the total bilirubin if it is greater than 5 mg/dL. Direct hyperbilirubinemia first appears after the resolution of physiologic jaundice (see Chapter 24). Jaundice is often associated with pale stool and dark urine. Histologic study demonstrates bile duct remnants and a progressive inflammatory process. In the fetal embryonic form of BA, which represents 10% to 35% of cases, there is a congenital absence of biliary ductal patency and an absence of bile duct remnants. Many infants have associated congenital anomalies. Varying degrees of cholestasis occur, resulting in retention of irritants and toxins. Injury to the liver occurs as a result of the inflammation caused by the cholestasis.

Diagnostic Evaluation

Early diagnosis is the key to the survival of children with BA. Infants who undergo surgery in the first 60 days of life have an 80% chance of establishing bile flow. Between 60 to 90 days of life the chance of reestablishing flow drops to 50%, and after 90 days to 10% (Chen, Chang, Du, et al., 2006). The typical infant is thriving, appears well, and has only very mild jaundice during the first 6 to 8 weeks (Emerick and Whitington, 2006) but soon begins failing to grow. Several clinical signs may indicate the presence of BA (Box 41-12). Blood tests should include a CBC, electrolytes, bilirubin, and liver enzymes. Additional laboratory analyses, including α_1-antitrypsin level, TORCH titers (see Maternal Infections, Chapter 25), hepatitis serology, α-fetoprotein, urine CMV, and a sweat chloride test, are indicated to rule out other conditions that cause persistent cholestasis and jaundice. Abdominal ultrasonography allows inspection of the liver and biliary system. Hepatobiliary scintigraphy demonstrates biliary patency but does not provide diagnostic certainty. Endoscopic retrograde cholangiopancreatography is performed in very young infants. This procedure, which is done using general anesthesia, has an 80% reported diagnostic accuracy. Percutaneous liver biopsy is highly reliable when the biopsy contains specimens from a number of portal areas. Definitive diagnosis of BA is obtained during surgical laparotomy and an intraoperative cholangiogram.

BOX 41-12 CLINICAL MANIFESTATIONS OF BILIARY ATRESIA

- Jaundice
  - Earliest manifestation and most striking feature of disorder
  - First observed in sclera
  - May be present at birth but usually not apparent until age 2 to 3 weeks
- Urine dark
- Stools lighter than expected or white or tan
- Hepatomegaly and abdominal distention common
- Splenomegaly occurs later
- Poor fat metabolism results in:
  - Poor weight gain
  - General growth failure
- Pruritus
- Irritability; difficulty comforting infant

Therapeutic Management

The primary treatment of BA is *hepatic portoenterostomy* (Kasai procedure) in which a segment of intestine is anastomosed to the resected porta hepatis to attempt bile drainage. A Roux-en-Y jejunal limb is then anastomosed to the porta hepatis (a Y-shaped anastomosis performed to provide bile drainage without reflux). This procedure has several variations. Bile drainage is achieved in approximately 80% to 90% of infants who undergo surgery when younger than 8 weeks of age (A-Kader and Balistreri, 2011). However, progressive cirrhosis still occurs in many children, necessitating liver transplantation. Prophylactic antibiotics are given after the Kasai procedure to minimize the risk of ascending cholangitis.

Medical management of BA is primarily supportive. It includes nutritional support with infant formulas that contain medium-chain triglycerides and essential fatty acids. Supplementation with fat-soluble vitamins (A, D, E, K); a multivitamin; and minerals, including iron, zinc, and selenium, is usually required. Aggressive nutritional support in the form of continuous gastrostomy feedings or TPN may be indicated for moderate-to-severe growth failure; the enteral solution should be low in sodium. Phenobarbital may be prescribed after hepatic portoenterostomy to stimulate bile flow, and

ursodeoxycholic acid may be used to decrease cholestasis and the intense pruritus from jaundice. In cases of advanced liver dysfunction management is the same as in infants with cirrhosis.

Prognosis. Untreated BA results in progressive cirrhosis and death in most children by 2 years of age. The Kasai procedure improves the prognosis but is not a cure. Biliary drainage can often be achieved if the surgery is done before the intrahepatic bile ducts are destroyed. Long-term survival has been reported in children who receive the Kasai procedure; however, even with successful bile drainage, many children ultimately develop liver failure.

Advances in surgical techniques and the use of immunosuppressive and antifungal drugs have improved the success of transplantation. The major obstacle continues to be a shortage of donor livers. Reduced-size, split-liver transplantation, retransplantation, and increased public awareness may improve donor organ availability in the future.

CARE MANAGEMENT

Nursing interventions for the child with BA include support of the family before, during, and after surgical procedures and education regarding the treatment plan. In the postoperative period of a portoenterostomy, nursing care is similar to that after major abdominal surgery. Teaching includes the proper administration of medications. Administration of nutritional therapy, including special formulas, vitamin and mineral supplements, gastrostomy feedings, or PN, is an essential nursing responsibility. Growth failure in such infants is common, and increased metabolic needs combined with ascites, pruritus, and nutritional anorexia constitute a challenge for care. The nurse teaches caregivers how to monitor and administer nutritional therapy in the home. Pruritus may be a significant problem that is addressed by drug therapy and comfort measures such as baths in colloidal oatmeal compounds and trimming of fingernails. The risk of complications of BA such as cholangitis, portal hypertension, GI bleeding, and ascites should be explained to the caregivers.

Children and their families also need psychosocial support. The uncertain prognosis, discomfort, and waiting for transplantation produce stress; and hospitalizations, pharmacologic therapy, and nutritional therapy impose financial burdens on the family. Families can receive help from the Children's Liver Association for Support Services,* an organization that provides educational materials, programs, and support systems, and the American Liver Foundation.†

STRUCTURAL DEFECTS

Cleft Lip and Cleft Palate

Clefts of the lip (CL) and palate (CP) are facial malformations that occur during embryonic development and are the most common congenital deformities in the United States. They may appear separately or more often together. CL results from failure of the maxillary and median nasal processes to fuse; CP is a midline fissure of the palate that results from failure of the two palatal processes to fuse.

The palate can be divided into the primary and secondary palates. The primary palate consists of the medial portion of the upper lip and the portion of the alveolar ridge that contains the central and lateral incisors. The secondary palate consists of the remaining portion of the hard palate and all of the soft palate. CL may vary from a small notch in the upper lip to a complete cleft extending into the base of the nose, including the lip and the alveolar ridge (Fig. 41-4). CL can be unilateral or bilateral. Deformed dental structures are associated with CL. Isolated CP occurs in the midline of the secondary palate and may also vary from a bifid uvula (the mildest form of CP) to a complete cleft extending from the soft to the hard palate.

Cleft lip and palate (CL/P) is more common than CP alone and varies by ethnicity. The occurrence is one in 1000 births in Caucasians, 1.7 per 1000 in Asians, 3.6 per 1000 in Native Americans and one in 2000 in African-Americans (Moller and Glaze, 2009). CP occurs alone in only one in 2500 cases and does not display variation by ethnicity (Wilkins-Haug, 2010). CL/P tends to be more common in boys, and isolated CP occurs more frequently in girls.

Etiology

Cleft deformities may be an isolated anomaly, or they may occur with a recognized syndrome. CL/P and CP are distinct from isolated

†75 Maiden Lane, Suite 603, New York, NY 10038, 212-668-1000, www.liverfoundation.org/education/info/biliaryatresia.

CP. Clefts of the secondary palate alone are more likely to be associated with syndromes than are isolated CL or CL/P.

Most cases of CL/P have multifactorial inheritance, which is generally caused by a combination of genetic and environmental factors. Researchers do not yet know which gene(s) are responsible for clefting or to what extent environmental factors impact the developing structures. Exposure to teratogens such as alcohol, cigarette smoking, anticonvulsants, steroids, and retinoids are associated with higher rates of oral clefting. Folate deficiency is also a risk factor for clefting.

Pathophysiology

Cleft deformities represent a defect in cell migration that results in a failure of the maxillary and premaxillary processes to come together between the fourth and tenth weeks of embryonic development. Although often appearing together, CL/P are distinct malformations embryologically, occurring at different times during the developmental process. Merging of the primary palate (upper lip and alveolus bilaterally) is completed by the seventh week of gestation. Fusion of the secondary palate (hard and soft palate) takes place later, between the seventh and tenth weeks of gestation. In the process of migrating to a horizontal position, the palates are separated by the tongue for a short time. If there is delay in this movement or if the tongue fails to descend soon enough, the remainder of development proceeds, but the palate never fuses.

Diagnostic Evaluation

Cleft lip and CL/P are apparent at birth. The defect may elicit severe emotional reactions in parents. CP is less obvious than CL and may not be detected immediately without a thorough assessment of the oropharynx. CP is identified through visual examination of the oropharynx or when the examiner places a gloved finger directly on the palate. Clefts of the hard and soft palate form a continuous opening between the mouth and the nasal cavity. The severity of the CP has an impact on feeding; the infant is unable to create suction in the oral cavity that is necessary for feeding. However, in most cases the infant's ability to swallow is normal.

Prenatal diagnosis with fetal ultrasonography is not reliable until the soft tissues of the fetal face can be visualized at 13 to 14 weeks. About 20% to 30% of infants with CL and CL/P are prenatally diagnosed through ultrasonography (Robbins, Damiano, Druschel, et al., 2010), although infants with CP only are rarely diagnosed prenatally.

Therapeutic Management

Treatment of the child with CL/P involves the cooperative efforts of a cleft/craniofacial multidisciplinary health care team, including pediatrics, plastic surgery, orthodontics, otolaryngology, speech/language pathology, audiology, nursing, and social work. Management is directed toward closure of the cleft(s), prevention of complications, and facilitation of normal growth and development in the child.

Surgical Correction of Cleft Lip. CL repair typically occurs at most centers between 2 and 3 months of age. Common procedures for repair of CL include the Tennison-Randall triangular flap (Z-plasty), the Fisher technique, and the Millard rotational advancement technique. Improved surgical techniques have minimized scar retraction, and in the absence of infection or trauma healing occurs with little scar formation. Nasoalveolar molding (NAM) may also be used to bring the cleft segments closer together before definitive CL repair, reducing the need for CL revision. However, optimal cosmetic results may be difficult to obtain in severe defects. Additional revisions may be necessary at a later age.

Surgical Correction of Cleft Palate. CP repair typically occurs between 6 and 12 months. There is concern that early CP repair interferes with skeletal growth of the midface, but postponing palate closure beyond the child's first words may result in increased speech disorders (Chapman, Hardin-Jones, Goldstein, et al., 2008). Common techniques to repair CP include the Veau-Wardill-Kilner V-Y pushback procedure and the Furlow double-opposing Z-plasty. Approximately 20% to 30% of children with repaired CP need a secondary surgery to improve velopharyngeal closure for speech. A small number of these children will have velopharyngeal dysfunction with hypernasality and nasal air emission. Secondary procedures may include palatal lengthening, pharyngeal flap, sphincter pharyngoplasty, or posterior pharyngeal wall augmentation to improve velopharyngeal closure. If the child is not a candidate for surgical revision to improve velopharyngeal function, prosthetic management may be considered.

! NURSING ALERT

Avoid the use of suction or other objects in the mouth such as tongue depressors, thermometers, pacifiers, spoons, or straws following a palatoplasty to maintain the integrity of the surgically repaired palate.

Prognosis. Children with CL may require multiple surgeries to achieve optimal aesthetic outcomes but are not at risk for increased speech problems. Although some children with CP and CL/P do not require speech therapy, many have some degree of speech impairment that requires speech therapy at some point throughout childhood. Articulation errors result from a history of velopharyngeal dysfunction, incorrect articulatory placement, improper tooth alignment, and varying degrees of hearing loss. Improper drainage of the middle ear as a result of inefficient function of the eustachian tube relating to the history of CP contributes to recurrent otitis media, which leads to conductive hearing loss in many children with CP. As a prophylactic measure, many children with palatal clefts have pressure-equalization tubes placed. Extensive orthodontics and prosthodontics may be needed to correct malposition of the teeth and maxillary arches. Academic achievement, social adjustment, and behavior should be monitored, particularly in children with syndromic cleft conditions.

CARE MANAGEMENT

The immediate nursing problems for an infant with CL/P deformities are related to feeding. Parents of newborns with clefts place high priority on learning how to feed their infants and identify when they are sick, but they also express interest in learning about the infant's "normal" features. Whenever possible, they should be referred to a comprehensive CP team.

Feeding. Feeding the infant with a cleft presents a challenge to nurses and parents. Growth failure in infants with CL/P or CP has been attributed to preoperative feeding difficulties. After surgical repair most infants who have isolated CL, CP, or CL/P with no associated syndromes gain weight or achieve adequate weight and height for age.

CL may interfere with an infant's ability to achieve an adequate anterior lip seal. An infant with an isolated CL typically has no difficulty breastfeeding because the breast tissue is able to conform to the cleft. Cheek support (squeezing the cheeks together to decrease

the width of the cleft) may be useful in improving lip seal during feeding.

Infants with CP and CL/P are often unable to feed using conventional methods before surgical management. CP reduces the infant's ability to suck, which interferes with breastfeeding and traditional bottle-feeding. Modifications to positioning, bottle selection, and feeder supportive techniques can help infants with CP feed efficiently. Begin by positioning an infant with CP in an upright position with the head supported by the caregiver's hand or cradled in the arm; this position allows gravity to assist with the flow of the liquid so it is swallowed instead of resulting in a loss of liquid through the nose.

Suction is almost certainly impaired in infants with CP because the velum is unable to elevate and separate the oral nasal cavities while generating adequate negative intraoral pressure. Several types of bottles work well with infants unable to generate adequate suction, including the Special Needs Feeder (formerly Haberman), the Pigeon bottle, and the Mead-Johnson Cleft Palate Nurser. The Special Needs Feeder and the Pigeon bottles use a one-way flow valve that allows the infant to feed successfully by compressing the nipple with the intact segments of the palate and the mandible or tongue. With the one-way flow valve in place, the liquid flows into the oral cavity rather than back into the bottle chamber when the nipple is compressed. The Special Needs Feeder also has a large nipple chamber that allows the feeder to provide extra assistance by squeezing the chamber if needed. The tip has a slit cut, which allows the feeder to control the flow of liquid by positioning the slit vertically or horizontally within the mouth, which can reduce choking and gagging. The Pigeon bottle has a bulbous tip that fits naturally into the oral cavity with a Y-cut nipple that increases the flow of liquid. The third bottle, the Mead Johnson Cleft Palate Nurser, is a squeezable bottle with a long, thin X-cut nipple; this bottle requires the feeder to pulse the bottle throughout the feeding and does not require the infant to actively compress the nipple during the feeding.

Infants with clefts tend to swallow excessive air during feedings; thus it is important to pause during feedings and burp the infant. Some CP specialists advocate for the use of feeding obturators to help with feeding; these devices may increase compression surfaces within the oral cavity but do not improve feeding efficiency or growth within the first year of life (Masarei, Wade, Mars, et al., 2007).

Regardless of the feeding method used, the mother should begin feeding the infant as soon as possible, preferably after the initial nursery feeding. When maternal feeding is initiated early, the mother can help to determine the method best suited to her, and the infant and can become adept in the technique before discharge from the hospital.

Preoperative Care. In preparation for surgical repair, parents may be taught to use alternative feeding systems (e.g., syringes) several days before surgery.

Postoperative Care. The major efforts in the postoperative period are directed toward protecting the operative site. For CL parents may be advised to apply petroleum jelly to the operative site for several days after surgery. For CL, CP, or CL/P, elbow immobilizers may be used to prevent the infant from rubbing or disturbing the suture line; they are applied immediately after surgery and may be used for 7 to 10 days. Some centers advocate using a syringe for feeding for 7 to 10 days after CL or CP repair. Adequate analgesia is required to relieve postoperative pain and prevent restlessness. Feeding is resumed when tolerated. An upright or infant seat position is helpful in the immediate postoperative period (especially for infants who have difficulty handling secretions). Avoid the use of suction or other objects in the mouth such as tongue depressors, thermometers, pacifiers, spoons, and straws.

The older infant or child may be discharged on a blenderized or soft diet, and parents are instructed to continue the diet until the surgeon directs them otherwise. Parents are cautioned against allowing the child to eat hard items (e.g., toast, hard cookies, and potato chips) that can damage the repaired palate.

Long-Term Care. Children with CL/P often require a variety of services during recovery. Family members need support and encouragement by health professionals and guidance in activities that facilitate a normal outcome for their child. Parents frequently cite financial stress as a difficult issue. With the combined efforts of the family and the health team, most children achieve a satisfactory outcome. Many children with CL/P have surgical correction that creates a near normal–appearing lip and permits good function of the palate for speech and feeding. Parents need to understand the function of speech therapy. the purpose and care of all orthodontic appliances, and the importance of establishing good mouth care and proper brushing habits.

Throughout the child's development, an important goal is the development of a healthy personality and self-esteem. Many communities have CP parents' groups that offer help and support to families. Agencies that provide services and information for children with CL/P and their families include the American Cleft Palate–Craniofacial Association (www.acpa-cpf.org), the Cleft Palate Foundation (www.cleftline.org), Cleft Advocate (www.cleftadvocate.org), the March of Dimes (www.marchforbabies.org), and various state children's medical services.

Esophageal Atresia and Tracheoesophageal Fistula

Congenital EA and tracheoesophageal fistula (TEF) are rare malformations that represent a failure of the esophagus to develop as a continuous passage and a failure of the trachea and esophagus to separate into distinct structures. These defects may occur as separate entities or in combination; without early diagnosis and treatment they pose a serious threat to the infant's well-being.

Etiology

EA with or without an associated TEF is the most common esophageal malformation, occurring in approximately 90% of the one in 4000 affected neonates (Khan and Orenstein, 2011). There appears to be an equal sex incidence; but the birth weight of most affected infants is significantly lower than average, and the incidence of preterm birth is high. A history of maternal polyhydramnios is present in approximately 50% of infants with the defect.

Approximately 50% of the cases of EA/TEF are a component of VATER or VACTERL association, acronyms used to describe associated anomalies (VATER for *v*ertebral defects, imperforate *a*nus, tracheo*e*sophageal fistula, and *r*adial and *r*enal dysplasia; and VACTERL for *v*ertebral, *a*nal, *c*ardiac, *t*racheal, *e*sophageal, *r*enal, and *l*imb) (Khan and Orenstein, 2011). Other associated conditions include DiGeorge syndrome, Down syndrome, Pierre-Robin sequence, Fanconi syndrome, and CHARGE syndrome (coloboma, heart defects, choanal atresia, developmental restriction, genital hypoplasia, and ear deformities) (Guidry and McGahren, 2012).

Pathophysiology

The cause of EA/TEF is unknown. In the most frequently encountered form of EA and TEF (80% to 95% of cases), the proximal esophageal segment terminates in a blind pouch, and the distal segment is connected to the trachea or primary bronchus by a short fistula at or near the bifurcation. The second most common variety

BOX 41-13 CLINICAL MANIFESTATIONS OF TRACHEOESOPHAGEAL FISTULA

- Excessive salivation and drooling
- Three *C's* of tracheoesophageal fistula:
  - *C*oughing
  - *C*hoking
  - *C*yanosis
- Apnea
- Increased respiratory distress during and after feeding
- Abdominal distention

(5% to 8%) consists of a blind pouch at each end, widely separated and with no communication to the trachea. An H-type EA refers to an otherwise normal trachea and esophagus connected by a fistula (4% to 5%). Extremely rare anomalies involve a fistula from the trachea to the upper esophageal segment (0.8%) or to both the upper and lower segments (0.7% to 6%).

Diagnostic Evaluation

The disorder is suspected on the basis of clinical manifestations (Box 41-13). EA should also be suspected in cases of maternal polyhydramnios. Although the diagnosis is established on the basis of clinical signs and symptoms, the exact type of anomaly is determined by radiographic studies. A radiopaque catheter is inserted into the hypopharynx and advanced until it encounters an obstruction. Chest radiographs are taken to ascertain esophageal patency or the presence and level of a blind pouch. Sometimes fistulas are not patent, which makes them more difficult to diagnose. The presence of gas in the stomach or small bowel indicates a coexisting TEF. Prenatal diagnosis is possible with ultrasonography or MRI, and delivery at a tertiary care center is desired (Guidry and McGahren, 2012).

Therapeutic Management

The treatment of patients with EA and TEF includes maintenance of a patent airway, prevention of pneumonia, gastric or blind pouch decompression, supportive therapy, and surgical repair of the anomaly.

When EA with a TEF is suspected, the infant is immediately deprived of oral intake, IV fluids are initiated, and the infant is positioned prone or semi-upright to facilitate drainage of secretions and decrease the likelihood of aspiration. Accumulated secretions are suctioned frequently from the mouth and pharynx. A double-lumen catheter should be placed into the upper esophageal pouch and attached to intermittent or continuous low suction. The infant's head is kept upright to facilitate removal of fluid collected in the pouch and prevent aspiration of gastric contents. Broad-spectrum antibiotic therapy is often instituted if there is a concern about aspiration of gastric contents.

Most malformations can be corrected surgically in one operation or in two or more staged procedures. The success depends on early diagnosis before complications occur and on the presence and severity of associated anomalies and illness factors, including preterm birth. With measures instituted to prevent aspiration pneumonia and ensure adequate hydration and nutrition, surgery may be postponed to allow for more effective treatment of pneumonia and physiologic stabilization so the infant can better withstand the complex surgery. The delay also offers an opportunity for further evaluation and assessment to rule out any associated anomalies and optimize respiratory support.

The surgery consists of a thoracotomy with division and ligation of the TEF and an end-to-end or end-to-side anastomosis of the esophagus. A chest tube may be inserted to drain intrapleural air and fluid. For infants who are not stable enough to undergo definitive repair or those with a lengthy gap between the proximal and distal esophagus, a staged operation is preferred that involves gastrostomy, ligation of the TEF, and constant drainage of the esophageal pouch. A delayed esophageal anastomosis is usually attempted after several weeks to months. Thoracoscopic repair of EA/TEF is being used successfully, thus negating the need for a thoracotomy and minimizing associated postoperative complications and morbidities (Guidry and McGahren, 2012; MacKinlay, 2009; Rothenberg, 2009).

If an esophageal anastomosis cannot be accomplished, a gastrostomy is recommended; a cervical esophagostomy (to allow drainage of saliva through a stoma in the neck) was performed in cases of a long gap atresia but this is no longer recommended because it makes subsequent surgical repair more difficult (Kunisaki and Foker, 2012).

A primary anastomosis may be impossible because of insufficient length of the two segments of esophagus. This occurs if the distance between the two segments is 3 to 4 cm (1.2 to 1.6 inches) or greater; this is often referred to as *long-gap EA* (Khan and Orenstein, 2011). In these cases an esophageal replacement procedure using a part of the colon or gastric tube interposition may be necessary to bridge the missing esophageal segment. An esophageal growth induction procedure may also be used; this is described in the Kunisaki and Foker (2012) reference.

Tracheomalacia may occur as a result of weakness in the tracheal wall that exists when a dilated proximal pouch compresses the trachea early in fetal life. It may also occur as a result of inadequate intratracheal pressure causing abnormal tracheal development. Clinical signs of tracheomalacia include a barking cough, stridor, wheezing, recurrent respiratory tract infections, cyanosis, and sometimes apnea. Tracheomalacia may occur in up to 75% of children with EA/TEF but may be clinically significant in only 10% to 20% of infants with EA/TEF; surgical intervention is required in severe cases (Achildi and Grewal, 2007).

Prognosis. The survival rate is nearly 100% in otherwise healthy children. Most deaths are the result of extreme prematurity or other lethal associated anomalies. Potential complications after the surgical repair of EA and TEF depend on the type of defect and surgical correction. Complications of repair include an anastomotic leak, strictures caused by tension or ischemia, esophageal motility disorders causing dysphagia, respiratory compromise, scoliosis, chest wall deformity, and GER. Anastomotic esophageal strictures may cause dysphagia, choking, and respiratory distress. The strictures are often treated with routine esophageal dilation. Feeding difficulties are often present for months or years after surgery, and the infant must be monitored closely to ensure adequate weight gain, growth, and development. In some cases laparoscopic fundoplication may be required. At times the infant must be fed via gastrostomy or jejunostomy to provide adequate caloric intake.

CARE MANAGEMENT

Nursing responsibility for detection of this serious malformation begins immediately after birth. For an infant with the classic signs

and symptoms of EA, the major concern is the establishment of a patent airway and prevention of further respiratory compromise. Cyanosis is usually a result of laryngeal spasm caused by overflow of saliva into the larynx from the proximal esophageal pouch or aspiration; it normally resolves after removal of the secretions from the oropharynx by suctioning. The passage of a small-gauge orogastric feeding tube via the mouth into the stomach during the initial nursing physical assessment is helpful to rule out EA or other obstructive defects.

! NURSING ALERT

Any infant who has an excessive amount of frothy saliva in the mouth or difficulty with secretions and unexplained episodes of apnea, cyanosis, or oxygen desaturation should be suspected of having an EA or TEF and referred immediately for medical evaluation.

Preoperative Care. The nurse carefully suctions the mouth and nasopharynx and places the infant in an optimum position to facilitate drainage and avoid aspiration. The most desirable position for a newborn who is suspected of having the typical EA with a TEF (e.g., type C) is supine (or sometimes prone) with the head elevated on an inclined plane of at least 30 degrees. This positioning minimizes the reflux of gastric secretions at the distal esophagus into the trachea and bronchi, especially when intraabdominal pressure is elevated.

It is imperative to immediately remove any secretions that can be aspirated. Until surgery the blind pouch is kept empty by intermittent or continuous suction through an indwelling double-lumen or Replogle catheter passed orally or nasally to the end of the pouch. In some cases a percutaneous gastrostomy tube is inserted and left open so any air entering the stomach through the fistula can escape, thus minimizing the danger of gastric contents being regurgitated into the trachea. The gastrostomy tube is emptied by gravity drainage. Feedings through the gastrostomy tube and irrigations with fluid are contraindicated before surgery in an infant with a distal TEF.

Nursing interventions include respiratory assessment, airway management, thermoregulation, fluid and electrolyte management, and PN support.

Often the infant must be transferred to a hospital with a specialized care unit and pediatric surgical team. The nurse advises the parents of the infant's condition and provides them with necessary support and information.

Postoperative Care. Postoperative care for these infants is the same as for any high-risk newborn. The infant is returned to a radiant warmer or isolette, the double-lumen NG catheter is attached to low-suction or gravity drainage, PN is provided, and the gastrostomy tube (if applicable) is returned to gravity drainage until feedings are tolerated. If a thoracotomy is performed and a chest tube is inserted, attention to the appropriate function of the closed drainage system is imperative. Pain management in the postoperative period is important even if only a thoracoscopic approach is used. In the first 24 to 36 hours the nurse should provide pain management for the neonate just as for an adult undergoing a similar surgical procedure. Tracheal suction should only be done using a premeasured catheter and with extreme caution to avoid injury to the suture line.

If tolerated, gastrostomy feedings may be initiated and continued until the esophageal anastomosis is healed. Before oral feedings are initiated and the chest tube is removed a contrast study or esophagram will verify the integrity of the esophageal anastomosis.

The nurse must observe the initial attempt at oral feeding carefully to make certain the infant is able to swallow without choking. Until the infant is able to take a sufficient amount by mouth, oral intake may need to be supplemented by bolus or continuous gastrostomy feedings. Ordinarily infants are not discharged until they can take oral fluids well. The gastrostomy tube may be removed before discharge or maintained for supplemental feedings at home.

Special Problems. Upper respiratory tract complications are a threat to life in both the preoperative and postoperative periods. In addition to pneumonia, there is a constant danger of respiratory distress resulting from atelectasis, pneumothorax, and laryngeal edema. Any persistent respiratory difficulty after removal of secretions is reported to the surgeon immediately. The infant is monitored for anastomotic leaks, as evidenced by purulent chest tube drainage, increased WBC count, and temperature instability.

For an infant who requires esophageal replacement, nonnutritive sucking is provided by a pacifier. Other appropriate oral stimulation prevents feeding aversion. Infants who remain NPO for an extended period or who have not received oral stimulation have difficulty eating by mouth after corrective surgery and may develop oral hypersensitivity and food aversion. They require patient, firm guidance to learn how to take food into the mouth and swallow after repair. A referral to a multidisciplinary feeding behavior program is recommended.

Some infants and children with EA/TEF may require periodic esophageal dilations on an outpatient basis. Discharge education should include instructions about feeding techniques in the child with a repaired esophagus, including a semi-upright feeding position, small feedings, and observation for adequacy of swallowing (regurgitation, cyanosis, choking). *Tracheomalacia* is often a complication; and parents are educated regarding the signs and symptoms of this condition, which include a barking cough, stridor, wheezing, recurrent respiratory tract infections, cyanosis, and sometimes apnea. GER may also occur when feedings resume and may contribute to reactive airway disease with wheezing and labored respirations as the prominent clinical manifestations. Problems with thriving and gaining weight may occur in the first 5 years of life in the child with EA/TEF, especially if the infant is born preterm; the nurse should be alert to the achievement of developmental milestones that indicate a need for early intervention and multidisciplinary referral.

As with any congenital anomaly, parents need support in adjusting to the child's condition (see Chapter 36). One difficulty is the immediate transfer of the sick newborn to the ICU and the length of hospitalization. Encouraging parents to visit the infant, participate in care when appropriate, and express their feelings regarding his or her condition facilitates the attachment process. The nurse in the ICU should assume responsibility for ensuring that the parents are kept fully informed of the infant's progress.

Preparing parents for discharge involves teaching them skills they will need at home. Parents are taught to observe for behaviors that indicate the need for suctioning and signs of respiratory distress and constriction of the esophagus (e.g., poor feeding, dysphagia, drooling, regurgitation of undigested food). Discharge planning also includes obtaining the necessary equipment and home nursing services to provide home care.

Hernias

A hernia is a protrusion of a portion of an organ or organs through an abnormal opening. The danger from herniation arises when the organ protruding through the opening is constricted to the extent that circulation is impaired or when the protruding organs encroach on and impair the function of other structures. An inguinal hernia that cannot be reduced easily is called an *incarcerated hernia.* A *strangulated inguinal hernia* is one in which the blood supply to the herniated organ is impaired. The herniations of concern are those that protrude through the diaphragm, the abdominal wall, or the inguinal canal. The hernias of significance to the pediatric age-groups are outlined in Table 41-11. The abdominal wall defects gastroschisis and omphalocele are considered separately in Table 41-12.

OBSTRUCTIVE DISORDERS

Obstruction in the GI tract occurs when the passage of nutrients and secretions is impeded by a constricted or occluded lumen or when there is impaired motility *(paralytic ileus).* Obstructions may be congenital or acquired. Many congenital obstructions such as atresia, imperforate anus, meconium plug, and meconium ileus usually appear in the neonatal period. Other obstructions of congenital etiology such as malrotation, HD, pyloric stenosis, volvulus, incarcerated hernia, and Meckel diverticulum appear after the first few weeks of life. Intestinal obstruction from acquired causes such as intussusception and tumors may occur in infancy or childhood. Intestinal obstructions from any cause are characterized by similar signs and symptoms (Box 41-14).

Hypertrophic Pyloric Stenosis

Hypertrophic pyloric stenosis (HPS) occurs when the circumferential muscle of the pyloric sphincter becomes thickened, resulting in elongation and narrowing of the pyloric channel. This produces an outlet obstruction and compensatory dilation, hypertrophy, and hyperperistalsis of the stomach. This condition usually develops in the first 2 to 5 weeks of life, causing projectile nonbilious vomiting, dehydration, metabolic alkalosis, and growth failure if detection is delayed. The precise etiology is unknown. The reported incidence is one to three per 1000 live births with a male-to-female ratio of 4 to 6:1. There is a genetic predisposition, and siblings and offspring of affected persons are at increased risk of developing HPS. It is more common in full-term than in preterm infants and is seen less frequently in African-American and Asian infants than in white infants.

Pathophysiology

The circular muscle of the pylorus thickens as a result of hypertrophy (increased size) and hyperplasia (increased mass). This produces severe narrowing of the pyloric canal between the stomach and the duodenum, causing partial obstruction of the lumen (Fig. 41-5, *A*). Over time inflammation and edema further reduce the size of the opening, resulting in complete obstruction. The hypertrophied pylorus may be palpable as an olivelike mass in the upper abdomen. Pyloric stenosis is not a congenital disorder. Substantial evidence supports decreased expression of neuronal nitric oxide synthase in the nerve fibers of the pyloric circular muscle in infants with HPS (Hunter and Liacouras, 2011). In most cases HPS is an isolated lesion; however, it may be associated with intestinal malrotation, esophageal and duodenal atresia, and anorectal anomalies. HPS has also been linked to the administration of erythromycin in the first few weeks of life as well as eosinophilic gastroenteritis, Apert syndrome, Cornelia de Lange syndrome, Zellweger syndrome, trisomy 18, and Smith-Lemli-Opitz syndrome (Hunter and Liacouras, 2011).

Diagnostic Evaluation

The diagnosis of HPS is often made after the history and physical examination. The olivelike mass is palpated easily when the stomach is empty, the infant is quiet, and the abdominal muscles are relaxed. Vomiting usually occurs 30 to 60 minutes after feeding and becomes projectile as the obstruction progresses. Emesis is nonbilious, usually consisting of stale milk. These infants may become dehydrated and appear malnourished if an early diagnosis is not established.

If the diagnosis is inconclusive from the history and physical signs (Box 41-15), ultrasonography demonstrates an elongated, sausage-shaped mass with an elongated pyloric channel. If ultrasonography fails to demonstrate a hypertrophied pylorus, an upper GI radiography should be done to rule out other causes of vomiting. Laboratory findings reflect the metabolic alterations (hypochloremic, hypokalemic metabolic alkalosis) created by severe depletion of both fluid and electrolytes from extensive and prolonged vomiting. Hyperbilirubinemia (unconjugated) may also be present and often resolves after surgical correction of the obstruction occurs (Hunter and Liacouras, 2011).

Therapeutic Management

Surgical relief of the pyloric obstruction by **pyloromyotomy** is the standard therapy for this disorder. Before surgery the infant must be rehydrated, and metabolic alkalosis corrected with parenteral fluid and electrolyte administration. Replacement fluid therapy may delay surgery for 24 to 48 hours. The stomach is decompressed with an NG tube. In infants with no evidence of fluid and electrolyte imbalance, surgery is performed without delay.

The surgical procedure is often performed by laparoscope and consists of a longitudinal incision through the circular muscle fibers of the pylorus down to, but not including, the submucosa (pyloromyotomy, sometimes called *Fredet-Ramstedt procedure*) (see Fig. 41-5, *B*). The procedure has a high success rate. Laparoscopic surgery through a single small incision often results in a shorter surgical time, more rapid postoperative feeding, and shorter hospital stay (Sola and Neville, 2009).

Feedings are usually begun 3 to 6 hours after surgery, beginning with small, frequent feedings of an electrolyte solution such as Pedialyte or sterile water. If clear fluids are retained, formula or breast feedings are initiated to the infant's tolerance. The amount and the interval between feedings are gradually increased until a full feeding schedule is reinstated, which usually takes about 24 to 48 hours.

Prognosis. Most infants recover completely and rapidly after pyloromyotomy. Postoperative complications include persistent pyloric obstruction and rarely wound dehiscence.

CARE MANAGEMENT

The diagnosis of HPS is considered in very young infants who appear alert but fail to gain weight and have a history of vomiting after feedings. Assessment is based on observation of eating behaviors and evidence of other characteristic clinical manifestations.

Preoperative Care. Before surgery the emphasis is placed on restoring hydration and electrolyte balance. Infants are usually made NPO and receive IV fluids with dextrose and electrolyte replacement based on laboratory serum electrolyte values and clinical appearance.

Observations also include assessment of vital signs, particularly those that might indicate fluid or electrolyte imbalances. These

TABLE 41-11 SUMMARY OUTLINE OF HERNIAS

MANIFESTATIONS AND TYPE	DIAGNOSTIC EVALUATION	NURSING CARE MANAGEMENT
Congenital Diaphragmatic		
Protrusion of abdominal organs through opening in diaphragm, commonly on left side, causing severe respiratory compromise and inability to adequately expand affected lung, which may be hypoplastic	**Symptoms**—Commonly severe respiratory distress at birth or within a few hours; tachypnea, cyanosis, dyspnea, a scaphoid abdomen; absent breath sounds on affected side; impaired cardiac output; possible symptoms of shock, severe acidosis Milder cases may be seen after birth without severe respiratory distress. **Diagnosis**—Suspected on basis of symptoms, confirmed by radiographic study; often diagnosed prenatally as early as 25th week of gestation	**Therapeutic:** Provide prompt recognition, resuscitation, and stabilization. Avoid bag and mask ventilation in diagnosed or suspected CDH because this fills stomach with air and further compromises respiratory function. Provide supportive treatment of respiratory distress and correction of pulmonary hypertension and persistence of fetal circulation; correct acidosis*; endotracheal intubation, GI decompression. Additional treatments to reverse pulmonary hypertension may involve administration of inhaled nitric oxide, use of high-frequency oscillation, sildenafil, or ECMO. Administer prophylactic antibiotics. Perform surgical reduction of hernia and repair of defect after respiratory status is stable (corrected acidosis*; pulmonary hypertension). **Nursing:** *Preoperative:* Monitor respiratory status; provide supplemental oxygen; assist with and monitor mechanical ventilation. Monitor cardiovascular status; support with inotropes may be necessary. Reduce stimulation—environmental and nursing care activities (cluster care to prevent constant interruptions). Maintain NG suction, oxygen, and IV fluids. Administer medications: sedation, muscular paralysis, inotropes, sildenafil (to reverse pulmonary hypertension). *Postoperative:* Carry out routine postoperative care and observation for acutely ill infant. Relieve pain and provide comfort. Support family because this is a critical illness.
Hiatal		
Sliding—Protrusion of an abdominal structure (usually stomach) through esophageal hiatus	**Symptoms**—Dysphagia, failure to thrive, vomiting, neck contortions, frequent unexplained respiratory problems, bleeding; usually associated with GER; may cause gastric volvulus and obstruction **Diagnosis**—Made by fluoroscopy	**Therapeutic:** Manage GER symptoms; provide patient positioning, pharmacologic treatment, and dietary management. Surgical treatment is necessary when complications are related to GER despite medical management. **Nursing:** Be alert to significant signs and carry out routine postoperative care.
Abdominal		
Umbilical—Weakness in abdominal wall around umbilicus; incomplete closure of abdominal wall, allowing intestinal contents to protrude through opening	**Symptoms**—Noted by inspection and palpation of the abdomen High incidence in preterm and African-American infants Usually closes spontaneously by 1-2 years of age	**Therapeutic:** No treatment is necessary for small defects. Provide operative repair if persists to ages 4-6 years or if defect is >1.5-2 cm by age 2 years. Strangulation requires immediate attention. **Nursing:** Discourage use of home remedies (e.g., belly bands, coins). Reassure parents.

*Some advocate for permissive hypercapnia and mild acidosis during acute phase of illness.

CDH, Congenital diaphragmatic hernia; *ECMO,* extracorporeal membrane oxygenation; *GER,* gastroesophageal reflux; *GI,* gastrointestinal; *IV,* intravenous; *NG,* nasogastric.

TABLE 41-12 ABDOMINAL WALL DEFECTS

DEFECT	SYMPTOMS	NURSING MANAGEMENT
Omphalocele—Protrusion of intraabdominal viscera into base of umbilical cord; sac covered with peritoneum without skin	Usually obvious on inspection; however, small omphalocele may appear to be a hematoma in umbilical cord Observe for associated malformations	**Therapeutic:** Surgical repair of defect **Nursing:** *Preoperative:* Protect defect from trauma or drying. Keep sac or viscera moist with saline-soaked dressings. Maintain thermoregulation. Carry out routine care of IV fluids and line. Administer prophylactic antibiotics as prescribed. Provide nasogastric suction for gastric decompression. Keep patient NPO. Assess for associated birth defects such as CL or CP. *Postoperative:* Monitor vital signs and BP. Assess for and manage pain Bowel decompression–NG tube IV fluid intake Monitor return of bowel function.
Gastroschisis—Protrusion of intraabdominal contents through defect in abdominal wall lateral to umbilical ring; no peritoneal sac covering the exposed bowel	Defect obvious at delivery if not detected prenatally by ultrasonography	**Therapeutic:** Surgical repair of defect. For large lesions provide gradual reduction of abdominal contents via Siloh pouch before surgical closure. **Nursing:** *Preoperative:* Keep sac covered with a bowel bag to prevent trauma, drying of viscera. NG decompression. Maintain thermoregulation. Administer IV fluids. Administer antibiotics. Observe exposed bowel for signs of necrosis or constriction at exit site. *Postoperative:* Monitor vital signs and BP. Bowel decompression with NG tube. Administer IV fluids. Assess for and manage pain. Monitor surgical closure site for infection. Monitor lower extremities for pulses and circulation (in case of vena cava compression by large bowel in small abdominal cavity). Monitor for return of bowel function and peristalsis. In event of Siloh pouch, nursing care should also include monitoring vital signs, keeping pouch clean, and aseptic technique with dressing changes (if not done by surgeon). Monitor lower extremities for circulation (as noted previously). Provide emotional support for parents. Long-term problems associated with feeding and weight gain for gastroschisis and large omphalocele.

BP, Blood pressure; *CL,* cleft lip; *CP,* cleft palate; *IV,* intravenous; *NG,* nasogastric; *NPO,* nothing by mouth.

infants are prone to metabolic alkalosis from loss of hydrogen ions and to potassium, sodium, and chloride depletion. The skin, mucous membranes, and daily weight are assessed for alterations in hydration status and water gain or loss.

If stomach decompression and gastric lavage are used before surgery, the nurse is responsible for ensuring that the tube is patent and functioning properly and for measuring and recording the type and amount of drainage. Parental involvement is encouraged and promoted.

Postoperative Care. Postoperative vomiting is common, and even with successful surgery most infants exhibit some vomiting during the first 24 to 48 hours. IV fluids are administered until the infant is taking and retaining adequate amounts by mouth. Much of the same care that was instituted before surgery is continued after surgery, including observation of vital signs, monitoring of IV fluids, and careful monitoring of fluid intake and output. In addition, the infant is observed for responses to the stress of surgery and evidence of pain. Appropriate analgesics should be given around the clock

BOX 41-14 CLINICAL MANIFESTATIONS OF MECHANICAL/PARALYTIC INTESTINAL OBSTRUCTION

Colicky abdominal pain—From peristalsis attempting to overcome the obstruction
Abdominal distention—As a result of accumulation of gas and fluid above the level of the obstruction
Vomiting—Often the earliest sign of a high obstruction; a later sign of lower obstruction (may be bilious or feculent)
Constipation and obstipation—Early signs of low obstructions; later signs of higher obstructions
Dehydration—From losses of large quantities of fluid and electrolytes into the intestine
Rigid and boardlike abdomen—From increased distention and infection (peritonitis)
Bowel sounds—Gradually diminish and cease
Respiratory distress—Occurs as the diaphragm is pushed up into the pleural cavity
Shock—Plasma volume diminishes as fluids and electrolytes are lost from the bloodstream into the intestinal lumen (third spacing)
Sepsis—Caused by bacterial proliferation with invasion into the circulation

BOX 41-15 CLINICAL MANIFESTATIONS OF HYPERTROPHIC PYLORIC STENOSIS

- Projectile vomiting
  - May be ejected 3 to 4 feet from the child when in a side-lying position, 1 foot or more when in a back-lying position
  - Occurs shortly after a feeding (may not occur for several hours)
  - May follow each feeding or appear intermittently
  - Nonbilious vomitus; may be blood tinged
- Infant hungry, avid nurser; eagerly accepts a second feeding after vomiting episode
- No evidence of pain or discomfort except that of chronic hunger
- Weight loss
- Signs of dehydration
- Distended upper abdomen
- Readily palpable olive-shaped tumor in the epigastrium just to the right of the umbilicus
- Visible gastric peristaltic waves that move from left to right across the epigastrium

because pain is continuous. The surgical incision(s) is inspected for drainage or erythema, and any signs of infection are reported to the surgeon. A surgical adhesive may be used for incision closure, and parents are instructed regarding the care of the incision and any dressings before discharge. With laparoscopic surgery, the infant may have one to three small incisions.

Feedings are usually instituted soon after surgery, beginning with clear liquids and advancing to formula or breast milk as tolerated. Observation and recording of feedings and the infant's responses to feedings are a vital part of postoperative care. Care of the operative site consists of observation for any drainage or signs of inflammation and care of the incision.

Parents are encouraged to remain with their child and become involved in the child's care. Vomiting of a projectile nature is frightening to parents, and they often believe that they may have done something wrong or that surgery was not successful. Most parents need support and reassurance that the condition is caused by a structural problem and is in no way a reflection on their parenting skills and capacities.

Intussusception

Intussusception is the most common cause of intestinal obstruction in children between the ages of 3 months and 3 years (Pepper, Stanfill, and Pearl, 2012; Waseem and Rosenberg, 2008). Intussusception is more common in boys than in girls. Although specific intestinal lesions occur in a small percentage of the children, generally the cause is not known. More than 90% of intussusceptions do not have a pathologic lead point such as a polyp, lymphoma, or Meckel diverticulum. The idiopathic cases may be caused by hypertrophy of intestinal lymphoid tissue secondary to viral infection

Pathophysiology

Intussusception occurs when a proximal segment of the bowel invaginates into the distal segment, pulling the mesentery with it

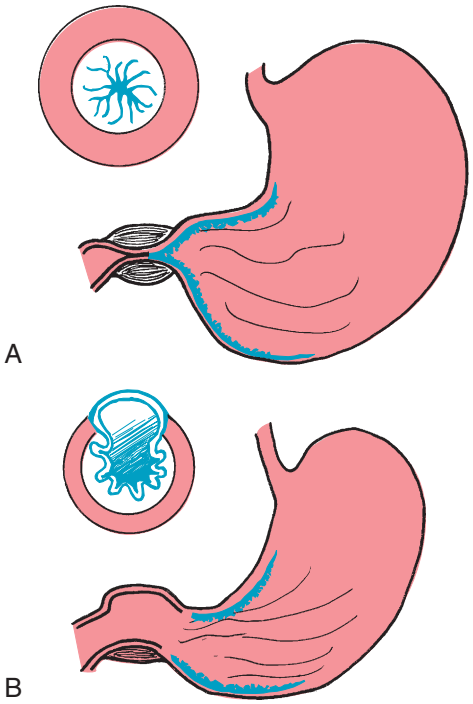

FIG 41-5 Hypertrophic pyloric stenosis. **A,** Enlarged muscular area nearly obliterates pyloric channel. **B,** Longitudinal surgical division of muscle down to submucosa establishes adequate passageway.

(Pepper, Stanfill, and Pearl, 2012). The mesentery is compressed and angled, resulting in lymphatic and venous obstruction. As the edema from the obstruction increases, pressure within the area of intussusception increases. When the pressure equals the arterial pressure, arterial blood flow stops, resulting in ischemia and the pouring of mucus into the intestine. Venous engorgement also leads to leaking of blood and mucus into the intestinal lumen, forming the classic currant jelly–like stools. The most common site is the ileocecal valve (ileocolic), where the ileum invaginates into the cecum and then

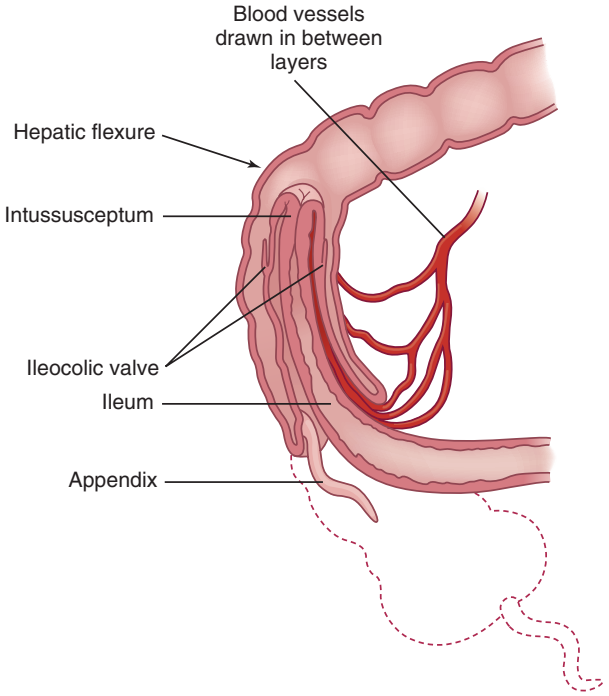

FIG 41-6 Ileocecal intussusception.

further into the colon (Fig. 41-6). Other forms include ileoileal (one part of the ileum invaginates into another section of the ileum) and colocolic (one part of the colon invaginates into another area of the colon) intussusceptions, usually in the area of the hepatic or splenic flexure or at some point along the transverse colon.

! NURSING ALERT

The classic triad of intussusception symptoms (abdominal pain, abdominal mass, bloody stools) is present in fewer than 15% of children (Chu and Liacouras, 2011). Children might also be seen initially with screaming, irritability, lethargy, vomiting, diarrhea or constipation, fever, dehydration, and shock. Because intussusception is potentially life threatening, the nurse should be aware of alternate presentations, observe these children closely, and refer them for further evaluation.

Diagnostic Evaluation

Frequently subjective findings lead to the diagnosis (Box 41-16), which can be confirmed by ultrasonography. Spontaneous reduction occurs in up to 10% of patients.

Therapeutic Management

Conservative treatment consists of radiologist-guided pneumoenema (air enema) with or without water-soluble contrast or ultrasound-guided hydrostatic (saline) enema; the advantage of the latter is that no ionizing radiation is needed (Pepper, Stanfill, and Pearl, 2012). Recurrence of intussusception after conservative treatment is rare. Herwig, Brenkert, and Losek (2009) found that hospitalized children needed minimal interventions after undergoing enema-reduced intussusception.

IV fluids, NG decompression, and antibiotic therapy may be used before hydrostatic reduction is attempted. If these procedures are not successful, the child may require surgical intervention. Surgery involves manually reducing the invagination and, when indicated, resecting any nonviable intestine.

Prognosis. Nonoperative reduction is successful in approximately 80% of cases (Huppertz, Soriano-Gabarro, Grimprel, et al., 2006). Surgery is required for patients in whom the hydrostatic enema is unsuccessful. With early diagnosis and treatment, serious complications and death are uncommon.

BOX 41-16 CLINICAL MANIFESTATIONS OF INTUSSUSCEPTION

- Sudden acute abdominal pain
- Child screaming and drawing the knees toward the chest
- Child appearing comfortable during intervals between episodes of pain
- Vomiting
- Lethargy
- Passage of red, currant jelly–like stools (stool mixed with blood and mucus)
- Tender, distended abdomen
- Palpable sausage-shaped mass in upper right quadrant
- Empty lower right quadrant (Dance sign)
- Eventual fever, prostration, and other signs of peritonitis

CARE MANAGEMENT

The nurse can help establish a diagnosis by listening to the parent's description of the child's physical and behavioral symptoms. It is not unusual for parents to state that they thought something was seriously wrong before others shared their concerns. The description of the child's severe colicky abdominal pain combined with vomiting is a significant sign of intussusception.

As soon as a possible diagnosis of intussusception is made, the nurse prepares the parents for the immediate need for hospitalization, the nonsurgical technique of hydrostatic reduction, and the possibility of surgery. It is important to explain the basic defect of intussusception. A model of the defect is demonstrated easily by pushing the end of a finger on a rubber glove back into itself or using the example of a telescoping rod. The principle of reduction by hydrostatic pressure can be simulated by filling the glove with water, which pushes the "finger" into a fully extended position.

Physical care of the child does not differ from that for any child undergoing abdominal surgery. Even though nonsurgical intervention may be successful, the usual preoperative procedures such as maintenance of NPO status, routine laboratory testing (CBC and urinalysis), signed parental consent, and preanesthetic sedation, are performed. For the child with signs of electrolyte imbalance, hemorrhage, or peritonitis, additional preparation such as replacement fluids, whole blood or plasma, and NG suctioning may be needed. Before surgery the nurse monitors all stools.

! NURSING ALERT

Passage of a normal brown stool usually indicates that the intussusception has reduced itself. This is reported to the practitioner immediately, who may choose to alter the diagnostic and therapeutic care plan.

Postprocedural care includes observations of vital signs, blood pressure, intact sutures and dressing, and the return of bowel sounds. After spontaneous or hydrostatic reduction, the nurse observes for passage of water-soluble contrast material (if used) and

the stool patterns because the intussusception may recur. Children may be admitted to the hospital or monitored on an outpatient basis. A recurrence of intussusception is treated with the conservative reduction techniques described previously, but a laparotomy is considered for multiple recurrences.

Because hospitalization may be the child's first separation from the parents, it is important to preserve the parent-child relationship by encouraging rooming-in or extended visiting. It may be the parents' first experience with hospitalization, necessitating their preparation for procedures such as IV therapy, frequent vital sign and blood pressure monitoring, dressings, and NPO status. More commonly the child may be seen in the emergency department, and treatment initiated there with eventual discharge home in uncomplicated cases (Gilmore, Reed, and Tenenbein, 2011). Because of the rapidity of the onset, diagnosis, and treatment, parents may feel stunned or numb. They may ask few questions; or they may make inquiries constantly, sometimes the same ones several times. Because of the circumstances surrounding this condition, be accepting and understanding of the parents' reactions.

Malrotation and Volvulus

Malrotation of the intestine is caused by the abnormal rotation of the intestine around the superior mesenteric artery during embryologic development. It may manifest in utero or may be asymptomatic throughout life. Infants may have intermittent bilious vomiting, recurrent abdominal pain, distention, or lower GI bleeding. Malrotation is the most serious type of intestinal obstruction because, if the intestine undergoes complete volvulus (the intestine twisting around itself), compromise of the blood supply results in intestinal necrosis, peritonitis, perforation, and death.

Diagnostic Evaluation

It is imperative that malrotation and volvulus be diagnosed promptly and surgical treatment instituted quickly. An upper GI series is the definitive procedure to diagnose this condition.

Therapeutic Management

Surgery is indicated to remove the affected area. Because of the extensive nature of some lesions, short-gut syndrome is a postoperative complication.

CARE MANAGEMENT

Before surgery the nursing care is the same as that provided to an infant or child with intestinal obstruction. After surgery, the nursing care is similar to that provided to the infant or child who has undergone abdominal surgery.

Anorectal Malformations

Anorectal malformations are among the more common congenital malformations caused by abnormal development, with an incidence of approximately one in 5000 births (Levitt and Peña, 2007). These malformations may range from simple imperforate anus to include other associated complex anomalies of genitourinary (GU) and pelvic organs, which may require extensive treatment for fecal, urinary, and sexual function. Anorectal malformations may occur in isolation or as a part of the VACTERL association (see p. 1291). These anomalies are classified according to the newborn's gender and abnormal anatomic features, including GU defects.

The anus and rectum originate from an embryologic structure called the cloaca. Lateral growth of the cloaca forms the urorectal septum that separates the rectum dorsally from the urinary tract ventrally. The rectum and urinary tract separate completely by the seventh week of gestation. Anomalies that occur reflect the stage of development of these processes.

Rectal atresia and stenosis occur when the anal opening appears normal, there is a midline intergluteal groove, and usually no fistula exists between the rectum and urinary tract. *Rectal atresia* is a complete obstruction (inability to pass stool) and requires immediate surgical intervention. *Rectal stenosis* may not become apparent until later in infancy when the infant has a history of difficult stooling, abdominal distention, and ribbonlike stools.

A *persistent cloaca* is a complex anorectal malformation in which the rectum, vagina, and urethra drain into a common channel opening into the perineum (Fig. 41-7, *A*).

Imperforate anus includes several forms of malformation without an obvious opening (see Fig. 41-7, *B*). Frequently a *fistula* (an abnormal communication) leads from the distal rectum to the perineum or GU system (see Fig. 41-7, *A* to *C*). The fistula may be evidenced when meconium is evacuated through the vaginal opening, the perineum below the vagina, the male urethra, or the perineum under the scrotum. The presence of meconium on the perineum does not indicate anal patency. A fistula may not be apparent at birth, but as peristalsis increases, meconium is forced through the fistula into the urethra or onto the newborn's perineum.

Anorectal anomalies are classified according to gender and abnormal anatomic features, including GU and associated pelvic anomalies (Box 41-17). The classification of high, intermediate, and low may also be used; the level of rectal descent is determined by

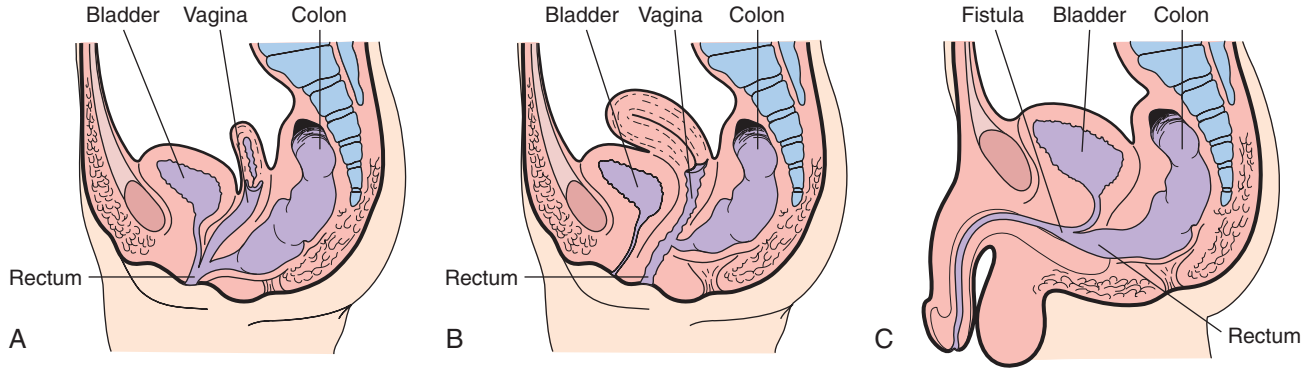

FIG 41-7 Anorectal malformations. **A,** Typical cloaca (female). **B,** Low rectovaginal fistula (female). **C,** Rectourethral bulbar fistula (male).

BOX 41-17 CLASSIFICATION OF ANORECTAL MALFORMATIONS

Male Defects	Female Defects
• Perineal fistula	• Perineal fistula
• Rectourethral bulbar fistula	• Vestibular fistula
• Rectourethral prostatic fistula	• Imperforate anus without fistula
• Rectovesicular (bladder neck) fistula	• Rectal atresia and stenosis
• Imperforate anus without fistula	• Cloaca
• Rectal atresia and stenosis	

From Peña A, Hong A: Advances in the management of anorectal malformations, *Am J Surg* 180(5):370–376, 2000.

the relationship of the termination of the bowel to the puborectalis sling of the levator ani musculature. About 50% of children with anorectal anomalies have a urologic problem.

Diagnostic Evaluation

The diagnosis of an anorectal malformation is based on the physical finding of an absent anal opening. Other symptoms may include abdominal distention, vomiting, absence of meconium passage, or presence of meconium in the urine. Additional physical findings with an anorectal malformation are a flat perineum and the absence of a midline intergluteal groove. The appearance of the perineum alone does not predict the extent of the defect and associated anomalies accurately. GU and spinal-vertebral anomalies associated with anorectal malformations should be considered when an anomaly is noted. EA with or without TEF, cardiac defects, and neural tube defects or vertebral anomalies may occur in association with anorectal malformations; the infant should be carefully evaluated for the presence of these and other anomalies.

A perineal fistula (see Box 41-17) may be diagnosed by clinical observation. The presence of a prominent anal dimple and a band of skin tissue commonly known as a *bucket handle* indicates a perineal fistula (Levitt and Peña, 2007). Abdominal and pelvic ultrasonography is performed to further evaluate the infant's anatomic malformation. An IV pyelogram and a voiding cystourethrogram are performed to evaluate associated anomalies involving the urinary tract. Other diagnostic examinations that may be performed include pelvic magnetic resonance imaging, radiography, ultrasonography, and fluoroscopic examination of pelvic anatomic contents and lower spinal anatomy.

Therapeutic Management

The primary management of anorectal malformations is surgical. After the defect has been identified, take steps to rule out associated life-threatening defects, which need immediate surgical intervention. Provided no immediate life-threatening problems exist, the newborn is stabilized and kept NPO for further evaluation. IV fluids are provided to maintain glucose and fluid and electrolyte balance. The current recommendation is that surgery be delayed at least 24 hours to evaluate for the presence of a fistula and possibly other anomalies properly (Levitt and Peña, 2007).

The surgical treatment of anorectal malformations varies according to the defect but usually involves one or possibly a combination of several of the following procedures: anoplasty, colostomy, *posterior sagittal anorectoplasty (PSARP)* or other pull-through with colostomy, and colostomy (take-down) closure. The Care Management discussion that follows outlines some aspects of preoperative and postoperative care.

A primary laparoscopic repair (without colostomy) of anorectal malformations is being performed successfully in some centers. This minimizes surgical risks, associated morbidity, and postoperative pain management.

CARE MANAGEMENT

The first nursing responsibility is helping to identify anorectal malformations. A newborn who does not pass stool within 24 hours after birth or has meconium that appears at a location other than the anal opening requires further assessment. Preoperative care includes diagnostic evaluation, GI decompression, bowel preparation, and IV fluids.

For the newborn with a perineal fistula an *anoplasty* is performed, which involves moving the fistula opening to the center of the sphincter and enlarging the rectal opening. Postoperative nursing care after anoplasty is primarily directed toward healing the surgical site without other complications. A program of anal dilations is usually initiated when the child returns for the 2-week check-up. Feedings are started soon after surgical repair, and breastfeeding is encouraged because it causes less constipation.

In neonates with anomalies such as cloaca (girls), rectourethral prostatic fistula (boys), and vestibular fistula (girls), a descending colostomy may be performed to allow fecal elimination and avoid fecal contamination of the distal imperforate section and subsequent urinary tract infection in infants with urorectal fistulas. With a colostomy postoperative nursing care is directed toward maintaining appropriate skin care at the stoma sites (both distal and proximal), managing postoperative pain, and administering IV fluids and antibiotics. Postoperative NG decompression may be required with laparotomy, and nursing care focuses on maintenance of appropriate drainage. (See Chapter 39 for colostomy care.)

The PSARP is a common surgical procedure for the repair of anorectal malformations in infants approximately 1 to 2 months after the initial colostomy. Preoperative PSARP care often involves irrigation of the distal stoma to prevent fecal contamination of the operative site. During this time parents must be given accurate yet simple information regarding the infant's appearance after surgery and expectations as to their level of involvement in the child's care.

In the PSARP procedure the repair is made via a posterior midline sacral approach to dissect the different muscle groups involved without damaging strategic innervation of pelvic structures so optimum postoperative bowel continence is achieved. A laparotomy may be required if the rectum is unidentifiable by the posterior approach. Laparoscopic-assisted PSARP has been described for recto–bladder neck fistula and high prostatic fistula (Bischoff, Peña, and Levitt, 2013). Additional management after successful repair involves a program of anal dilations, colostomy closure, and a bowel management program.

Parents are instructed in perineal and wound care or care of the colostomy as needed. Anal dilations may be necessary for some infants. Parents should observe stooling patterns and for signs of anal stricture or complications. Information about dietary modifications and administration of medications is included in counseling. Nurses have a vital role in helping families of a child with anorectal malformations provide optimum care so bowel management is successful and quality of life enhanced for the child and family.

Family Support, Discharge Planning, and Home Care. Long-term follow-up is important for children with complex malformations. After the definitive pull-through procedure, toilet training is delayed, and complete continence is seldom achieved at the usual age of 2 to 3 years. Prevention of constipation is important, and breastfeeding is encouraged after surgery. If a cow's milk–based formula is used, a mild laxative may be prescribed. Bowel habit training, diet modification, and administration of stool softeners or fiber are important aspects of bowel management. Optimum bowel function may not be achieved until late childhood or adolescence. Support and reassurance are important during the slow progression to normal function.

Parents are instructed in perineal and wound care or care of the colostomy. Anal dilations may be necessary for some infants. Parents are advised to observe stooling patterns and notify the health care provider if there are any signs of anal stricture or complications.

MALABSORPTION SYNDROMES

Chronic diarrhea and malabsorption of nutrients characterize malabsorption syndromes. An important complication of malabsorption syndromes in children is growth failure. Most cases are classified according to the location of the supposed anatomic or biochemical defect. The term celiac disease is often used to describe a symptom complex with four characteristics: (1) steatorrhea (fatty, foul, frothy, bulky stools), (2) general malnutrition, (3) abdominal distention, and (4) secondary vitamin deficiencies.

Digestive defects are conditions in which the enzymes necessary for digestion are diminished or absent, such as (1) cystic fibrosis, in which pancreatic enzymes are absent; (2) biliary or liver disease, in which bile flow is affected; or (3) lactase deficiency, in which there is congenital or secondary lactose intolerance.

Absorptive defects are conditions in which the intestinal mucosal transport system is impaired. This may occur because of a primary defect (e.g., celiac disease) or secondary to inflammatory disease of the bowel that results in impaired absorption because bowel motility is accelerated (e.g., UC). Obstructive disorders (e.g., HD) also cause secondary malabsorption from enterocolitis.

Anatomic defects such as extensive resection of the bowel or short-bowel syndrome (SBS) affect digestion by decreasing the transit time of substances and affect absorption by severely compromising the absorptive surface.

Celiac Disease (Gluten-Sensitive Enteropathy)

Celiac disease, also known as *gluten-induced enteropathy, gluten-sensitive enteropathy,* and *celiac sprue,* is a permanent intestinal intolerance to dietary wheat gliadin and related proteins that produces mucosal lesions in genetically susceptible individuals. It is second only to cystic fibrosis as a cause of malabsorption in children.

The incidence varies and has been reported in one in 3000 to one in 4000 people. More recently the incidence has been shown to be closer to one in 266 as a result of improved screening tests (McCabe, Toughill, Parkhill, et al., 2012). The disease is seen more frequently in Europe than in the United States. It is more prevalent in women than men and is rarely reported in Asians or African-Americans. Although the exact cause is unknown, it is now generally accepted that celiac disease is a T-cell–mediated autoimmune and genetic small intestine enteropathy (McCabe, Toughill, Parkhill, et al., 2012). The mucosal lesions contain features that suggest both humoral and cell-mediated immunologic overstimulation.

Infant feeding practices, including breastfeeding for at least 4 months and gradual introduction of gluten in the infant's diet, may play a role in the prevention of celiac disease. Infectious diseases in infancy, specifically rotavirus, have been noted to increase the incidence of this condition (Branski and Troncone, 2011; Ivarsson, Myléus, Norström, et al., 2013).

Pathophysiology

Celiac disease is characterized by villous atrophy in the small bowel in response to the protein gluten. Gluten is found in wheat, barley, rye, and oat grains. When individuals are unable to digest the gliadin component of gluten, an accumulation of a toxic substance that is damaging to the mucosal cells occurs. Damage to the mucosa of the small intestine leads to villous atrophy, hyperplasia of the crypts, and infiltration of the epithelial cells with lymphocytes. Villous atrophy leads to malabsorption caused by the reduced absorptive surface area.

Genetic predisposition is an essential factor in the development of celiac disease. Membrane receptors involved in preferential antigen presentation to $CD4^+$ T-cells play a crucial role in the immune response characteristic of celiac disease. Genes located on the human leukocyte antigen (HLA) region of chromosome 6 (i.e., *HLA-DQ2* or *HLA-DQ8)* are found in almost 100% of those affected with celiac disease (Murdock and Johnston, 2005). When the inflammatory reaction is activated by gluten, $CD4^+$ T-cells produce cytokines, which are likely to contribute to the intestinal damage. The damage consists of infiltration of the lamina propria, crypt hyperplasia, and villous atrophy and flattening. With sufficient villous atrophy, malabsorption occurs.

Classic symptoms of celiac disease are GI manifestations usually noted several months after the introduction of gluten-containing grains into the diet, typically between the ages of 6 months and 2 years (Box 41-18). Typically children are seen with impaired growth, chronic diarrhea, abdominal distention, muscle wasting with hypotonia, poor appetite, and lack of energy. The clinical manifestations are usually insidious and chronic. The first evidence may be growth failure and diarrhea. Less typical presentation has been observed in children ages 5 to 7 years who have abdominal pain; nausea; vomiting; bloating; constipation; or extraintestinal manifestations, including iron deficiency anemia, short stature, pubertal delay, dental enamel defects, alopecia, and abnormal LFT results. Older children have been found to have osteoporosis. Untreated celiac disease can evolve into celiac crisis, characterized by abdominal distention, explosive watery diarrhea, and dehydration with electrolyte imbalance, leading to hypotensive shock and lethargy.

Diagnostic Evaluation

The diagnosis of celiac disease is based on a biopsy of the small intestine demonstrating the characteristic changes of villous atrophy with hyperplasia of the crypts and abnormal surface epithelium while the individual is eating adequate amounts of gluten and a full clinical remission after gluten is withdrawn (Branski and Troncone, 2011). Within 1 or 2 days of instituting the diet, most children with celiac disease demonstrate a favorable response, including weight gain and improved appetite. Within a few weeks there is resolution of the diarrhea and steatorrhea.

Genetic testing for the HLA genes associated with celiac disease may help in ruling out the disease in individuals at high risk for the condition. A negative test indicates the individual does not have the condition; a positive test indicates there is an increased likelihood of having the condition, and antibody screening should be considered (University of Chicago Celiac Disease Center, 2013).

BOX 41-18 CLINICAL MANIFESTATIONS OF CELIAC DISEASE

Classic Celiac Disease
- Diarrhea
- Abdominal distention
- Failure to thrive, or weight loss
- Positive serology, HLA, and villous atrophy

Atypical Celiac Disease
- Iron deficiency anemia
- Osteoporosis
- Short stature
- Arthritis
- Infertility
- Peripheral neuropathy
- Abnormal LFTs, positive serology, HLA, and varying degrees of villous atrophy

Silent Celiac Disease
- Asymptomatic but with positive serology, HLA, and villous atrophy

Latent Celiac Disease
- Variation in expression between atypical and asymptomatic
- Positive or negative serology, HLA, and no villous atrophy

Modified from Scanlon SA, Murray JA: Update on celiac disease—etiology, differential diagnosis, drug tests, and management advances, *Clin Exp Gastroenterol* 4:297–311, 2011.
HLA, Human leukocyte antigen; *LFT,* liver function test.

Commercially available serologic tests for celiac disease include antigliadin antibodies of both the immunoglobulin A and G classes (IgA and IgG); antiendomysium IgA; and antitissue transglutaminase IgA (anti-TTG) and IgG antibodies for screening first-degree relatives of known celiac disease patients and those with known celiac disease–associated disorders such as type 1 diabetes, thyroiditis, arthritis, primary biliary cirrhosis, Down syndrome, Turner syndrome, Williams syndrome, and osteopenia or osteoporosis. False-positive results are likely when only one serologic test is used because patients with these disorders can also test positive for these antibodies. Use of more than one test increases diagnostic accuracy (Gelfond and Fasano, 2006). Ruling out total IgA deficiency is necessary to minimize false-negative results.

Therapeutic Management

Treatment of patients with chronic celiac disease is primarily dietary and consists of strict adherence to a gluten-free diet. Because gluten is found primarily in the grains of wheat and rye but also in smaller quantities in barley and oats, these four foods are eliminated. Corn and rice become substitute grain foods.

Children with untreated celiac disease may have lactose intolerance, especially if their mucosal lesions are extensive. Lactose intolerance usually improves as the mucosa heals with gluten withdrawal. Specific nutritional deficiencies such as iron, folic acid, and fat-soluble vitamin deficiencies are treated with appropriate supplements. Some patients may not respond to the gluten-free diet and exhibit refractory celiac disease; such individuals continue to have diarrhea and malabsorption and may need to rely on PN and immunosuppressants (McCabe, Toughill, Parkhill, et al., 2012).

Prognosis. Celiac disease is regarded as a chronic disease. The most severe symptoms usually occur in early childhood and again in adult life. Strict dietary avoidance of gluten prevents symptoms and may minimize the risk of developing lymphoma, especially of the small intestine, the most serious complication of the disease.

CARE MANAGEMENT

The main nursing consideration is helping the child adhere to the dietary regimen. This requires a wheat-, barley-, and rye-free diet. Oats may be safe for most patients, but contamination with other gluten products may occur in harvesting; therefore caution should be exercised with oats. Children who have silent celiac disease, without clinical manifestations should also adhere to a strict gluten-free diet (Branski and Troncone, 2011). Considerable time is involved in explaining the disease process to the child and parents, the specific role of gluten in aggravating the disorder, and the foods that must be restricted. It is difficult to maintain a diet indefinitely when the child has no symptoms and temporary transgressions result in no difficulties. However, most individuals who relax their diet experience a relapse of their disease and possibly exhibit growth restriction, iron deficiency anemia, or osteomalacia. There is also the risk of developing malignant T-cell lymphoma of the small intestine or other GI malignancies.

Although the chief sources of gluten are cereal and baked goods, grains are frequently added to processed foods as thickeners or fillers. To compound the difficulty, gluten is added to many foods as hydrolyzed vegetable protein, which is derived from cereal grains. The nurse must advise parents of the necessity of reading all label ingredients carefully to avoid hidden sources of gluten.

Many of children's favorite foods contain gluten, including bread, cake, cookies, crackers, donuts, pies, spaghetti, pizza, prepared soups, some processed ice cream, many types of chocolate candy, milk preparations such as malts, hot dogs, luncheon meats, meat gravy, and some prepared hamburgers. Many of these products can be eliminated from an infant's or young child's diet fairly easily, but monitoring the diet of a school-age child or adolescent is more difficult. Luncheon preparation away from home is particularly difficult because bread, luncheon meats, and instant soups are not allowed. For families on restricted food budgets, the diet adds an additional financial burden because many inexpensive and convenient foods cannot be used.

In addition to restricting gluten, other dietary alterations may be necessary. For example, in some children who have more severe mucosal damage, the digestion of disaccharides is impaired, especially in relation to lactose. Therefore these children often need a temporarily lactose-free diet, which necessitates eliminating all milk products. In general dietary management includes a diet high in calories and proteins with simple carbohydrates such as fruits and vegetables but low in fats. Because the bowel is inflamed as a result of the pathologic processes in absorption, the child must avoid high-fiber foods such as nuts, raisins, raw vegetables, and raw fruits with skin until inflammation has subsided.

It is important to stress long-range complications and remind parents of the child's physical status before dietary treatment and the dramatic improvement after treatment. The nurse can be instrumental in allowing the child to express concerns and frustration while focusing on ways in which he or she can still feel normal. Encourage the child and parents to find new recipes using suitable ingredients such as Mexican or Chinese dishes that use corn or rice.

Consult a clinical dietician to provide children and their families with detailed dietary instructions and education.*

Several resources are available to help children and parents in all aspects of coping with celiac disease. The Celiac Sprue Association/United States of America† provides support and guidance to families and supplies educational materials concerning a gluten-free diet, food sources, recipes, and travel information.

Short-Bowel Syndrome

SBS is a malabsorptive disorder that occurs as a result of decreased mucosal surface area, usually because of extensive resection of the small intestine. Malabsorption may be exacerbated by other factors such as bacterial overgrowth and dysmotility. The most common causes of SBS in children are necrotizing enterocolitis, volvulus, jejunal atresias, and gastroschisis. Other causes include midgut volvulus and diffuse small-bowel CD in older children. Less frequent causes include trauma to the GI tract and Hirschprung disease (HD) with extension into the small bowel.

The definition of SBS includes two important findings: (1) decreased intestinal surface area for absorption of fluid, electrolytes, and nutrients; and (2) a need for PN (Goday, 2009). The prognosis for infants with SBS has improved dramatically in the past 20 to 30 years as a result of advances in PN and enteral feeding.

Therapeutic Management

The goals of therapy for infants and children with SBS include: (1) preserve as much length of bowel as possible during surgery; (2) maintain optimum nutritional status, growth, and development while intestinal adaptation occurs; (3) stimulate intestinal adaptation with enteral feeding; and (4) minimize complications related to the disease process and therapy (Goday, 2009).

Nutritional support is the long-term focus of care for children with SBS (Sadlier, 2008). The initial phase of therapy includes PN as the primary source of nutrition. The second phase is the introduction of enteral feeding, which usually begins as soon as possible after surgery. Elemental formulas containing glucose, sucrose and glucose polymers, hydrolyzed proteins, and medium-chain triglycerides facilitate absorption. Usually these formulas are given by continuous infusion through an NG or gastrostomy tube. As the enteral feedings are advanced, the PN solution is decreased in terms of calories, amount of fluid, and total hours of infusion per day.

The final phase of nutritional support occurs when growth and development are sustained exclusively by enteral feedings. When PN is discontinued, there is a risk of nutritional deficiency secondary to malabsorption of fat-soluble vitamins (A, D, E, and K) and trace minerals (iron, selenium, and zinc). Obtain serum vitamin and mineral levels and require enteral supplementation of vitamins and minerals. Pharmacologic agents have been used to reduce secretory losses. H_2 blockers, PPIs, and octreotide inhibit gastric or pancreatic secretion. Cholestyramine is often prescribed to improve diarrhea that is associated with bile salt malabsorption. Growth factors have also been used to hasten adaptation and enhance mucosal growth, but these uses are still experimental.

Numerous complications are associated with SBS and long-term PN. Infectious, metabolic, and technical complications can occur. Catheter sepsis can occur after improper care of the catheter. The GI tract can also be a source of microbial seeding of the catheter. Bowel atrophy may foster increased intestinal permeability of bacteria. A lack of adequate sites for central lines may become a significant problem for the child in need of long-term PN. Hepatic dysfunction, hepatomegaly with abnormal LFTs, and cholestasis may also occur (Diamond, Sterescu, Pencharz, et al., 2009).

Bacterial overgrowth is likely to occur when the ileocecal valve is absent or when stasis exists as a result of a partial obstruction or a dilated segment of bowel with poor motility. Alternating cycles of broad-spectrum antibiotics are used to reduce bacterial overgrowth. This treatment may also decrease the risk of bacterial translocation and subsequent central venous catheter infections. Other complications of bacterial overgrowth and malabsorption include metabolic acidosis and gastric hypersecretion.

Many surgical interventions, including intestinal valves, tapering enteroplasty or stricturoplasty, intestinal lengthening, and interposed segments, have been used to slow intestinal transit, reduce bacterial overgrowth, or increase mucosal surface area. Intestinal transplantation has been performed successfully in children. Only children with a permanent dependence on PN or severe complications of long-term PN are candidates for transplantation.

Prognosis. The prognosis for infants with SBS has improved with advances in PN and with the understanding of the importance of intraluminal nutrition. Improved surgical techniques for the management of therapy-related problems and the development of more specific immunosuppressive medications for transplantation have all contributed to improved management. The prognosis depends in part on the length of the residual small intestine. An intact ileocecal valve also improves the prognosis. Infants and children with SBS die from PN-related problems such as fulminant sepsis or severe PN cholestasis.

CARE MANAGEMENT

The most important components of nursing care are administering and monitoring nutritional therapy. During TPN therapy care must be taken to minimize the risk of complications related to the central venous access device (i.e., catheter infections, occlusions, dislodgment, or accidental removal). Care of enteral feeding tubes and monitoring of enteral feeding tolerance are also important nursing responsibilities.

When long-term PN is required, preparing the family for home care is a major nursing responsibility that should be initiated early to prevent a lengthy hospitalization with subsequent problems such as family dysfunction and developmental delays. Many infants and children can be cared for at home successfully with enteral nutrition and PN when the family is prepared and provided with adequate support services. Follow-up by a multidisciplinary nutritional support team is essential. The nurse plays an active and important role in the success of a home nutrition program. Home infusion companies provide portable infusion equipment, which enables the child and family to maintain a more normal lifestyle.

Many infants with SBS have an intestinal ostomy performed at the time of the initial bowel resection. Routine ostomy care is another important nursing responsibility. Because infants and children with SBS have chronic diarrhea, perineal skin irritation is often a problem after ostomy closure. Frequent diaper changes, gentle perineal cleansing, and protective skin barriers help prevent skin breakdown.

*A booklet, *Pointers for Parents: Coping with Celiac Sprue,* provides information on shopping, cooking, and living with an affected child and is available from the Clinical Dietetics Department, Children's Memorial Hospital, 2300 Children's Plaza, Chicago, IL 60614, 773-880-4793.

†PO Box 31700, Omaha, NE 68131-0700, 877-CSA-4CSA or 402-558-0600, www.csaceliacs.org. In Canada: Canadian Celiac Association, 5025 Orbitor Dr., Suite 400, Mississauga, Ontario, Canada L4W 4Y5, 800-363-7296, 905-507-6208, www.celiac.ca.

When hospitalization is prolonged, the child's developmental and emotional needs must be met. This often requires special planning to promote normal family adjustment and adaptation of the hospital routines. Care of hospitalized children is discussed in Chapter 38.

INGESTION OF INJURIOUS AGENTS

Since the passage of the Poison Prevention Packaging Act of 1970, which requires that certain potentially hazardous drugs and household products be sold in child-resistant containers, the incidence of poisonings in children has decreased dramatically. However, despite these advances poisoning remains a significant health concern, with most cases (48.9% in 2009) occurring in children younger than 6 years of age (Bronstein, Spyker, Cantilena, et al., 2012). The home environment lends itself to injury in this vulnerable age-group of children (Dessypris, Dikalioti, Skalkidis, et al., 2009). Although pharmaceuticals such as analgesics, cough and cold preparations, topical preparations, antibiotics, vitamins, GI preparations, hormones, and antihistamines are frequently the agents of poisonings, a variety of other substances can also poison children. According to the 2011 report of the American Association of Poison Control Centers, the highest number of exposure fatalities in children age 5 years or less were attributed to analgesics (21.1%) (Bronstein, Spyker, Cantilena, et al., 2012). The type of analgesic was unspecified, but in past years acetaminophen has been associated with a large number of accidental poisonings in children under 5 years of age and intentional poisoning in adolescents. The most frequently ingested poisons include (Bronstein, Spyker, Cantilena, et al., 2012; Franklin and Rodgers, 2008):*

- Cosmetics and personal care products (perfume, cologne, aftershave)
- Cleaning products (hypochlorite [household] bleach, pine oil disinfectants)
- Plants (nontoxic GI irritants, oxalates)
- Foreign bodies, toys, and miscellaneous substances (desiccants, thermometers, bubble-blowing solutions)

Disk or button battery ingestion has recently emerged as the primary cause of fatal ingestions in children younger than 5 years of age; lithium batteries are reported to cause the most harm (CDC, 2012; Panella, Kirse, Pranikoff, et al., 2013; Sharpe, Rochette, and Smith, 2012). Esophageal perforation and liquefaction necrosis may result in serious harm, and emergent removal is recommended (Ikenberry, Jue, Anderson, et al., 2011).

Children are exposed to toxic substances more frequently than any other age-group (Eldridge, Van Eyk, and Kornegay, 2007). Many poisonings reflect the ready accessibility of the products in the home, where more than 90% of poisonings occur. A significant number of poisonings take place elsewhere such as in a grandparent's or friend's home, school, or health care facility.

The developmental characteristics of young children predispose them to poisoning by ingestion. Infants and toddlers explore their environment through oral experimentation. Because their sense of taste is not discriminating at this age, they ingest many unpalatable substances. In addition, toddlers and preschoolers are developing autonomy and initiative, which increase their curiosity and noncompliant behavior. Imitation is also a powerful motivator, especially when combined with a lack of awareness of danger.

*The most common substances in each category are in parentheses. Substances ingested are not necessarily the most toxic but often are readily available.

EMERGENCY

Poisoning

1. Assess the victim:
   - Initiate cardiorespiratory support if needed (airway, breathing, circulation).
   - Take vital signs; reevaluate routinely.
   - Treat associated complications.
2. Terminate exposure:
   - Empty mouth of pills, plant parts, or other material.
   - Flush eyes continuously with normal saline (or room-temperature tap water at home) for 15 to 20 minutes.
   - Flush skin and wash with soap and a soft cloth; remove contaminated clothes, especially if a pesticide, acid, alkali, or hydrocarbon is involved.
   - Bring victim of an inhalation poisoning into fresh air.
3. Identify the poison:
   - Question the victim and witnesses.
   - Look for environmental clues (empty container, nearby spill, odor on breath) and save all evidence of poison (container, vomitus, urine).
   - In absence of other evidence, be alert to signs and symptoms of potential poisoning in the absence of other evidence, including symptoms of ocular or dermal exposure.
   - Call the *poison control center* or other competent emergency facility for immediate advice regarding treatment.
4. Prevent poison absorption:
   - Place the child in a side-lying, sitting, or kneeling position with the head below the chest to prevent aspiration.
   - Administer activated charcoal if ordered (unless used repeatedly, usual dose is 1 g/kg unless the amount of toxin is known), administer drug antidote, or perform gastric lavage.

This section is concerned primarily with the immediate emergency treatment of ingestion of injurious agents. Box 41-19 summarizes specific management of corrosive, hydrocarbon, acetaminophen, salicylate, iron, and plant poisoning. Because of the importance of lead poisoning among young children, ingestion of lead is discussed separately.

Principles of Emergency Treatment

A poisoning may or may not require emergency intervention, but in every instance medical evaluation is necessary to initiate appropriate action. Advise parents to call the poison control center (PCC) *before* initiating any intervention (after terminating exposure [see Emergency box]). Parents should post the local PCC telephone number (usually listed in the front of the telephone directory) near each phone in the house* (see Emergency box).

NURSING ALERT

The national number for the PCC is 800-222-1222; or online at American Association of Poison Control Centers, www.aapcc.org.

Based on the initial telephone assessment, the PCC counsels the parents to begin treatment at home or to take the child to an emergency facility. When a call is taken, the name and telephone number of the caller are recorded to reestablish contact if the connection is interrupted. Because most poisonings are managed in the home, expert advice is essential to minimize adverse effects. When the exact

*Also available by calling 800-222-1222 or online at American Association of Poison Control Centers, www.aapcc.org.

BOX 41-19 SELECTED ACCIDENTAL POISONINGS IN CHILDREN

Corrosives (Strong Acids or Alkali)

- Drain, toilet, or oven cleaners
- Electric dishwasher detergent (liquid, because of higher pH, is more hazardous than granular)
- Mildew remover
- Batteries (disk or button)—lithium
- Clinitest tablets
- Denture cleaners
- Bleach

Clinical Manifestations

- Severe burning pain in mouth, throat, and stomach
- White, swollen mucous membranes; edema of lips, tongue, and pharynx (respiratory obstruction)
- Violent vomiting (hemoptysis)
- Drooling and inability to clear secretions
- Signs of shock
- Anxiety and agitation

Comments

- Household bleach is a frequently ingested corrosive but rarely causes serious damage.
- Liquid corrosives cause more damage than granular preparations.

Treatment

- Assess child's breathing and level of consciousness.
- Contact poison control center (800-222-1222) for advice.
- Inducing emesis is contraindicated (vomiting redamages the mucosa).
- Dilute corrosive with water or milk (usually no more than 120 mL [4 oz]).
- *Do not neutralize.* Neutralization can cause an exothermic reaction (which produces heat and causes increased symptoms or produces both a thermal and a chemical burn).
- Maintain patent airway as needed.
- Administer analgesics (under medical supervision).
- Do not allow oral intake.
- Esophageal stricture may require repeated dilations or surgery.

Hydrocarbons

- Gasoline
- Kerosene
- Lamp oil
- Mineral seal oil (found in furniture polish)
- Lighter fluid
- Turpentine
- Paint thinner and remover (some types)

Clinical Manifestations

- Gagging, choking, and coughing
- Nausea
- Vomiting
- Alterations in sensorium such as lethargy
- Weakness
- Respiratory symptoms of pulmonary involvement
  - Tachypnea
  - Cyanosis
  - Retractions
  - Grunting

Comments

- Immediate danger is aspiration (even small amounts can cause bronchitis and chemical pneumonia).
- Gasoline, kerosene, lighter fluid, mineral seal oil, and turpentine cause severe pneumonia.

Treatment

- Contact poison control center (800-222-1222).
- Inducing emesis is generally contraindicated.
- Gastric decontamination and emptying are questionable, even when the hydrocarbon contains a heavy metal or pesticide; if gastric lavage must be performed, a cuffed endotracheal tube should be in place before lavage because of a high risk of aspiration.
- Symptomatic treatment of chemical pneumonia includes high humidity, oxygen, hydration, and antibiotics for secondary infection.

Acetaminophen

Clinical Manifestations

Occurs in four stages:

1. Initial period (2 to 4 hours after ingestion)
   - Nausea
   - Vomiting
   - Sweating
   - Pallor
2. Latent period (24 to 36 hours)
   - Patient improves
3. Hepatic involvement (may last up to 7 days and be permanent)
   - Pain in right upper quadrant
   - Jaundice
   - Confusion
   - Stupor
   - Coagulation abnormalities
4. Patients who do not die in hepatic stage gradually recover.

Comments

- It is the most common drug poisoning in children.
- It occurs from acute ingestion.
- Toxic dose is 150 mg/kg or greater in children.
- Because of multiple formulations and concentrations, chronic acetaminophen toxicity is a significant problem.
- Parents should be counseled to read product packaging carefully and consult a health care professional to avoid inappropriate dosing.

Treatment

- Antidote *N*-acetylcysteine (Mucomyst) can usually be given orally but is first diluted in fruit juice or soda because of the antidote's offensive odor.
- It is given as 1 loading dose and usually 17 maintenance doses in different dosages.
- It may be given intravenously, but use is investigational.

Aspirin (Acetylsalicylic Acid [ASA])

Clinical Manifestations

- Acute poisoning
  - Nausea
  - Disorientation
  - Vomiting
  - Dehydration

Continued

BOX 41-19 SELECTED ACCIDENTAL POISONINGS IN CHILDREN—cont'd

- Diaphoresis
- Hyperpnea
- Hyperpyrexia
- Oliguria
- Tinnitus
- Coma
- Convulsions

- Chronic poisoning
  - Same as for acute poisoning but subtle onset (often mistaken for viral illness)
  - Dehydration, coma, and seizures may be more severe
  - Bleeding tendencies

Comments

- It may be caused by acute ingestion (severe toxicity occurs with 300 to 500 mg/kg).
- It may be caused by chronic ingestion (i.e., more than 100 mg/kg/day for 2 or more days) and can be more serious than acute ingestion.
- Time to peak serum salicylate level can vary with enteric aspirin or the presence of concretions (bezoars).

Treatment

- Hospitalization is required for severe toxicity.
- Emesis, lavage, activated charcoal, or cathartic measures may be used.
- Lavage will not remove concretions of ASA.
- Activated charcoal is important early in ASA toxicity.
- Sodium bicarbonate (intravenous) to correct metabolic acidosis and urinary alkalinization may be effective in enhancing elimination; urinary alkalinization is very difficult to achieve.
- Be aware of the risk for fluid overload and pulmonary edema.
- Prescribe:
  - External cooling for hyperpyrexia.
  - Anticonvulsants.
  - Oxygen and ventilation for respiratory depression.
  - Vitamin K for bleeding.
- In severe cases hemodialysis (not peritoneal dialysis) may be used.

Iron

- Mineral supplement or vitamin containing iron

Clinical Manifestations

Occurs in five stages:

1. Initial period (0.5 to 6 hours after ingestion) (if child does not develop gastrointestinal symptoms in 6 hours, toxicity is unlikely)
   - Vomiting
   - Hematemesis
   - Diarrhea
   - Hematochezia (bloody stools)
   - Gastric pain
2. Latency (2 to 12 hours)
   - Patient improves
3. Systemic toxicity (4 to 24 hours after ingestion)
   - Metabolic acidosis
   - Fever
   - Hyperglycemia
   - Bleeding
   - Shock
   - Death (may occur)
4. Hepatic injury (48 to 96 hours)
   - Seizures
   - Coma
5. Rarely pyloric stenosis develops at 2 to 5 weeks

Comments

- Factors related to frequency of iron poisoning:
  - Widespread availability
  - Packaging of large quantities in individual containers
  - Lack of parental awareness of iron toxicity
  - Resemblance of iron tablets to candy (e.g., M&M's)
- Toxic dose is based on the amount of elemental iron in various salts (sulfate, gluconate, fumarate), which ranges from 20% to 33%; ingestions of 60 mg/kg are considered dangerous.

Treatment

- Emesis or lavage may be used.
- For toxic doses lavage may be necessary for all chewable tablets or liquids if spontaneous vomiting has not occurred.
- Chelation therapy with deferoxamine is used in severe intoxication (may turn urine a red to orange color).
- If intravenous deferoxamine is given too rapidly, hypotension, facial flushing, rash, urticaria, tachycardia, and shock may occur; stop the infusion, maintain the intravenous line with normal saline, and notify the practitioner immediately.

Plants

Clinical Manifestations

- Depends on type of plant ingested
- May cause local irritation of oropharynx and entire gastrointestinal tract
- May cause respiratory, renal, and central nervous system symptoms
- Topical contact with plants can cause dermatitis

Comments

- Plants are some of the most frequently ingested substances.
- Plant ingestions rarely cause serious problems, although some can be fatal.
- Plants can also cause choking and allergic reactions.

Treatment

- Induce emesis.
- Wash from skin or eyes.
- Supportive care as needed.

quantity or type of ingested toxin is not known, admission to a health care facility with pediatric emergency treatment services for laboratory evaluation and surveillance during the time after ingestion is critical.

Assessment

The first and most important principle in dealing with a poisoning is to treat the child first, not the poison. This requires an immediate concern for life support. Vital signs are taken, and respiratory or circulatory support is instituted as needed. The child's condition is reevaluated routinely. Because shock is a complication of several types of household poisons, particularly corrosives, measures to reduce the effects of shock are important, beginning with the ABCs (airway, breathing, and circulation). Establishing and maintaining vascular access for rapid intravascular volume expansion is vital in the treatment of pediatric shock.

The emergency department nurse's responsibility is to be prepared for immediate intervention with all of the necessary equipment. Because time and speed are critical factors in recovery from serious poisonings, anticipation of potential problems and complications may mean the difference between life and death.

Gastric Decontamination

Although pediatric poison ingestions are common, they rarely result in significant morbidity or mortality (Albertson, Owen, Sutter, et al., 2011; Bronstein, Spyker, Cantilena, et al., 2012; Greene, Harris, and Singer, 2008). Consider using *GI decontamination (GID)* only after careful evaluation of the potential toxicity of the poison and the risks versus benefits. When GID is needed, the immediate treatment is to remove the ingested poison by adsorbing the toxin with activated charcoal (AC), performing gastric lavage, or increasing bowel motility (catharsis). Because of continuing controversy regarding the use of these methods, treat each toxic ingestion individually (Albertson, Owen, Sutter, et al., 2011; Eldridge, Van Eyk, and Kornegay, 2007; Madden, 2008). Specific antidotes may be administered for certain poisonings.

Syrup of ipecac, an emetic that exerts its action through irritation of the gastric mucosa and by stimulation of the vomiting center, is no longer recommended for routine treatment of poison ingestion (Criddle, 2007; Greene, Harris, and Singer, 2008; McGregor, Parkar, and Rao, 2009; Sheffield and Serwint, 2008).

! NURSING ALERT

Ipecac is not recommended for routine poison treatment intervention in the home because it induces vomiting. Once the ingested poison has been neutralized, the goal of treatment is to hydrate the victim with oral fluids; ipecac prevents adequate intake of oral fluids because of its emetic properties.

Medications such as calcium channel blockers and benzodiazepines either produce a rapid onset of adverse symptoms (e.g., sedation, seizures, coma) or exaggerate the vagal response induced by gagging, which can lead to significant bradycardia. Under either circumstance uncontrolled vomiting becomes an undesirable and unsafe event.

A commonly used method of GID is the use of *activated charcoal* (AC), an odorless, tasteless, fine black powder that adsorbs many compounds, creating a stable complex (Frithsen and Simpson, 2010; Sheffield and Serwint, 2008). AC is mixed with water or a saline cathartic to form slurry. Slurries are neither gritty nor distasteful but resemble black mud. To increase the child's acceptance of AC, the nurse should mix it with diet soda and serve it through a straw in an opaque container with a cover (e.g., a disposable coffee cup and lid) or an ordinary cup covered with aluminum foil or placed inside a small paper bag. For small children an NG tube may be required to administer AC (Greene, Harris, and Singer, 2008). However, recent data indicate that, except in cases of severe poisoning, the use of AC has not significantly improved clinical outcomes (Albertson, Owen, Sutter, et al., 2011). Best results are achieved when AC is administered within 30 to 60 minutes of a poison ingestion.

There is discussion about the use of AC in the home for pediatric poison ingestion. The evidence is not clear regarding the risk versus benefit of home AC administration (Eldridge, Van Eyk, and Kornegay, 2007). Potential complications from the use of AC include aspiration (usually in patients with impaired gag reflexes), constipation, and intestinal obstruction (in multiple doses) (Sheffield and Serwint, 2008). Superactivated charcoal products for gastric decontamination are often more palatable and just as effective (Criddle, 2007).

If the child is admitted to an emergency facility, gastric lavage may be performed to empty the stomach of the toxic agent; however, this procedure can be associated with serious complications (GI perforation, hypoxia, aspiration), and it is no longer recommended in all cases of ingestion. There is no conclusive evidence that gastric lavage decreases morbidity (Criddle, 2007; Greene, Harris, and Singer, 2008; Sheffield and Serwint, 2008). In addition, gastric lavage may be of little benefit if used later than 1 hour after ingestion (Frithsen and Simpson, 2010; Greene, Harris, and Singer, 2008). Conditions that may be appropriate for the use of gastric lavage include presentation within 1 hour of ingestion of a toxin, ingestion in patient who has decreased GI motility, the ingestion of a toxic amount of sustained-release medication, and a massive or life-threatening amount of poison (Criddle, 2007; Madden, 2008). When gastric lavage is used, the patient requires a protected airway, possible sedation, and the largest diameter tube that can be inserted to facilitate passage of gastric contents.

In a minority of poisonings, specific antidotes are available to counteract the poison. They are highly effective and should be available in all emergency facilities. The supply of antidotes should be checked routinely and replaced as used or according to expiration dates. Antidotes available to treat toxin ingestion include *N*-acetylcysteine for acetaminophen poisoning, oxygen for carbon monoxide inhalation, naloxone for opioid overdose, flumazenil (Romazicon) for benzodiazepines (diazepam [Valium], midazolam [Versed]) overdose, digoxin immune Fab (Digibind) for digoxin toxicity, amyl nitrate for cyanide, and antivenin for certain poisonous bites.

Prevention of Recurrence

The ultimate objective is to prevent poisonings from occurring or recurring. Home safety education improves poison prevention practices (Kendrick, Smith, Sutton, et al., 2008). Research supports the effectiveness of parent education on preventing unintentional injuries (Kendrick, Barlow, Hampshire, et al., 2007; Kendrick, Coupland, Mulvaney, et al., 2007). One effective counseling method is first to discuss the difficulties of constantly watching and safeguarding young children (see Family-Centered Care box). In this way the challenging task of raising children can lead to a discussion of injury prevention as part of the parental role. This approach also incorporates contributory causes for the incident such as inadequate support systems; marital discord; discipline techniques (especially use of physical punishment); and any disruption in the family or family activities such as vacations, moves, visitors, illnesses, or births. A visit to the home, especially after repeat poisonings, is recommended as part of the follow-up care to assess hazards, including family factors, and to evaluate appropriate injury-proofing measures. One method of identifying risk areas is to ask specific questions or have the parent complete a questionnaire designed to isolate factors that predispose children to poisoning. Another approach is to encourage parents to bend down to the child's eye level and survey the home environment for potential hazards. Have the parents try to open cabinets and reach shelves to access poisons.

Passive measures (those that do not require active participation) have been the most successful in preventing poisoning and include using child-resistant closures and limiting the number of tablets in one container. However, these measures alone are not sufficient to prevent poisoning because most toxic agents in the home do not have safety closures. Therefore active measures (those that require

FAMILY-CENTERED CARE

Accidental Poisoning

An accidental poisoning is more than a physical emergency for the child; it usually represents an emotional crisis for the parents, particularly in terms of guilt, self-reproach, and insecurity in the parenting role. The emergency department is no place to admonish the family for negligence, lack of appropriate supervision, or failure to injury-proof the home. Rather it is a time to calm and support the child and parents while unaccusingly exploring the circumstances of the injury. If the nurse prematurely attempts to discuss ways of preventing such an incident from recurring, the parents' anxiety will block out any suggestions or offered guidance. Therefore it is preferable for the nurse to delay the discussion until the child's condition is stabilized or, if the child is discharged immediately after emergency treatment, to make a public health referral or send a packet of information.

GUIDELINES

Poison Prevention

- Assess possible contributing factors in occurrence of injury such as discipline, parent-child relationship, developmental ability, environmental factors, and behavior problems.
- Institute anticipatory guidance for possible future injuries based on child's age and maturational level.
- Refer to visiting nurse agency to evaluate home environment and need for injury-proofing measures.
- Provide assistance with environmental manipulation such as lead removal when necessary.
- Educate parents regarding safe storage of toxic substances.
- Advise parents to take drugs out of sight of children.
- Teach children the hazards of ingesting nonfood items.
- Advise parents against using plants for teas or medicine.
- Discuss problems of discipline and children's noncompliance and offer strategies for effective discipline.
- Instruct parents regarding correct administration of drugs for therapeutic purposes and discontinuation of drug if there is evidence of mild toxicity.
- Advise parents to contact the poison control center or practitioner immediately when a poisoning occurs.
- Post number of regional poison control center (800-222-1222) with emergency phone list by telephone.
- Include by the telephone the home address with nearest cross street in case an ambulance is needed. (In an emergency family members may not remember the house address, and baby-sitters may not be aware of the information.)

participation) are essential. The Guidelines box lists the guidelines for preventing the occurrence or recurrence of a poisoning.

Heavy Metal Poisoning

Heavy metal poisoning can occur from the ingestion of a variety of substances, the most common being lead. Other sources that are important in terms of children are iron and mercury. Mercury toxicity, a rare form of heavy metal poisoning, has occurred in children from a variety of sources such as broken thermometers or thermostats, broken fluorescent light bulbs, disk batteries, topical medications, gas regulators, cathartics, and interior latex house paint (Bose-O'Reilly, McCarthy, Steckling, et al., 2010; Clifton, 2007). Elemental mercury (also called *metallic mercury* or *quicksilver)* is nontoxic if ingested and if the GI tract is healthy (e.g., has no fistulas). However, mercury is volatile at room temperature and enters the bloodstream after it is inhaled, causing toxicity (tremors, memory loss, insomnia, gingivitis, diarrhea, anorexia, weight loss). The classic form of mercury poisoning is called **acrodynia** (or "painful extremities").

NURSING ALERT

Mercury thermometers are no longer recommended because if they are broken the inhaled vapors can cause toxicity. To prevent inhalation clean up spilled mercury quickly, using disposable towels and rubber gloves and washing the hands well afterward.

Heavy metals have an affinity for certain essential tissue chemicals, which must remain free for adequate cell functioning. When metals are bound to these substances, cellular enzyme systems are inactivated. Treatment involves *chelation,* use of a chemical compound that combines with the metal for rapid and safe excretion.

Lead Poisoning

Poisoning from lead has been a problem throughout history and throughout the world. In the United States the problem became apparent in the early 1900s when white lead was added to paints and tetraethyl lead was added to gasoline as an antiknock compound. Lead content in paint was decreased in 1950, and in 1978 the use of lead in household paint was banned. The use of lead in paint and leaded gasoline has been banned in the United States. After this change in policy, the average blood lead level (BLL) in the United States for people ages 1 to 74 years dropped from 12.8 mcg/dL in 1980 to 1.9 mcg/dL in 1999 (AAP Committee on Environmental Health, 2005). However, children continue to be exposed to lead; an estimated 1.6% of U.S. children had BLLs of more than 10 mcg/dL in 2002, and almost 14% had BLLs of 5 to 9 mcg/dL (Levin, Brown, Kashtock, et al., 2008). Therefore the CDC recently issued a recommendation that the BLL of 10 mcg no longer be considered a "level of concern" but that a reference value of 97.5 percentile of BLL among children ages 1 to 5 years be used to guide treatment; the 97.5 percentile (based on the most recent NHANES data) currently represents a BLL of 5 mcg/dL, but this would be subject to review within 4 years (CDC Advisory Committee on Childhood Lead Poisoning Prevention, 2012). This recommendation further emphasizes that there is currently no safe level of blood lead at which children may not experience adverse health effects.

Causes of Lead Poisoning

Although there are numerous sources of lead (Box 41-20), in most instances of acute childhood lead poisoning the source is nonintact lead-based paint in an older home or lead-contaminated bare soil in the yard. Microparticles of lead gain entrance into a child's body through ingestion or inhalation and, in the case of an exposed pregnant woman, by placental transfer. When measured, a mother's lead level is nearly the same as that of her unborn child. However, although the level of lead may not be harmful to adult women, it can be harmful to fetuses.

Inhalation exposure usually occurs during renovation and remodeling activities in the home, but ingestion happens during normal day-to-day play and mouthing activities. Sometimes a child actually swallows loose chips of lead-based paint because it has a sweet taste. Water and food may also be contaminated with lead. A

BOX 41-20 SOURCES OF LEAD*

- Lead-based paint in deteriorating condition
- Lead solder
- Lead crystal
- Battery casings
- Lead fishing sinkers
- Lead curtain weights
- Lead bullets
- The following may contain lead:
  - Ceramic ware
  - Water
  - Pottery
  - Pewter
  - Dyes
  - Industrial factories
  - Vinyl miniblinds
  - Playground equipment
  - Collectible toys
  - Artists' paints
  - Pool cue chalk
  - Some imported toys or children's metal jewelry
- Occupations and hobbies involving lead:
  - Battery and aircraft manufacturing
  - Lead smelting
  - Brass foundry work
  - Radiator repair
  - Construction work
  - Bridge repair work
  - Painting contracting
  - Mining
  - Ceramics work
  - Stained-glass making
  - Jewelry making

*The U.S. Consumer Product Safety Commission issues alerts and recalls for products that contain lead and that may unexpectedly pose a hazard to young children.

CULTURAL COMPETENCE

Sources of Lead

In some cultures the use of traditional ethnic remedies that contain lead may increase children's risk of lead poisoning. These remedies include the following:

Azarcon (Mexico)—For digestive problems; a bright orange powder; usual dose is 0.25 to 1 tsp, often mixed with oil, milk, or sugar or sometimes given as a tea; sometimes a pinch is added to a baby bottle or tortilla dough for preventive purposes

Greta (Mexico)—Yellow-orange powder used in the same way as azarcon

Paylooah (Southeast Asia)—Used for rash or fever; an orange-red powder given as 0.5 tsp straight or in a tea

Surma (India)—Black powder applied to the inner lower eyelid that is used as a cosmetic to improve eyesight

Unknown ayurvedic (Tibet)—Small, gray-brown balls used to improve slow development; two balls are given orally 3 times a day

Tamarindo jellied, fruit candy (Mexico)—Fruit candy packaged in paper wrappers that contain high lead levels

Lozeena (Iraq)—Bright orange powder used to color meat and rice

Modified from Centers for Disease Control and Prevention: Lead poisoning associated with use of traditional ethnic remedies—California, 1991-1992, *MMWR Morb Mortal Wkly Rep* 42(27):521–524, 1993; Centers for Disease Control and Prevention: Lead poisoning associated with imported candy and powdered food coloring—California and Michigan, *MMWR Morb Mortal Wkly Rep* 47(48):1041–1043, 1998; Centers for Disease Control and Prevention: Childhood lead poisoning associated with tamarind candy and folk remedies—California, 1992-2000, *MMWR Morb Mortal Wkly Rep* 51(31):684–686, 2002.

child does not need to eat loose paint chips to be exposed to the toxin; normal hand-to-mouth behavior, coupled with the presence of lead dust in the environment that has settled over decades, is the usual method of poisoning (AAP Committee on Environmental Health, 2005; Bose-O'Reilly, McCarthy, Steckling, et al., 2010; Erickson and Thompson, 2005; Frazer, 2008).

Because of family, cultural, or ethnic traditions, a source of lead may be a routine part of life for a child. Nurses must educate themselves about the practices of their patients and identify when such products may be a source of lead. The use of pottery or dishes containing lead may be an issue, as may the use of folk remedies for stomachaches or the use of some cosmetics (see Cultural Competence box). Children of immigrants and internationally adopted children may have been exposed to sources of lead before arrival in the United States and should also be carefully evaluated for lead exposure (Woolf, Goldman, and Bellinger, 2007). Other risk factors for having an elevated BLL include living in poverty, being younger than 6 years of age, dwelling in urban areas, and living in older rental homes where lead decontamination may not be a priority. Nurses are often in a position to observe or elicit information about these practices and educate families about their potential harm.

Pathophysiology and Clinical Manifestations

Lead can affect any part of the body, including the renal, hematologic, and neurologic systems (Fig. 41-8). Of most concern for young children is the developing brain and nervous system, which are more vulnerable than those of older children and adults. Lead in the body moves via an equilibration process between the blood, the soft tissues and organs, and the bones and teeth. It ultimately settles in the bones and teeth, where it remains inert and in storage. This makes up the largest portion of the body burden, approximately 75% to 90%. At the cellular level it competes with molecules of calcium, interfering with the regulating action of calcium. In the brain lead disrupts the biochemical processes and may have a direct effect on the release of neurotransmitters, may cause alterations in the blood-brain barrier, and may interfere with the regulation of synaptic activity (Lidsky and Schneider, 2006).

There is a relationship between anemia and lead poisoning. Children who are iron deficient absorb lead more readily than those with sufficient iron stores. Lead can interfere with the binding of iron onto the heme molecule. This sometimes creates a picture of anemia even though the child is not iron deficient. Lead toxicity to the erythrocytes leads to the release of the enzyme erythrocyte protoporphyrin (EP). Because EP is not sensitive to BLLs of less than approximately 16 to 25 mcg/dL, it is no longer used as a screening test. Therefore the BLL test is currently used for screening and diagnosis. However, elevation of the EP level (>35 mcg/dL of whole blood) is a good indicator of toxicity from lead and reflects the length of exposure and body burden of lead in an individual child.

Although adults have been shown to experience adverse renal effects from occupational lead exposure, few studies document renal effects in children except at extremely high lead levels. One can hypothesize that lead can affect the renal integrity of both children and adults. Therefore the renal system of a child is still considered a potential target for the harmful effects of lead.

The lead levels identified in children have declined since the initiation of screening for children at risk for lead poisoning. With earlier intervention the most prevalent effects have changed. Since the late 1960s children have rarely died of lead poisoning, and seizures or cognitive impairment have become less likely. However, even mild and moderate lead poisoning can cause a number of cognitive and behavioral problems in young children, including aggression, hyperactivity, impulsivity, delinquency, disinterest, and

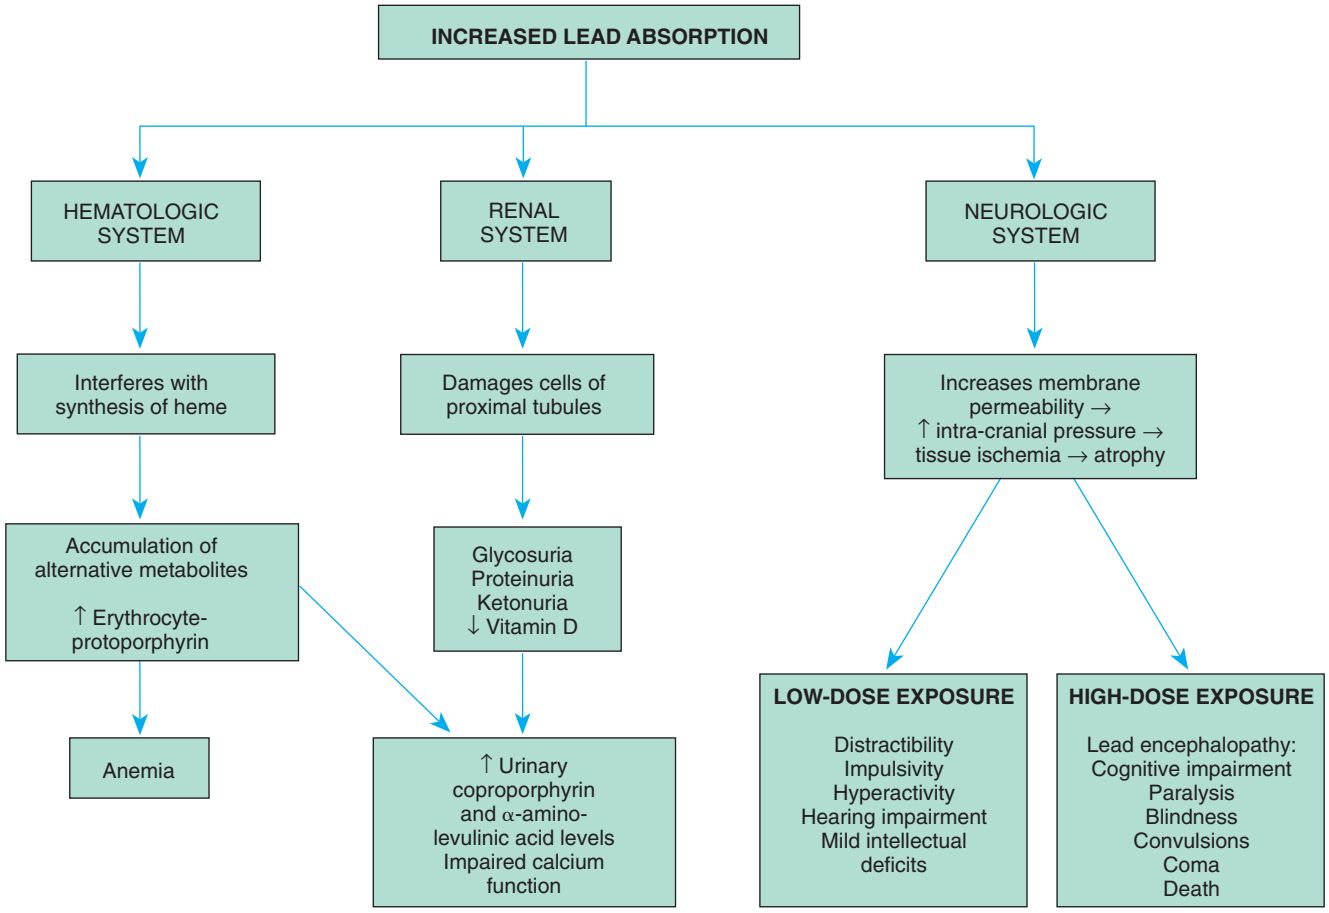

FIG 41-8 Main effects of lead on body systems.

withdrawal. Long-term neurocognitive signs of lead poisoning include developmental delays, lowered intelligence quotient (IQ), reading skill deficits, visual-spatial problems, visual-motor problems, learning disabilities, and lower academic success. Chronic lead toxicity may also affect physical growth and reproductive efficiency (Woolf, Goldman, and Bellinger, 2007).

! NURSING ALERT

Acute signs of lead poisoning include nausea, vomiting, constipation, anorexia, and abdominal pain. Additional clinical manifestations are hypophosphatemia, glycosuria, and aminoaciduria (Erickson and Thompson, 2005).

Diagnostic Evaluation

Children with lead poisoning rarely have symptoms, even at levels requiring chelation therapy. A diagnosis of lead poisoning is based only on the lead testing of a venous blood specimen from a venipuncture. The collection process is important. Blood must be collected carefully to avoid contamination by lead on the skin. As noted on p. 1308, a BLL of concern is now considered a BLL in the 97.5 percentile, which is currently 5 mcg/dL in children 1 to 5 years of age.

Anticipatory Guidance

Anticipatory guidance lends support to primary prevention efforts. The CDC (2005) recommends that the following information be made available to families beginning during prenatal care, at 3 to 6 months, and at 1 year of age:

- Hazards of lead-based paint in older housing
- Ways to control lead hazards safely
- How to choose safe toys
- Hazards accompanying repainting and renovating homes built before 1978
- Other exposure sources such as traditional remedies that might be relevant for a family

There has been recent concern regarding toys and other imported items with which children play that were found to contain lead. Parents should carefully evaluate the source of the toy (manufacturer) or item with which the child may play and not assume that it is safe because it is sold in a U.S. market. The U.S. Consumer Product Safety Commission (www.cpsc.gov) is an excellent resource for parents and caregivers concerned about the safety of a given toy or product that may be harmful.

Screening for Lead Poisoning

When primary prevention fails, secondary prevention screening efforts for elevated BLLs can identify children much earlier than in the past. Guidelines recommend universal or targeted screening (Levin, Brown, Kashtock, et al., 2008). This need is established using blood lead surveillance and other risk factor data collected over time to establish the status and risk of children throughout the state. In areas without available data, universal screening is recommended.

Universal screening should be done at ages 1 and 2 years. Any child between the ages of 3 and 6 years who has not been screened previously should also be tested. All children with risk factors should be screened more often.

Targeted screening is acceptable when an area has been determined by existing data to have less risk. Children should be screened when they live in a high-risk geographic area or are members of a group determined to be at risk (e.g., Medicaid recipients) or if their family cannot answer "no" to the following personal risk questions:

- Does your child live in or regularly visit a house that was built before 1950?
- Does your child live in or regularly visit a house built before 1978 with recent or ongoing renovations or remodeling within the past 6 months?
- Does your child have a sibling or playmate who has or had lead poisoning?

Therapeutic Management

The degree of concern, urgency, and need for medical intervention change as the lead level increases. Education is one of the most important elements of the treatment process. Several areas that the nurse needs to discuss with the family of every child who has an elevated BLL (≥5 mcg/dL) include (Heavey, 2008; Levin, Brown, Kashtock, et al., 2008):

- The child's BLL and what it means
- Potential adverse health effects of an elevated BLL
- Sources of lead exposure and suggestions on how to reduce exposure such as the importance of wet cleaning to remove lead dust on floors, windowsills, and other surfaces
- Importance of proper nutrition in reducing the absorption and effects of lead; for people with poor nutritional patterns, adequate intake of calcium and iron and importance of regular meals
- Need for follow-up testing to monitor the child's BLL
- Results of an environmental investigation if applicable
- Hazards of improper removal of lead paint (dry sanding, scraping, or open-flame burning)

Treatment actions vary, depending on the child's BLL. Based on a diagnosis from a venous BLL test, the CDC Advisory Committee on Childhood Lead Poisoning Prevention (2012) recommends that a BLL of 45 mcg/dL entails consideration of chelation therapy. Additional guidelines are expected to appear in publication in relation to the new recommendation that children ages 1 to 5 years with BLLs of 5 mcg/dL or more receive education and guidance for decreasing BLLs.

Chelation Therapy. Chelation is the term used for removing lead from circulating blood and theoretically some lead from organs and tissues. It is unclear whether chelation affects lead stores in bones. Although not an antidote in the truest sense, it does serve a similar purpose in that the toxic substance or poison is removed from the body. However, chelation does not counteract any effects of the lead.

Historically, two chelating agents have been used consistently: calcium disodium edetate ($CaNa_2EDTA$, or calcium EDTA) and succimer (Chemet, *meso*-2,3-dimercaptosuccinic acid [DMSA]). British antilewisite (BAL, dimercaprol, dimercaptopropanol) is used in conjunction with EDTA. All of the agents have potential toxic side effects and contraindications. Renal, hepatic, and hematologic parameters should be monitored.

Because of the equilibration process between blood, soft tissues, and other sites in the body, there is often a rebound of the BLL after chelation. After the body burden of lead is reduced enough to stabilize the BLL, rebound ceases. Multiple chelation treatments may be necessary. Adequate hydration is essential during therapy because the chelates are excreted via the kidneys.

BAL must not be used in the presence of a glucose 6-phosphate dehydrogenase deficiency or peanut allergy, nor should it be given in conjunction with iron. It is never used as a single-agent therapy, only in conjunction with EDTA. BAL must be given only at a deep intramuscular site. EDTA should be given intravenously over several hours or may be given intramuscularly when necessary to restrict fluids.

Succimer is given orally over a 19-day course of treatment. The capsule is opened and sprinkled on a small amount of food or may be swallowed whole. Adverse effects include nausea, vomiting, diarrhea, loss of appetite, rash, elevated LFTs, and neutropenia.

An oral chelating agent, D-penicillamine, is sometimes used to treat lead poisoning, but low doses should be used in children. Monitoring renal function and blood counts during administration is essential (Woolf, Goldman, and Bellinger, 2007).

Prognosis. Although most of the pathophysiologic effects of lead are reversible, the most serious consequences of both high and low lead exposure are the effects on the CNS. In children with lead encephalopathy, permanent brain damage can result in cognitive impairment, behavior changes, possible paralysis, and seizures. However, moderate- to low-dose exposure may also cause permanent neurologic deficits. Increased distractibility, short attention span, impulsivity, reading disabilities, and school failure have been associated with lead exposure. Some evidence indicates that treatment of moderate levels of lead poisoning can result in cognitive improvement (AAP Committee on Environmental Health, 2005; CDC Advisory Committee on Childhood Lead Poisoning Prevention, 2007).

CARE MANAGEMENT

The primary nursing goal in lead poisoning is to prevent the child's initial or further exposure to lead. For children with low-level exposure, this requires identifying the sources of lead in the environment. Careful history taking is the most useful and most valuable tool and should concentrate on the personal risk questions listed at left. Suggestions for reducing lead in the child's environment are listed in the Community Focus box.

The nurse prepares children who undergo chelation therapy for the injections and makes all efforts to reduce injection pain. Chelating agents are administered deeply into a large muscle mass. To lessen the pain from EDTA, the local anesthetic procaine is injected with the drug. Rotation of sites is essential to prevent the formation of painful areas of fibrotic tissue. Because EDTA and lead are toxic to the kidneys, keep records of fluid intake and output and assess the results of urinalysis to monitor renal functioning.

! NURSING ALERT

Calcium EDTA is only administered when there is adequate urinary output. Children receiving the drug intramuscularly must be able to maintain adequate oral intake of fluids.

Discharge planning for children with lead poisoning must include thorough education of families regarding safety from lead

COMMUNITY FOCUS

Reducing Blood Lead Levels

- Make sure that child does not have access to peeling paint or chewable surfaces painted with lead-based paint, especially window sills and wells.
- If a house was built before 1960 (possibly before 1980) and has hard-surface floors, wet mop them at least once per week. Wipe other hard surfaces (e.g., window sills, baseboards). If there are loose paint chips in an area such as a window well, use a wet disposable cloth to pick up and discard them. Do not vacuum hard-surfaced floors or windowsills or wells because this spreads dust. Use vacuum cleaners with agitators to remove dust from rugs rather than vacuum cleaners with suction only. If a rug is known to contain lead dust and cannot be washed, it should be discarded.
- Wash and dry child's hands and face frequently, especially before eating.
- Wash toys and pacifiers frequently.
- If soil around home is or is likely to be contaminated with lead (e.g., if home was built before 1960 or is near a major highway), plant grass or other ground cover; plant bushes around outside of house so child cannot play there.
- During remodeling of older homes be sure to follow correct procedures. Be certain that children and pregnant women are not in the home, day or night, until process is completed. After deleading thoroughly clean house using cleaning solution to damp mop and dust before inhabitants return.
- In areas where lead content of water exceeds the drinking water standard and a particular faucet has not been used for 6 hours or more, "flush" the cold-water pipes by running the water until it becomes as cold as it will get (30 seconds to more than 2 minutes). The more time water has been sitting in pipes, the more lead it may contain.*
- *Use only cold water* for consumption (drinking, cooking, and especially for making infant formula).
- Hot water dissolves lead more quickly than cold water and thus contains higher levels of lead. First-flush water may be used for nonconsumption uses.
- Have water tested by a competent laboratory. This action is especially important for apartment dwellers; flushing may not be effective in high-rise buildings or other buildings with lead-soldered central piping.
- Do not store food in open cans, particularly if cans are imported.
- Do not use pottery or ceramic ware that was inadequately fired or is meant for decorative use for food storage or service. Do not store drinks or food in lead crystal.
- Avoid folk remedies or cosmetics that contain lead.
- Make sure that home exposure is not occurring from parental occupations or hobbies. Household members employed in occupations such as lead smelting should shower and change into clean clothing before leaving work. Construction and lead abatement workers may also bring home lead contaminants.
- Make sure that child eats regular meals because more lead is absorbed on an empty stomach.
- Make sure that child's diet contains sufficient iron and calcium and not excessive fat.

*For more information, contact the county or state department of health or environment for information on local water quality. For general information on lead, call the EPA Safe Drinking Water Hotline, 800-426-4791, www.epa.gov; National Lead Information Center, 422 S. Clinton Ave., Rochester, NY 14620, 800-424-LEAD (5323), www.epa.gov/lead/pubs/nlic.htm; Water Quality Association, 630-505-0160, www.wqa.org; or NSF International, 877-867-3435, www.nsf.org.

hazards, clear instructions regarding medication administration and follow-up, and confirmation that the child will be discharged to a home without lead hazards. Although the nurse must use caution to avoid alarming parents unnecessarily, it is important that they know the risk implications for their child's behavior and cognitive functions. Nurses should observe the development and behavior of children who are hospitalized. Thoroughly evaluate any concerns that are identified. Referral to a child development or speech and language specialist may be necessary.

As in any situational crisis, parents need support and understanding if their child is treated for lead poisoning. Many families at the highest risk for lead poisoning have the fewest resources to comply with measures such as relocation or removal of lead from the environment where the child experiences exposure.

KEY POINTS

- Common nutritional disorders of infancy and early childhood may result from vitamin and mineral deficiency or excess, some types of vegetarian diets, PEM, and food intolerance.
- Food consumption varies among vegetarians; therefore a detailed dietary intake is essential for planning adequate intakes, particularly in children and pregnant and lactating women.
- PEM may occur as a complication of underlying disease, lack of parental education about infant nutrition, inappropriate management of food allergy, or incorrect preparation of formula.
- Food intolerance encompasses food allergies and food sensitivities, which can have a number of systemic and local clinical manifestations. CMA and lactose intolerance may occur in some children.
- Infants are subject to fluid depletion because of their greater surface area relative to body mass, high rate of metabolism, and immature kidney function.
- Dehydration can be classified as isotonic, hypotonic, and hypertonic.
- Vomiting and diarrhea account for significant fluid depletion, especially in infants and small children.
- The amount, frequency, and characteristics of stool and vomitus are important nursing observations.
- Diarrhea can be caused by an inflammatory process of infectious origin, a toxic reaction to ingestion of poisonous substances, dietary indiscretions, or infections outside the alimentary tract. The primary treatment of diarrhea is the use of an oral rehydrating solution.
- Structural disorders of the GI tract include CL, CP, EA with TEF, anorectal malformations, and BA.
- CL/P, the most common facial malformation, may involve nutritional, dental, and speech problems.
- Hernias related to the GI tract can be minor (umbilical) or life-threatening (diaphragmatic, gastroschisis, omphalocele).
- HD requires surgical removal of aganglionic segments of bowel.
- Postoperative care of the child with abdominal surgery involves assessing the abdomen and providing hydration and nutrition,

IV fluids, proper positioning, wound care, and psychologic support.
- Nursing care of GER is aimed at identifying children with suggestive symptoms, helping parents with home care feeding and possibly regurgitation, and caring for the child undergoing surgical intervention, if indicated.
- Although the cause of appendicitis is poorly understood, it is typically a result of obstruction of the lumen, usually by a fecalith. Common signs and symptoms are right lower quadrant abdominal pain, tenderness, and fever.
- Meckel diverticulum is a congenital malformation of the GI tract characterized by bloody stools.
- IBD refers to UC and CD.
- Peptic ulcers are poorly understood, but contributing factors include interference with the normal protective mechanisms of the mucosal lining and the presence of *Helicobacter pylori*.
- Viral hepatitis is caused by six types of virus: HAV, HBV, HCV, HDV, HEV, and HGV.
- HAV is spread by the fecal-oral route, whereas HBV and HCV are transmitted primarily by the parenteral route. The most effective measure in prevention and control of hepatitis in any setting is hand washing.
- BA is a serious condition, often causing progressive liver failure, which is an indication for liver transplantation.
- General signs of intestinal obstruction include colicky abdominal pain, nausea and vomiting, abdominal distention, and decreased stool output.
- HPS is recognized by characteristic projectile vomiting, malnutrition, dehydration, and sometimes a palpable mass in the epigastrium and is relieved by pyloromyotomy.
- Intussusception is one of the most common causes of intestinal obstruction during infancy and is characterized by abdominal pain and blood in stools. Treatment is either nonsurgical enema reduction or surgical reduction.
- Malabsorption syndromes are disorders associated with some degree of impaired digestion or absorption. They include digestive, absorptive, and anatomic defects.
- Celiac disease is characterized by an intolerance to gluten. The postulated causes include genetic, environmental, and immune factors that result in significant malabsorption.
- SBS is characterized by a loss of intestine resulting in a diminished ability to absorb a regular diet normally. Specialized enteral and parenteral nutrition is a major element of care for these children.
- Intestinal parasitic diseases constitute the most common infections in the world; giardiasis and enterobiasis are the most widespread parasitic infections among children in the United States.
- Although the incidence of poisoning has decreased in the past 30 years as a result of more stringent packaging regulations, accidental childhood poisoning remains a serious health concern.
- The major principles of treatment for poisoning include assessment and the ABCs (airway, breathing and measures to support circulation); minimization of poison absorption, prevention of complications, family support, and prevention of recurrence.
- Communication with the area PCC is essential in the treatment of any poisoning.
- The most important factor contributing to lead poisoning is its availability in the child's environment. Lead-based paint is the most toxic source of lead.
- Because of increasing awareness of the detrimental effects of low levels of lead on the developing nervous system, acceptable BLLs have been decreasing; but children with cognitive and health effects are still seen. The latest guidelines recommend using a BLL reference value of 97.5 percentile which is roughly 5 mcg/dL to guide treatment.

CHAPTER

42

Cardiovascular Dysfunction

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Design a plan for assisting children during cardiac diagnostic procedures.
- Demonstrate an understanding of the hemodynamics, distinctive manifestations, and therapeutic management of congenital heart disease.
- Outline a care plan for an infant or child with heart failure.
- Describe the care for a child who has hypoxia.
- Describe the care for an infant or a child with a congenital heart defect and its surgical repair.
- Discuss the nurse's role in helping the child and family cope with congenital heart disease.
- Differentiate between rheumatic fever and rheumatic heart disease.
- List the criteria for selected cholesterol screening of children.
- Discuss the assessment and management of hypertension in children and adolescents.
- Outline a care plan for a child with Kawasaki disease.
- Describe the emergency treatment for shock, including anaphylaxis.

CARDIOVASCULAR DYSFUNCTION

Cardiovascular disorders in children are divided into two major groups—congenital heart disease and acquired heart disorders. **Congenital heart disease (CHD)** includes primarily anatomic abnormalities present at birth that result in abnormal cardiac function. The clinical consequences of congenital heart defects fall into two broad categories—heart failure (HF) and hypoxemia. Acquired cardiac disorders are disease processes or abnormalities that occur after birth and can be seen in the normal heart or in the presence of congenital heart defects. They result from various factors, including infection, autoimmune responses, environmental factors, and familial tendencies. The pathophysiology review found in Fig. 42-1 describes the flow of blood through the heart.

History and Physical Examination

Taking an accurate health history is an important first step in assessing an infant or child for possible heart disease. Parents may have specific concerns, such as an infant with poor feeding or fast breathing or a 7-year-old who can no longer keep up with friends on the soccer field. Others may not realize that their child has a medical problem because their baby has always been pale and fussy.

Asking details about the mother's health history, pregnancy, and birth history is important in assessing infants. Mothers with chronic health conditions, such as diabetes or lupus, are more likely to have infants with heart disease. Some medications, such as phenytoin (Dilantin), are teratogenic to fetuses. Maternal alcohol use or illicit drug use increases the risk for congenital heart defects. Exposures to infections, such as rubella, early in pregnancy may result in congenital anomalies. Infants with low birth weight resulting from intrauterine growth restriction are more likely to have congenital anomalies. High-birth-weight infants have an increased incidence of heart disease.

A detailed family history is also important. There is an increased incidence of congenital cardiac defects if either parent or a sibling has a heart defect. Some diseases, such as Marfan syndrome, and some cardiomyopathies are hereditary. A family history of frequent fetal loss, sudden infant death, and sudden death in adults may indicate heart disease. Congenital heart defects are seen in many syndromes such as Down and Turner syndromes.

The physical assessment of suspected cardiac disease begins with observation of general appearance and then proceeds with more specific observations. The following are supplementary to the general assessment techniques described for physical examination of the chest and heart in Chapter 29:

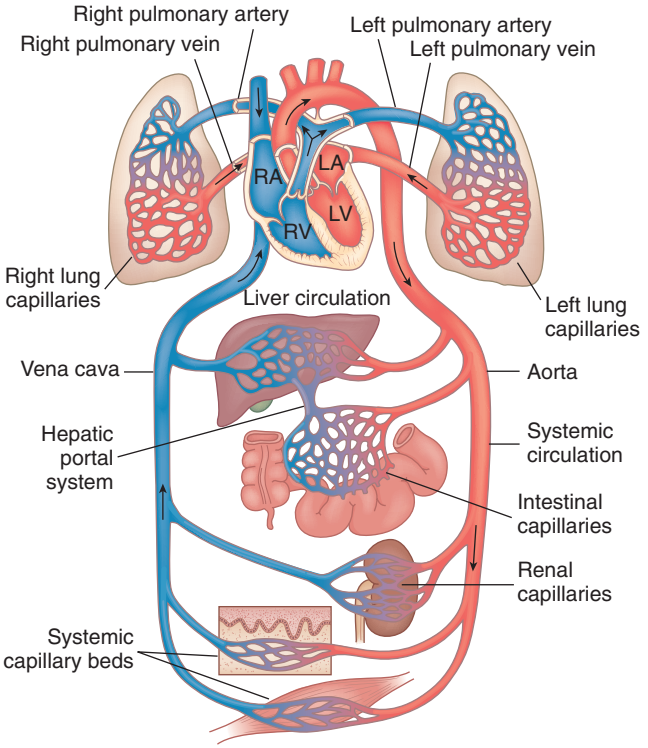

FIG 42-1 Diagram showing serially connected pulmonary and systemic circulatory systems and how to trace the flow of blood. Right heart chambers propel unoxygenated blood through the systemic circulation. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. (From McCance KL, Heuther SE: *Pathophysiology: the biological basis for disease in adults and children,* ed 6, St Louis, 2010, Mosby.)

Inspection

Nutritional state—Failure to thrive or poor weight gain is associated with heart disease.

Color—Cyanosis is a common feature of CHD, and pallor is associated with poor perfusion.

Chest deformities—An enlarged heart sometimes distorts the chest configuration.

Unusual pulsations—Visible pulsations of the neck veins are seen in some patients.

Respiratory excursion—This refers to the ease or difficulty of respiration (e.g., tachypnea, dyspnea, expiratory grunt).

Clubbing of fingers—This is associated with cyanosis.

Palpation and Percussion

Chest—These maneuvers help discern heart size and other characteristics (e.g., thrills) associated with heart disease.

Abdomen—Hepatomegaly or splenomegaly may be evident.

Peripheral pulses—Rate, regularity, and amplitude (strength) may reveal discrepancies.

Auscultation

Heart rate and rhythm—Listen for fast heart rates (tachycardia), slow heart rates (bradycardia), and irregular rhythms.

Character of heart sounds—Listen for distinct or muffled sounds, murmurs, and additional heart sounds.

Diagnostic Evaluation

A variety of invasive and noninvasive tests may be used in the diagnosis of heart disease. Some of the more common diagnostic tools that require nursing assessment and intervention are described here.

Electrocardiogram

Bedside cardiac monitoring with the electrocardiogram (ECG) is commonly used in pediatrics, especially in the care of children with heart disease. The bedside monitor provides valuable information about heart rate and rhythm through a graphic display of the ECG tracing and a digital display. An alarm can be set with parameters for individual patient requirements and will sound if the heart rate is above or below the set parameters. Gelfoam electrodes are commonly placed on the right side of the chest (above the level of the heart) and on the left side of the chest, and a ground electrode is placed on the abdomen. Electrodes should be changed every 1 or 2 days because they irritate the skin. Bedside monitors are an adjunct to patient care and should never be substituted for direct assessment and auscultation of heart sounds. The nurse should assess the patient, not the monitor.

! NURSING ALERT

Electrodes for cardiac monitoring are often color coded: white for right, green (or red) for ground, and black for left. Always check to ensure that these colors are placed correctly.

Echocardiography

Echocardiography is one of the most frequently used tests for detecting cardiac dysfunction in children. Recent improvements in echocardiographic techniques have made it increasingly possible to confirm the diagnosis without resorting to cardiac catheterization. In more and more cases, a prenatal diagnosis of CHD can be made by fetal echocardiography.

Echocardiography involves the use of ultra-high-frequency sound waves to produce an image of the heart's structure. A transducer placed directly on the chest wall delivers repetitive pulses of ultrasound and processes the returned signals (echoes).

Although the test is noninvasive, painless, and associated with no known side effects, it can be stressful for children. The child must lie quietly in the standard echocardiographic positions; crying, nursing, or sitting up often leads to diagnostic errors or omissions. Therefore infants and young children may need a mild sedative; older children benefit from psychologic preparation for the test. The distraction of a video or movie is often helpful.

Cardiac Catheterization

Cardiac catheterization is an invasive diagnostic procedure in which a radiopaque catheter is inserted through a peripheral blood vessel into the heart. The catheter is usually introduced through percutaneous technique, in which the catheter is threaded through a large-bore needle that is inserted into the vein. The catheter is guided through the heart with the aid of fluoroscopy. After the tip of the catheter is within a heart chamber, contrast material is injected and films are taken of the dilution and circulation of the material (angiography). Types of cardiac catheterizations include:

Diagnostic catheterizations—These studies are used to diagnose congenital cardiac defects, particularly in symptomatic infants and before surgical repair. They are divided into (1) right-sided catheterizations, in which the catheter is introduced through a vein (usually the femoral vein) and threaded to the right atrium (most common); and (2) left-sided

catheterizations, in which the catheter is threaded through an artery into the aorta and into the heart.

Interventional catheterizations (therapeutic catheterizations)—A balloon catheter or other device is used to alter the cardiac anatomy. Examples include dilating stenotic valves or vessels or closing abnormal connections.

Electrophysiology studies—Catheters with tiny electrodes that record the impulses of the heart directly from the conduction system are used to evaluate dysrhythmias and sometimes destroy accessory pathways that cause some tachydysrhythmias.

CARE MANAGEMENT

Cardiac catheterization has become a routine diagnostic procedure and may be done on an outpatient basis. However, it is not without risks, especially in neonates and seriously ill infants and children. Possible complications include acute hemorrhage from the entry site (more likely with interventional procedures because larger catheters are used), low-grade fever, nausea, vomiting, loss of pulse in the catheterized extremity (usually transient, resulting from a clot, hematoma, or intimal tear), and transient dysrhythmias (generally catheter induced) (Uzark, 2001). Rare risks include stroke, seizures, tamponade, and death.

Preprocedural Care

A complete nursing assessment is necessary to ensure a safe procedure with minimum complications. This assessment should include accurate height (essential for correct catheter selection) and weight. Obtaining a history of allergic reactions is important because some of the contrast agents are iodine based. Specific attention to signs and symptoms of infection is crucial. Severe diaper rash may be a reason to cancel the procedure if femoral access is required. Because assessment of pedal pulses is important after catheterization, the nurse should assess and mark the pulses (dorsalis pedis, posterior tibial) before the child goes to the catheterization room. The presence and quality of pulses in both feet are clearly documented. Baseline oxygen saturation using pulse oximetry in children with cyanosis is also recorded.

Preparing the child and family for the procedure is the joint responsibility of the patient care team. School-age children and adolescents benefit from a description of the catheterization laboratory and a chronologic explanation of the procedure, emphasizing what they will see, feel, and hear. Older children and adolescents may bring earphones and favorite music so they can listen during the catheterization procedure. Preparation materials such as picture books, videotapes, or tours of the catheterization laboratory may be helpful. Preparation should be geared to the child's developmental level. The child's caregivers often benefit from the same explanations. Additional information, such as the expected length of the catheterization, description of the child's appearance after catheterization, and usual postprocedure care, should be outlined. (See also Prepare the Child and Family for Invasive Procedures, p. 1341.)

Methods of sedation vary among institutions and may include oral or intravenous (IV) medications. The child's age, heart defect, clinical status, and type of catheterization procedure planned are considered when sedation is determined. General anesthesia may be needed for some interventional procedures. Children are allowed nothing by mouth (NPO) for 4 to 6 hours or more before the procedure according to institutional guidelines. Infants and patients with polycythemia may need IV fluids to prevent dehydration and hypoglycemia.

Postprocedural Care

Patients may recover from the procedure in a recovery unit, their hospital room, or, occasionally, an intensive care unit (ICU). Patients are placed on a cardiac monitor and a pulse oximeter for the first few hours of recovery. The most important nursing responsibility is observation of the following for signs of complications:

- **Pulses**, especially below the catheterization site, for equality and symmetry (Pulse distal to the site may be weaker for the first few hours after catheterization but should gradually increase in strength.)
- **Temperature and color of the affected extremity,** because coolness or blanching may indicate arterial obstruction
- **Vital signs**, which are taken as frequently as every 15 minutes, with special emphasis on heart rate, which is counted for 1 full minute for evidence of dysrhythmias or bradycardia
- **Blood pressure (BP)**, especially for hypotension, which may indicate hemorrhage from cardiac perforation or bleeding at the site of initial catheterization
- **Dressing**, for evidence of bleeding or hematoma formation in the femoral or antecubital area
- **Fluid intake**, both IV and oral, to ensure adequate hydration (Blood loss in the catheterization laboratory, the child's NPO status, and diuretic actions of dyes used during the procedure put children at risk for hypovolemia and dehydration.)
- **Blood glucose levels,** for hypoglycemia, especially in infants, who should receive dextrose-containing IV fluids

! NURSING ALERT

If bleeding occurs, direct continuous pressure is applied 2.5 cm (1 inch) above the percutaneous skin site to localize pressure over the vessel puncture.

Depending on hospital policy, the child may be kept in bed with the affected extremity maintained straight for 4 to 6 hours after venous catheterization and 6 to 8 hours after arterial catheterization to facilitate healing of the cannulated vessel. If younger children have difficulty complying, they can be held in the parent's lap with the leg maintained in the correct position. The child's usual diet can be resumed as soon as tolerated, beginning with sips of clear liquids and advancing as the condition allows. The child is encouraged to void to clear the contrast material from the blood. Generally, there is only slight discomfort at the percutaneous site. To prevent infection, the catheterization area is protected from possible contamination. If the child wears diapers, the dressing can be kept dry by covering it with a piece of plastic film and sealing the edges of the film to the skin with tape. However, the nurse must be careful to continue observing the site for any evidence of bleeding (see Family-Centered Care box and Critical Thinking Case Study).

CONGENITAL HEART DISEASE

The incidence of CHD in children is approximately 5 to 8 per 1000 live births (Park, 2008). About 2 or 3 in 1000 infants will be symptomatic during the first year of life with significant heart disease that requires treatment (Hoffman and Kaplan, 2002). CHD is the major cause of death (other than prematurity) in the first year of life. Although there are more than 35 well-recognized cardiac defects, the most common heart anomaly is ventricular septal defect (VSD).

The exact cause of most congenital cardiac defects is unknown. Most are thought to be a result of multiple factors, including a

FAMILY-CENTERED CARE

After Cardiac Catheterization

- Remove pressure dressing the day after catheterization. Cover site with an adhesive bandage strip for several days.
- Keep site clean and dry. Avoid tub baths for several days; patient may shower.
- Observe site for redness, swelling, drainage, and bleeding. Monitor for fever. Notify health care practitioner if these occur.
- Avoid strenuous exercise for several days; patient may attend school.
- Resume regular diet without restrictions.
- Use acetaminophen or ibuprofen for pain.
- Keep follow-up appointments per health care practitioner's instruction.

Adapted from Children's Hospital (Boston) Cardiovascular Program, 1996.

CRITICAL THINKING CASE STUDY

Cardiac Catheterization

Tommy, a 3-year-old boy with tetralogy of Fallot, has just returned to his hospital room from the cardiac catheterization recovery room. His mother calls you to the bedside to tell you that he is vomiting and bleeding. You arrive to find Tommy anxious, pale, crying, and sitting in a puddle of blood.

1. Evidence—Is there sufficient evidence to draw conclusions about Tommy's situation?
2. Assumptions—Describe an underlying assumption about each of the following:
   a. Risks of cardiac catheterization
   b. Association between vomiting and bleeding after cardiac catheterization
   c. Concerns related to acute blood loss
3. What priorities for nursing care should be established for Tommy?
4. Does the evidence support your nursing interventions?

complex interaction of genetic and environmental influences. Some risk factors are known to be associated with increased incidence of congenital heart defects. Maternal risk factors include chronic illnesses such as diabetes or poorly controlled phenylketonuria, alcohol consumption, and exposure to environmental toxins and infections. Family history of a cardiac defect in a parent or sibling increases the likelihood of a cardiac anomaly. The risk for CHD increases if a first-degree relative (parent or sibling) is affected. The familial risk is higher with left-sided obstructive lesions.

Congenital heart anomalies are often associated with chromosomal abnormalities, specific syndromes, or congenital defects in other body systems. Down syndrome (trisomy 21) and trisomies 13 and 18 are highly correlated with congenital heart defects. Syndromes associated with heart defects include DiGeorge syndrome, a syndrome characterized by deletion of part of chromosome 22q11 (interrupted aortic arch, truncus arteriosus, tetralogy of Fallot, and posterior malaligned VSDs), Noonan syndrome (pulmonic valve anomalies and cardiomyopathy), Williams syndrome (aortic and pulmonic stenosis), and Holt-Oram syndrome (upper limb anomalies and atrial septal defect [ASD]). Extracardiac defects such as tracheoesophageal fistula, renal abnormalities, and diaphragmatic hernia are seen in association with heart anomalies.

Altered Hemodynamics

To appreciate the physiology of heart defects, it is necessary to understand the role of pressure gradients, flow, and resistance within the circulation. As blood is pumped through the heart, it (1) flows from an area of high pressure to one of low pressure and (2) takes the path of least resistance. In general, the higher the pressure gradient, the faster the rate of flow; the higher the resistance, the slower the rate of flow.

Normally, the pressure on the right side of the heart is lower than that on the left side and the resistance in the pulmonary circulation is less than that in the systemic circulation. Vessels entering or exiting these chambers have corresponding pressures. Therefore, if an abnormal connection exists between the heart chambers (e.g., a septal defect), blood will necessarily flow from an area of higher pressure (left side) to one of lower pressure (right side). Such a flow of blood is termed a left-to-right shunt. Anomalies resulting in cyanosis may result from a change in pressure so that the blood is shunted from the right to the left side of the heart (right-to-left shunt) because of either increased pulmonary vascular resistance or obstruction to blood flow through the pulmonic valve and artery. Cyanosis may also result from a defect that allows mixing of oxygenated and deoxygenated blood within the heart chambers or great arteries, such as occurs in truncus arteriosus.

Classification of Defects

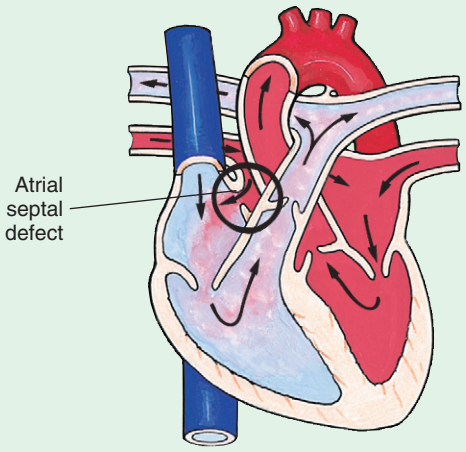
There are typically two classification systems used to categorize congenital heart defects. Traditionally, cyanosis, a physical characteristic, has been used as the distinguishing feature, dividing anomalies into acyanotic defects and cyanotic defects (Fig. 42-2). In clinical practice, this system is problematic because children with acyanotic defects may develop cyanosis. Also, more often, those with cyanotic defects may appear pink and have more clinical signs of HF.

A more useful classification system is based on hemodynamic characteristics (blood flow patterns within the heart). These blood flow patterns are (1) increased pulmonary blood flow; (2) decreased pulmonary blood flow; (3) obstruction to blood flow out of the heart; and (4) mixed blood flow, in which saturated and desaturated blood mix within the heart or great arteries. As a comparison, Fig. 42-3 outlines both classification systems. With the hemodynamic classification system, the clinical manifestations of each group are more uniform and predictable. Defects that allow blood flow from the higher-pressure left side of the heart to the lower-pressure right side (left-to-right shunt) result in increased pulmonary blood flow and cause heart failure (HF). Obstructive defects impede blood flow out of the ventricles; whereas obstruction on the left side of the heart results in HF, severe obstruction on the right side causes cyanosis. Defects that cause decreased pulmonary blood flow result in cyanosis. Mixed lesions present a variable clinical picture based on the degree of mixing and amount of pulmonary blood flow; hypoxemia (with or without cyanosis) and HF usually occur together. Using this classification system, the clinical presentation and management of the most common defects are outlined in the following sections and Box 42-1.

The outcomes of surgical treatment for patients with moderate to severe disease are variable. Patient risk factors for increased morbidity and mortality include prematurity or low birth weight, a genetic syndrome, multiple cardiac defects, a noncardiac congenital anomaly, and age at time of surgery (neonates are a higher risk group). For example, aortic stenosis or coarctation manifesting in the first week of life is more severe and carries a higher mortality than if it becomes apparent at 1 year of age. Outcomes for surgical repair of similar congenital heart defects also vary among treatment centers. In general, the outcomes of surgical procedures have steadily improved in the past decade, with mortality rates for many severe

BOX 42-1 DEFECTS WITH INCREASED PULMONARY BLOOD FLOW

Atrial Septal Defect



Description—Abnormal opening between the atria, allowing blood from the higher-pressure left atrium to flow into the lower-pressure right atrium. There are three types of ASD:

- *Ostium primum (ASD 1)*—Opening at lower end of septum; may be associated with mitral valve abnormalities
- *Ostium secundum (ASD 2)*—Opening near center of septum
- *Sinus venosus defect*—Opening near junction of superior vena cava and right atrium; may be associated with partial anomalous pulmonary venous connection

Pathophysiology—Because left atrial pressure slightly exceeds right atrial pressure, blood flows from the left to the right atrium, causing an increased flow of oxygenated blood into the right side of the heart. Despite the low pressure difference, a high rate of flow can still occur because of low pulmonary vascular resistance and the greater distensibility of the right atrium, which further reduces flow resistance. This volume is well tolerated by the right ventricle because it is delivered under much lower pressure than with a VSD. Although there is right atrial and ventricular enlargement, cardiac failure is unusual in an uncomplicated ASD. Pulmonary vascular changes usually occur only after several decades if the defect is left unrepaired.

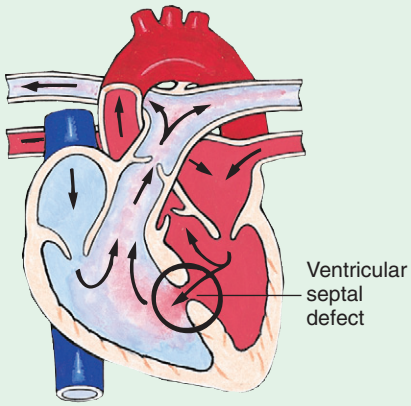
Clinical manifestations—Patients may be asymptomatic. They may develop HF. There is a characteristic systolic murmur with a fixed split second heart sound. There may also be a diastolic murmur. Patients are at risk for atrial dysrhythmias (probably caused by atrial enlargement and stretching of conduction fibers) and pulmonary vascular obstructive disease and emboli formation later in life from chronically increased pulmonary blood flow.

Surgical treatment—Surgical patch closure (pericardial patch or Dacron patch) is done for moderate to large defects. Open repair with cardiopulmonary bypass is usually performed before school age. In addition, the sinus venosus defect requires patch placement, so the anomalous right pulmonary venous return is directed to the left atrium with a baffle. ASD 1 type may require mitral valve repair or, rarely, replacement of the mitral valve.

Nonsurgical treatment—ASD 2 closure with a device during cardiac catheterization is becoming commonplace and can be done as an outpatient procedure. The Amplatzer Septal Occluder is most commonly used. Smaller defects that have a rim around them for attachment of the device can be closed with a device; large, irregular defects without a rim require surgical closure. Successful closure in appropriately selected patients yields results similar to those from surgery but involves shorter hospital stays and fewer complications. Patients receive low-dose aspirin for 6 months (Rome and Kreutzer, 2004).

Prognosis—Operative mortality is very low (<1%).

Ventricular Septal Defect



Description—Abnormal opening between the right and left ventricles. May be classified according to location: membranous (accounting for 80%); or muscular. May vary in size from a small pinhole to absence of the septum, which results in a common ventricle. VSDs are frequently associated with other defects, such as pulmonary stenosis, transposition of the great vessels, PDA, atrial defects, and COA. Many VSDs (20%-60%) close spontaneously. Spontaneous closure is most likely to occur during the first year of life in children having small or moderate defects. A left-to-right shunt is caused by the flow of blood from the higher-pressure left ventricle to the lower-pressure right ventricle.

Pathophysiology—Because of the higher pressure within the left ventricle and because the systemic arterial circulation offers more resistance than the pulmonary circulation, blood flows through the defect into the pulmonary artery. The increased blood volume is pumped into the lungs, which may eventually result in increased pulmonary vascular resistance. Increased pressure in the right ventricle as a result of left-to-right shunting and pulmonary resistance causes the muscle to hypertrophy. If the right ventricle is unable to accommodate the increased workload, the right atrium may also enlarge as it attempts to overcome the resistance offered by incomplete right ventricular emptying.

Clinical manifestations—HF is common. There is a characteristic loud holosystolic murmur heard best at the left sternal border. Patients are at risk for BE and pulmonary vascular obstructive disease.

Surgical Treatment

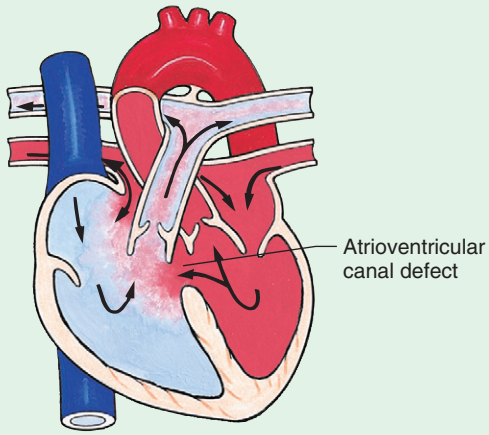
- *Palliative*—Pulmonary artery banding (placement of a band around the main pulmonary artery to decrease pulmonary blood flow) may be done in infants with multiple muscular VSDs or complex anatomy. Improvements in surgical techniques and postoperative care make complete repair in infancy the preferred approach.
- *Complete repair (procedure of choice)*—Small defects are repaired with sutures. Large defects usually require that a knitted Dacron patch be sewn over the opening. CPB is used for both procedures. The approach for the repair is generally through the right atrium and the tricuspid valve. Postoperative complications include residual VSD and conduction disturbances.

Nonsurgical treatment—Device closure during cardiac catheterization is being performed in some centers under investigational protocols. One device has been approved for closure of muscular defects, and another is in clinical trials. Early results are encouraging, with successful defect closure and few complications (Rome and Kreutzer, 2004).

Prognosis—Risks depend on the location of the defect, the number of defects, and the presence of other associated cardiac defects. Single-membranous defects are associated with low mortality (<2%); multiple muscular defects can carry a higher risk (Jacobs, Mavroudis, Jacobs, et al., 2004).

BOX 42-1 DEFECTS WITH INCREASED PULMONARY BLOOD FLOW—cont'd

Atrioventricular Canal Defect



Description—Incomplete fusion of the endocardial cushions. Consists of a low ASD that is continuous with a high VSD and clefts of the mitral and tricuspid valves, which create a large central AV valve that allows blood to flow between all four chambers of the heart. The directions and pathways of flow are determined by pulmonary and systemic resistance, left and right ventricular pressures, and the compliance of each chamber, although flow is generally from left to right. It is the most common cardiac defect in children with Down syndrome.

Pathophysiology—The alterations in hemodynamics depend on the severity of the defect and the child's pulmonary vascular resistance. Immediately after birth, while the newborn's pulmonary vascular resistance is high, there is minimum shunting of blood through the defect. When this resistance falls, left-to-right shunting occurs and pulmonary blood flow increases. The resultant pulmonary vascular engorgement predisposes the child to development of HF.

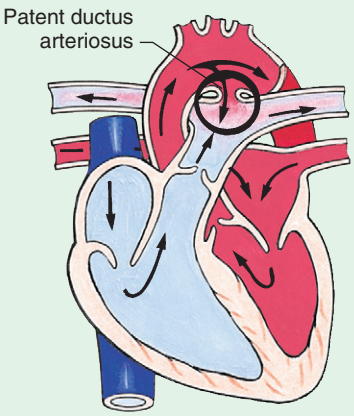
Clinical manifestations—Patients usually have moderate to severe HF. There is a loud systolic murmur. There may be mild cyanosis that increases with crying. Patients are at high risk for developing pulmonary vascular obstructive disease.

Surgical Treatment

- *Palliative*—Pulmonary artery banding is occasionally done in small infants with severe symptoms. Complete repair in infancy is most common.
- *Complete repair*—Surgical repair consists of patch closure of the septal defects and reconstruction of the AV valve tissue (either repair of the mitral valve cleft or fashioning of two AV valves). Postoperative complications include heart block, HF, mitral regurgitation, dysrhythmias, and pulmonary hypertension.

Prognosis—Operative mortality is less than 5% (Jacobs, Mavroudis, Jacobs, et al., 2004). A potential later problem is mitral regurgitation, which may require valve replacement.

Patent Ductus Arteriosus



Description—Failure of the fetal ductus arteriosus (artery connecting the aorta and pulmonary artery) to close within the first weeks of life. The continued patency of this vessel allows blood to flow from the higher-pressure aorta to the lower-pressure pulmonary artery, which causes a left-to-right shunt.

Pathophysiology—The hemodynamic consequences of PDA depend on the size of the ductus and the pulmonary vascular resistance. At birth, the resistance in the pulmonary and systemic circulations is almost identical, so that the resistance in the aorta and pulmonary artery is equalized. As the systemic pressure comes to exceed the pulmonary pressure, blood begins to shunt from the aorta across the duct to the pulmonary artery (left-to-right shunt). The additional blood is recirculated through the lungs and returned to the left atrium and left ventricle. The effects of this altered circulation are increased workload on the left side of the heart, increased pulmonary vascular congestion and possibly resistance, and potentially increased right ventricular pressure and hypertrophy.

Clinical manifestations—Patients may be asymptomatic or show signs of HF. There is a characteristic machinery-like murmur. A widened pulse pressure and bounding pulses result from runoff of blood from the aorta to the pulmonary artery. Patients are at risk for BE and pulmonary vascular obstructive disease in later life from chronic excessive pulmonary blood flow.

Medical management—Administration of indomethacin (a prostaglandin inhibitor) has proved successful in closing a PDA in preterm infants and some newborns.

Surgical treatment—Surgical division or ligation of the patent vessel is performed via a left thoracotomy. In a newer technique, video-assisted thoracoscopic surgery, a thoracoscope and instruments are inserted through three small incisions on the left side of the chest to place a clip on the ductus. The technique is used in some centers and eliminates the need for a thoracotomy, thereby speeding postoperative recovery.

Nonsurgical treatment—Coils to occlude the PDA are placed in the catheterization laboratory in many centers. Preterm or small infants (with small-diameter femoral arteries) and patients with large or unusual PDAs may require surgery.

Prognosis—Both surgical and nonsurgical procedures can be done at low risk with less than 1% mortality. PDA closure in very preterm infants has a higher mortality rate because of the additional significant medical problems.

defects below 10% and a decrease in the incidence of complications and length of hospital stay.

Defects with Increased Pulmonary Blood Flow

In this group of cardiac defects, intracardiac communications along the septum or an abnormal connection between the great arteries allows blood to flow from the higher pressure left side of the heart to the lower pressure right side of the heart. Increased blood volume on the right side of the heart increases pulmonary blood flow at the expense of systemic blood flow. Clinically, patients demonstrate signs and symptoms of HF. ASD, VSD, and patent ductus arteriosus are typical anomalies in this group (see Box 42-1).

Obstructive Defects

Obstructive defects are those in which blood exiting the heart meets an area of anatomic narrowing (stenosis), causing obstruction to blood flow. The pressure in the ventricle and in the great artery before the obstruction is increased, and the pressure in the area beyond the obstruction is decreased. The location of the narrowing is usually near the valve (Fig. 42-4), as follows:

- **Valvular**—At the site of the valve itself
- **Subvalvular**—Narrowing in the ventricle below the valve (also referred to as the ventricular outflow tract)
- **Supravalvular**—Narrowing in the great artery above the valve

Coarctation of the aorta (narrowing of the aortic arch), aortic stenosis, and pulmonic stenosis are typical defects in this group (Box 42-2). Hemodynamically, there is a pressure load on the ventricle and decreased cardiac output. Clinically, infants and children exhibit

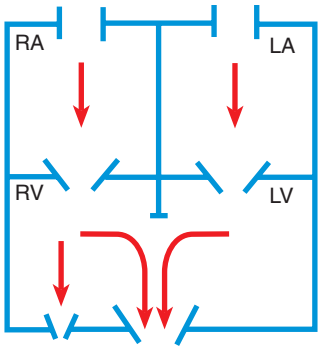

FIG 42-5 Hemodynamic defects with decreased pulmonary blood flow. *LA,* Left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle.

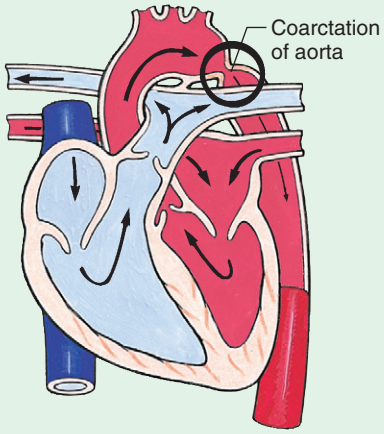
signs of HF. Children with mild obstruction may be asymptomatic. Rarely, as in severe pulmonic stenosis, hypoxemia may be seen.

Defects with Decreased Pulmonary Blood Flow

In this group of defects, there is obstruction of pulmonary blood flow and an anatomic defect (ASD or VSD) between the right and left sides of the heart (Fig. 42-5). Because blood has difficulty exiting the right side of the heart via the pulmonary artery, pressure on the right side increases, exceeding left-sided pressure. This allows

BOX 42-2 OBSTRUCTIVE DEFECTS

Coarctation of the Aorta



Description—Localized narrowing near the insertion of the ductus arteriosus, which results in increased pressure proximal to the defect (head and upper extremities) and decreased pressure distal to the obstruction (body and lower extremities).

Pathophysiology—The effect of a narrowing within the aorta is increased pressure proximal to the defect (upper extremities) and decreased pressure distal to it (lower extremities).

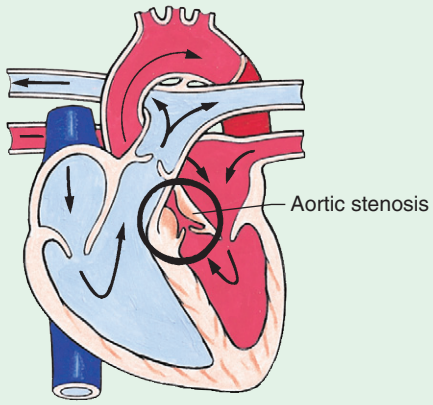
Clinical manifestations—The patient may have high blood pressure and bounding pulses in the arms, weak or absent femoral pulses, and cool lower extremities with lower blood pressure. There are signs of HF in infants. In infants with critical coarctation, the hemodynamic condition may deteriorate rapidly with severe acidosis and hypotension. Mechanical ventilation and inotropic support are often necessary before surgery. Older children may experience dizziness, headaches, fainting, and epistaxis resulting from hypertension. Patients are at risk for hypertension, ruptured aorta, aortic aneurysm, and stroke.

Surgical treatment—Surgical repair is the treatment of choice for infants younger than 6 months and for patients with long-segment stenosis or complex anatomy; it may be performed for all patients with coarctation. Repair is by resection of the coarctated portion with an end-to-end anastomosis of the aorta or enlargement of the constricted section using a graft of prosthetic material or a portion of the left subclavian artery. Because this defect is outside the heart and pericardium, cardiopulmonary bypass is not required and a thoracotomy incision is used. Postoperative hypertension is treated with intravenous sodium nitroprusside, esmolol, or milrinone followed by oral medications, such as ACE inhibitors or beta blockers. Residual permanent hypertension after repair of COA seems to be related to age and time of repair. To prevent both hypertension at rest and exercise-provoked systemic hypertension after repair, elective surgery for COA is advised within the first 2 years of life. There is a 15% to 30% risk for recurrence in patients who underwent surgical repair as infants (Beekman, 2001). Percutaneous balloon angioplasty techniques have proved to be effective in relieving residual postoperative coarctation gradients.

Nonsurgical treatment—Balloon angioplasty is being performed as a primary intervention for COA in older infants and children. In adolescents, stents may be placed in the aorta to maintain patency. Recent studies have demonstrated that balloon angioplasty is effective in children and that aneurysm formation is rare. The high restenosis rate in young infants limits its application in this group (Rome and Kreutzer, 2004).

Prognosis—Mortality is less than 5% in patients with isolated coarctation; the risk is increased in infants with other complex cardiac defects (Jacobs, Mavroudis, Jacobs, et al., 2004).

Aortic Stenosis



Description—Narrowing or stricture of the aortic valve, causing resistance to blood flow in the left ventricle, decreased cardiac output, left ventricular hypertrophy, and pulmonary vascular congestion. The prominent anatomic consequence of AS is the hypertrophy of the left ventricular wall, which eventually leads to increased end-diastolic pressure, resulting in pulmonary venous and pulmonary arterial hypertension. Left ventricular hypertrophy also interferes with coronary artery perfusion and may result in myocardial infarction or scarring of the papillary muscles of the left ventricle, which causes mitral insufficiency. Valvular stenosis, the most common type, is usually caused by malformed cusps that result in a bicuspid rather than tricuspid valve or fusion of the cusps. Subvalvular stenosis is a stricture caused by a fibrous ring below a normal valve; supravalvular stenosis occurs infrequently. Valvular AS is a serious defect for the following reasons: (1) the obstruction tends to be progressive; (2) sudden episodes of myocardial ischemia, or low cardiac output, can result in sudden death; and (3) surgical repair rarely results in a normal valve. This is one of the rare instances in which strenuous physical activity may be curtailed because of the cardiac condition.

Pathophysiology—A stricture in the aortic outflow tract causes resistance to ejection of blood from the left ventricle. The extra workload on the left ventricle causes hypertrophy. If left ventricular failure develops, left atrial pressure will increase; this causes increased pressure in the pulmonary veins, which results in pulmonary vascular congestion (pulmonary edema).

Clinical manifestations—Newborns with critical AS demonstrate signs of decreased cardiac output with faint pulses, hypotension, tachycardia, and poor feeding. Children show signs of exercise intolerance, chest pain, and dizziness when standing for a long period. A systolic ejection murmur may or may not be present. Patients are at risk for BE, coronary insufficiency, and ventricular dysfunction.

Valvular Aortic Stenosis

Surgical treatment—Aortic valvotomy is performed under inflow occlusion. Used rarely because balloon dilation in the catheterization laboratory is the first-line procedure. Newborns with critical AS and small left-sided structures may undergo a stage 1 Norwood procedure (see Hypoplastic Left Heart Syndrome, Box 42-4).

Continued

BOX 42-2 OBSTRUCTIVE DEFECTS—cont'd

Prognosis—Aortic valve replacement offers a good treatment option and may lead to normalization of left ventricular size and function (Arnold, Ley-Zaporozhan, Ley, et al., 2008). Results of aortic valvotomy in older children are very good, with mortality and morbidity close to 0% (Shanmugam, MacArthur, and Pollock, 2005). However, aortic valvotomy remains a palliative procedure and approximately 25% of patients require additional surgery within 10 years for recurrent stenosis. A valve replacement may be required at the second procedure. An aortic homograft with a valve may also be used (extended aortic root replacement), or the pulmonary valve may be moved to the aortic position and replaced with a homograft valve (Ross procedure).

Nonsurgical treatment—The narrowed valve is dilated using balloon angioplasty in the catheterization laboratory. This procedure is usually the first intervention.

Prognosis—Complications include aortic insufficiency or valvular regurgitation, tearing of the valve leaflets, and loss of pulse in the catheterized limb.

Subvalvular Aortic Stenosis

Surgical treatment—Procedure may involve incising a membrane if one exists or cutting the fibromuscular ring. If the obstruction results from narrowing of the left ventricular outflow tract and a small aortic valve annulus, a patch may be required to enlarge the entire left ventricular outflow tract and annulus and replace the aortic valve; this is known as the *Konno procedure.*

Prognosis—Mortality from surgical repairs of subvalvular AS is less than 5% in major centers; however, about 20% of these patients develop recurrent subaortic stenosis and require additional surgery (Freed, 2001).

Pulmonic Stenosis

Description—Narrowing at the entrance to the pulmonary artery. Resistance to blood flow causes right ventricular hypertrophy and decreased pulmonary blood flow. Pulmonary atresia is the extreme form of PS in that there is total fusion of the commissures and no blood flows to the lungs. The right ventricle may be hypoplastic.

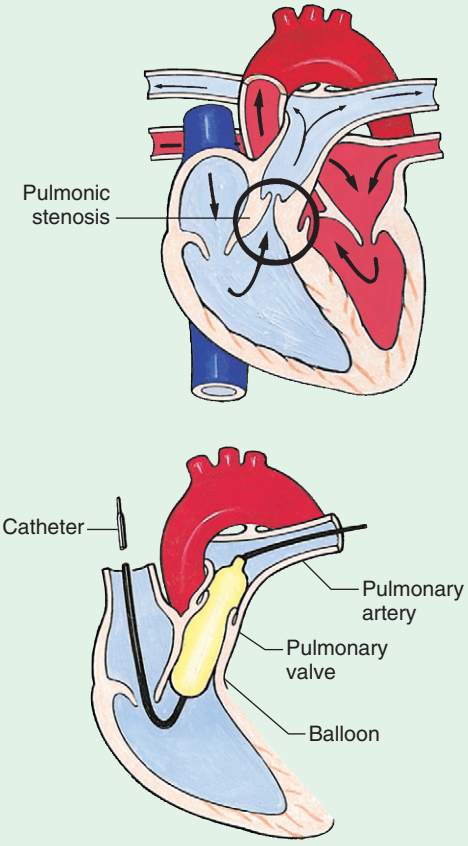
Pathophysiology—When PS is present, resistance to blood flow causes right ventricular hypertrophy. If right ventricular failure develops, right atrial pressure will increase and this may result in reopening of the foramen ovale, shunting of unoxygenated blood into the left atrium, and systemic cyanosis. If PS is severe, HF occurs and systemic venous engorgement will be noted. An associated defect such as a PDA partially compensates for the obstruction by shunting blood from the aorta to the pulmonary artery and into the lungs.

Clinical manifestations—Patients may be asymptomatic; some have mild cyanosis or HF. Progressive narrowing causes increased symptoms. Newborns with severe narrowing are cyanotic. A loud systolic ejection murmur at the upper left sternal border may be present. However, in severely ill patients, the murmur may be much softer because of decreased cardiac output and shunting of blood. Cardiomegaly is evident on chest radiography. Patients are at risk for BE.

Surgical treatment—In infants, transventricular (closed) valvotomy (Brock procedure). In children, pulmonary valvotomy with CPB. Need for surgical treatment is rare with widespread use of balloon angioplasty techniques.

Nonsurgical treatment—Balloon angioplasty in the cardiac catheterization laboratory to dilate the valve. A catheter is inserted across the stenotic pulmonic valve into the pulmonary artery, and a balloon at the end of the catheter is inflated and rapidly passed through the narrowed opening (see figure at right). The procedure is associated with few complications and has proved to be highly effective. It is the treatment of choice for discrete PS in most centers and can be done safely in neonates.

Prognosis—The risk is low for both surgical and nonsurgical procedures; mortality is lower than 1% and slightly higher in neonates (Latson, 2001). Both balloon dilation and surgical valvotomy leave the pulmonic valve incompetent because they involve opening the fused valve leaflets; however, these patients are clinically asymptomatic. Long-term problems with restenosis or valve incompetence may occur.



ACE, Angiotensin-converting enzyme; *AS,* aortic stenosis; *BE,* bacterial endocarditis; *COA,* coarctation of the aorta; *CPB,* cardiopulmonary bypass; *HF,* heart failure; *PDA,* patent ductus arteriosus; *PS,* pulmonic stenosis.

desaturated blood to shunt right to left, causing desaturation in the left side of the heart and in the systemic circulation. Clinically, these patients have hypoxemia and usually appear cyanotic. Tetralogy of Fallot and tricuspid atresia are the most common defects in this group (Box 42-3).

Mixed Defects

Many complex cardiac anomalies are classified together in the **mixed** category (Box 42-4) because survival in the postnatal period depends on mixing of blood from the pulmonary and systemic circulations within the heart chambers. Hemodynamically, fully saturated systemic blood flow mixes with the desaturated pulmonary blood flow, causing a relative desaturation of the systemic blood flow. Pulmonary congestion occurs because the differences in pulmonary artery pressure and aortic pressure favor pulmonary blood flow. Cardiac output decreases because of a volume load on the ventricle. Clinically, these patients have a variable picture that combines some degree of desaturation (although cyanosis is not always visible) and

BOX 42-3 DEFECTS WITH DECREASED PULMONARY BLOOD FLOW

Tetralogy of Fallot

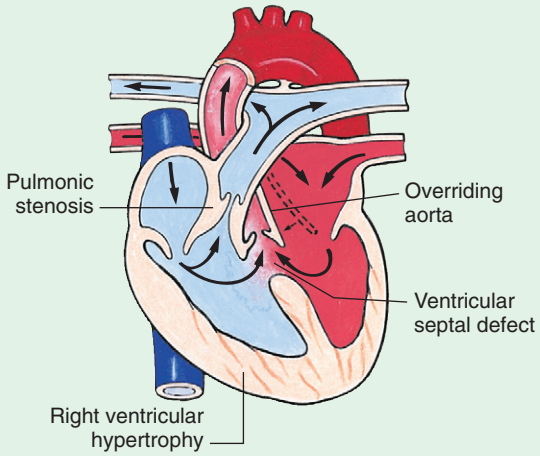
Description—The classic form includes four defects: (1) VSD, (2) PS, (3) overriding aorta, and (4) right ventricular hypertrophy.

Pathophysiology—The alteration in hemodynamics varies widely, depending primarily on the degree of PS but also on the size of the VSD and the pulmonary and systemic resistance to flow. Because the VSD is usually large, pressures may be equal in the right and left ventricles. Therefore the shunt direction depends on the difference between pulmonary and systemic vascular resistance. If pulmonary vascular resistance is higher than systemic resistance, the shunt is from right to left. If systemic resistance is higher than pulmonary resistance, the shunt is from left to right. PS decreases blood flow to the lungs and consequently the amount of oxygenated blood that returns to the left side of the heart. Depending on the position of the aorta, blood from both ventricles may be distributed systemically.

Clinical manifestations—Some infants may be acutely cyanotic at birth; others have mild cyanosis that progresses over the first year of life as the PS worsens. There is a characteristic systolic murmur that is often moderate in intensity. There may be acute episodes of cyanosis and hypoxia, called *blue spells* or *tet spells* (see p. 1337). Anoxic spells occur when the infant's oxygen requirements exceed the blood supply, usually during crying or after feeding. Patients are at risk for emboli, seizures, and loss of consciousness or sudden death after an anoxic spell.

Surgical Treatment

- *Palliative shunt*—In infants who cannot undergo primary repair, a palliative procedure to increase pulmonary blood flow and increase oxygen saturation may be performed. The preferred procedure is a modified Blalock-Taussig shunt operation, which provides blood flow to the pulmonary arteries from the left or right subclavian artery via a tube graft (see Table 42-2). In general, however, shunts are avoided because they may result in pulmonary artery distortion.



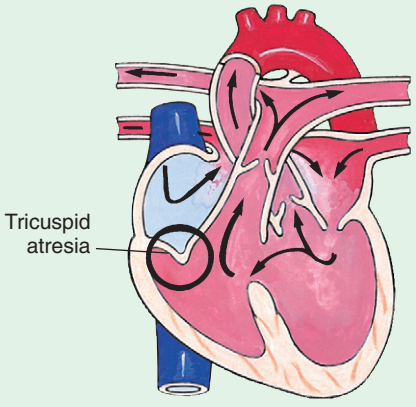
- *Complete repair*—Elective repair is usually performed in the first year of life. Indications for repair include increasing cyanosis and the development of hypercyanotic spells. Complete repair involves closure of the VSD and resection of the infundibular stenosis, with placement of a pericardial patch to enlarge the RVOT. In some repairs, the patch may extend across the pulmonary valve annulus (transannular patch), making the pulmonary valve incompetent. The procedure requires a median sternotomy and the use of cardiopulmonary bypass.

Prognosis—The operative mortality for total correction of tetralogy of Fallot is less than 3% (Jacobs, Mavroudis, Jacobs, et al., 2004). With improved surgical techniques, there is a lower incidence of dysrhythmias and sudden death; surgical heart block is rare. Heart failure may occur postoperatively.

Tricuspid Atresia

Description—The tricuspid valve fails to develop; consequently there is no communication from the right atrium to the right ventricle. Blood flows through an ASD or a patent foramen ovale to the left side of the heart and through a VSD to the right ventricle and out to the lungs. The condition is often associated with PS and TGA. There is complete mixing of unoxygenated and oxygenated blood in the left side of the heart, which results in systemic desaturation, and varying amounts of pulmonary obstruction, which causes decreased pulmonary blood flow.

Pathophysiology—At birth, the presence of a patent foramen ovale (or other atrial septal opening) is required to permit blood flow across the septum into the left atrium; the PDA allows blood flow to the pulmonary artery into the lungs for oxygenation. A VSD allows a modest amount of blood to enter the right ventricle and pulmonary artery for oxygenation. Pulmonary blood flow usually is diminished.



Continued

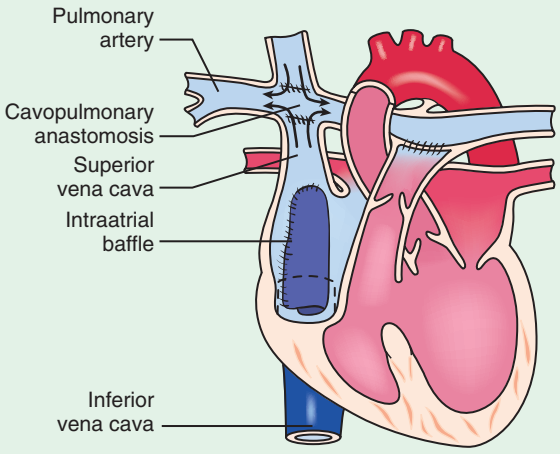
BOX 42-3 DEFECTS WITH DECREASED PULMONARY BLOOD FLOW—cont'd

Clinical manifestations—Cyanosis is usually seen in the newborn period. There may be tachycardia and dyspnea. Older children have signs of chronic hypoxemia with clubbing.

Therapeutic management—For neonates whose pulmonary blood flow depends on the patency of the ductus arteriosus, a continuous infusion of prostaglandin E_1 is started at 0.1 mcg/kg/min until surgical intervention can be arranged.

Surgical treatment—Palliative treatment is the placement of a shunt (pulmonary-to-systemic artery anastomosis) to increase blood flow to the lungs. If the ASD is small, an atrial septostomy is performed during cardiac catheterization. Some children have increased pulmonary blood flow and require pulmonary artery banding to lessen the volume of blood to the lungs. A bidirectional Glenn shunt (cavopulmonary anastomosis) may be performed at 4 to 9 months as a second stage.

- *Modified Fontan procedure*—Systemic venous return is directed to the lungs without a ventricular pump through surgical connections between the right atrium and the pulmonary artery. A fenestration (opening) is sometimes made in the right atrial baffle to relieve pressure. The patient must have normal ventricular function and a low pulmonary vascular resistance for the procedure to be successful. The modified Fontan procedure separates oxygenated and unoxygenated blood inside the heart and eliminates the excess volume load on the ventricle but does not restore normal anatomy or hemodynamics. This operation is also the final stage in the correction of many complex defects with a functional single ventricle, including hypoplastic left heart syndrome.



Prognosis—Surgical mortality is less than 5% (Jacobs, Mavroudis, Jacobs, et al., 2004); the rate increases when the anatomy is more complex and other risk factors are present. Postoperative complications include dysrhythmias, systemic venous hypertension, pleural and pericardial effusions, and ventricular dysfunction. Long-term concerns are the development of protein-losing enteropathy, atrial dysrhythmias, late ventricular dysfunction, and developmental delays.

ASD, Atrial septal defect; *PDA,* patent ductus arteriosus; *PS,* pulmonic stenosis; *RVOT,* right ventricular outflow tract; *TGA,* transposition of the great arteries; *VSD,* ventricular septal defect.

BOX 42-4 MIXED DEFECTS

Transposition of the Great Arteries, or Transposition of the Great Vessels

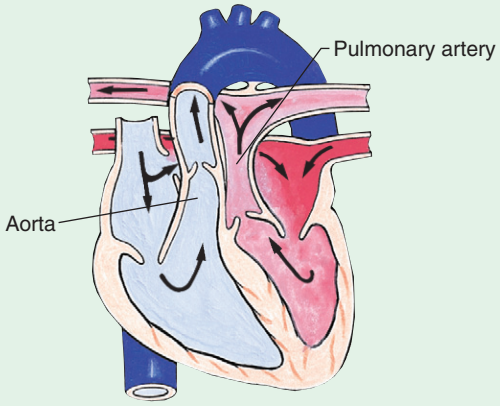
Description—The pulmonary artery leaves the left ventricle, and the aorta exits from the right ventricle with no communication between the systemic and pulmonary circulations.

Pathophysiology—Associated defects such as septal defects or PDA must be present to permit blood to enter the systemic circulation or the pulmonary circulation for mixing of saturated and desaturated blood. The most common defect associated with TGA is a patent foramen ovale. At birth, there is also a PDA, although in most instances, this closes after the neonatal period. Another associated defect may be a VSD. The presence of a VSD increases the risk for HF because it permits blood to flow from the right to the left ventricle, into the pulmonary artery, and finally to the lungs. However, it also produces high pulmonary blood flow under high pressure, which can result in high pulmonary vascular resistance.

Clinical manifestations—Depend on the type and size of the associated defects. Newborns with minimum communication are severely cyanotic and have depressed function at birth. Those with large septal defects or a PDA may be less cyanotic but have symptoms of HF. Heart sounds vary according to the type of defect present. Cardiomegaly is usually evident a few weeks after birth.

Therapeutic management (to provide intracardiac mixing)—The administration of intravenous prostaglandin E_1 may be initiated to keep the ductus arteriosus open to temporarily increase blood mixing and provide an oxygen saturation of 75% or to maintain cardiac output. During cardiac catheterization or under echocardiographic guidance, a balloon atrial septostomy (Rashkind procedure) may also be performed to increase mixing by opening the atrial septum.

Surgical treatment—An arterial switch procedure is the procedure of choice performed in the first weeks of life. It involves transecting the great



arteries and anastomosing the main pulmonary artery to the proximal aorta (just above the aortic valve) and anastomosing the ascending aorta to the proximal pulmonary artery. The coronary arteries are switched from the proximal aorta to the proximal pulmonary artery to create a new aorta. Reimplantation of the coronary arteries is critical to the infant's survival, and they must be reattached without torsion or kinking to provide the heart with its supply of oxygen. The advantage of the arterial switch procedure is the reestablishment of normal circulation, with the left ventricle acting as the systemic pump. Potential complications of the arterial switch include narrowing at the great artery anastomoses and coronary artery insufficiency.

- *Intraatrial baffle repairs*—Intraatrial baffle repairs are rarely performed, although many adolescents and adults survive today with repairs that were done more than 15 years ago. An intraatrial baffle is created to

BOX 42-4 MIXED DEFECTS—cont'd

divert venous blood to the mitral valve and pulmonary venous blood to the tricuspid valve using the patient's atrial septum (Senning procedure) or a prosthetic material (Mustard procedure). A disadvantage is the continuing role of the right ventricle as the systemic pump and the late development of right ventricular failure and rhythm disturbances. Other potential postoperative complications include loss of normal sinus rhythm, baffle leaks, and ventricular dysfunction.

- *Rastelli procedure*—This procedure is the operative choice in infants with TGA, VSD, and severe PS. It involves closure of the VSD with a baffle, so that left ventricular blood is directed through the VSD into the aorta. The pulmonic valve is then closed, and a conduit is placed from the right ventricle to the pulmonary artery to create a physiologically normal circulation. Unfortunately, this procedure requires multiple conduit replacements as the child grows.

Prognosis—Operative mortality is less than 2% (Jacobs, Mavroudis, Jacobs, et al., 2004). Potential long-term problems include suprapulmonic stenosis and neoaortal dilation and regurgitation.

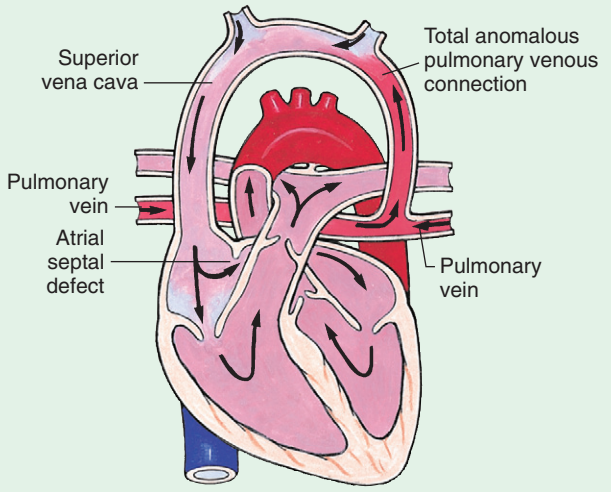
Total Anomalous Pulmonary Venous Connection

Description—Rare defect characterized by failure of the pulmonary veins to join the left atrium. Instead, the pulmonary veins are abnormally connected to the systemic venous circuit via the right atrium or various veins draining toward the right atrium, such as the SVC. The abnormal attachment results in mixed blood being returned to the right atrium and shunted from the right to the left through an ASD. TAPVC (also called *total anomalous pulmonary venous return* or *total anomalous pulmonary venous drainage*) is classified according to the pulmonary venous point of attachment as follows:

- *Supracardiac*—Attachment above the diaphragm, such as to the SVC (most common form)
- *Cardiac*—Direct attachment to the heart, such as to the right atrium or coronary sinus
- *Infradiaphragmatic*—Attachment below the diaphragm, such as to the IVC (most severe form)

Pathophysiology—The right atrium receives all the blood that normally would flow into the left atrium. As a result, whereas the right side of the heart hypertrophies, the left side, especially the left atrium, may remain small. An associated ASD or patent foramen ovale allows systemic venous blood to shunt from the higher-pressure right atrium to the left atrium and into the left side of the heart. As a result, the oxygen saturation of the blood in both sides of the heart (and ultimately in the systemic arterial circulation) is the same. If the pulmonary blood flow is large, pulmonary venous return is also large and the amount of saturated blood is relatively high. However, if there is obstruction to pulmonary venous drainage, pulmonary venous return is impeded, pulmonary venous pressure rises, and pulmonary interstitial edema develops and eventually contributes to HF. Infradiaphragmatic TAPVC is often associated with obstruction to pulmonary venous drainage and is a surgical emergency.

Clinical manifestations—Most infants develop cyanosis early in life. The degree of cyanosis is inversely related to the amount of pulmonary blood flow—the more pulmonary blood, the less cyanosis. Children with unobstructed TAPVC may be asymptomatic until pulmonary vascular resistance decreases during infancy, increasing pulmonary blood flow with resulting signs of HF. Cyanosis becomes worse with pulmonary vein obstruction; when obstruction occurs, the infant's condition usually deteriorates rapidly. Without intervention, cardiac failure will progress to death.



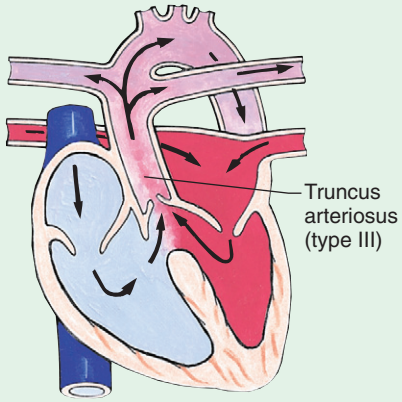
Surgical treatment—Corrective repair is performed in early infancy. The surgical approach varies with the anatomic defect. In general, however, the common pulmonary vein is anastomosed to the back of the left atrium, the ASD is closed, and the anomalous pulmonary venous connection is ligated. The cardiac type is most easily repaired; the infradiaphragmatic type carries the highest morbidity and mortality because of the higher incidence of pulmonary vein obstruction. Potential postoperative complications include reobstruction; bleeding; dysrhythmias, particularly heart block; pulmonary artery hypertension; and persistent heart failure.

Prognosis—Mortality for all types is less than 10% (Jacobs, Mavroudis, Jacobs, et al., 2004) and is lowest for the cardiac type; morbidity increases with the presence of pulmonary vein obstruction.

Truncus Arteriosus

Description—Failure of normal septation and division of the embryonic bulbar trunk into the pulmonary artery and the aorta, which results in development of a single vessel that overrides both ventricles. Blood from both ventricles mixes in the common great artery, which leads to desaturation and hypoxemia. Blood ejected from the heart flows preferentially to the lower-pressure pulmonary arteries, so that pulmonary blood flow is increased and systemic blood flow is reduced. There are three types:

- *Type I*—A single pulmonary trunk arises near the base of the truncus and divides into the left and right pulmonary arteries.
- *Type II*—The left and right pulmonary arteries arise separately but in close proximity and at the same level from the back of the truncus.
- *Type III*—The pulmonary arteries arise independently from the sides of the truncus.



Continued

BOX 42-4 MIXED DEFECTS—cont'd

Pathophysiology—Blood ejected from the left and right ventricles enters the common trunk so that pulmonary and systemic circulations are mixed. Blood flow is distributed to the pulmonary and systemic circulations according to the relative resistances of each system. The amount of pulmonary blood flow depends on the size of the pulmonary arteries and the pulmonary vascular resistance. Generally, resistance to pulmonary blood flow is less than systemic vascular resistance, which results in preferential blood flow to the lungs. Pulmonary vascular disease develops at an early age in patients with truncus arteriosus.

Clinical manifestations—Most infants are symptomatic with moderate to severe HF and variable cyanosis, poor growth, and activity intolerance. There is a holosystolic murmur at the left sternal murmur with a diastolic murmur present if truncal regurgitation is present. Thirty-five percent of patients have 22q11 deletions (Goldmuntz, Clark, Mitchell, et al., 1998).

Surgical treatment—Early repair is performed in the first month of life. It involves closing the VSD so that the truncus arteriosus receives the outflow from the left ventricle and excising the pulmonary arteries from the aorta and attaching them to the right ventricle by means of a homograft. Currently, homografts (segments of cadaver aorta and pulmonary artery that are treated with antibiotics and cryopreserved) are preferred over synthetic conduits to establish continuity between the right ventricle and pulmonary artery. Homografts are more flexible and easier to use during the procedure and appear less prone to obstruction. Postoperative complications include persistent heart failure, bleeding, pulmonary artery hypertension, dysrhythmias, and residual VSD. Because conduits are not living tissue, they will not grow along with the child and may also become narrowed with calcifications. One or more conduit replacements will be needed in childhood.

Prognosis—Mortality is greater than 10%; future operations are required to replace the conduits.

Hypoplastic Left Heart Syndrome

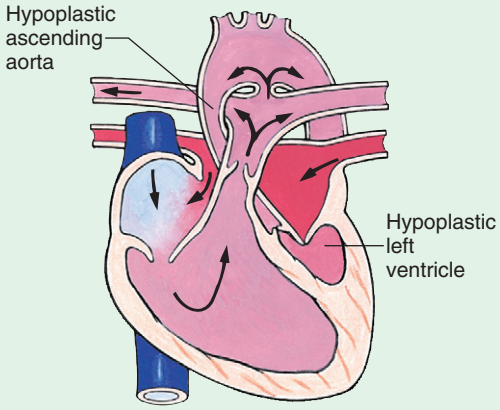
Description—Underdevelopment of the left side of the heart, resulting in a hypoplastic left ventricle and aortic atresia. Most blood from the left atrium flows across the patent foramen ovale to the right atrium, to the right ventricle, and out the pulmonary artery. The descending aorta receives blood from the PDA supplying systemic blood flow.

Pathophysiology—An ASD or patent foramen ovale allows saturated blood from the left atrium to mix with desaturated blood from the right atrium and to flow through the right ventricle and out into the pulmonary artery. From the pulmonary artery, the blood flows both to the lungs and through the ductus arteriosus into the aorta and out to the body. The amount of blood flow to the pulmonary and systemic circulations depends on the relationship between the pulmonary and systemic vascular resistances. The coronary and cerebral vessels receive blood by retrograde flow through the hypoplastic ascending aorta.

Clinical manifestations—The patient has mild cyanosis and signs of HF until the PDA closes and then progressive deterioration with cyanosis and decreased cardiac output, leading to cardiovascular collapse. The condition is usually fatal in the first months of life without intervention.

Therapeutic management—Neonates require stabilization with mechanical ventilation and inotropic support preoperatively. A prostaglandin E_1 infusion is needed to maintain ductal patency and ensure adequate systemic blood flow.

Surgical treatment—A multiple-stage approach is used. The first stage is a Norwood procedure, which involves an anastomosis of the main pulmonary artery to the aorta to create a new aorta, shunting to provide pulmonary blood flow (usually with a modified Blalock-Taussig shunt), and creation of a large ASD. Postoperative complications include imbalance of systemic and pulmonary blood flow, bleeding, low cardiac output, and persistent heart failure. A new modification of the first-stage repair is the use of a right ventricle-to-pulmonary artery homograft conduit instead of a shunt to supply pulmonary blood flow (Sano procedure). The second stage is often a bidirectional Glenn shunt procedure (see Fig. 42-8) or a hemi-Fontan operation. Both involve anastomosing the SVC to the right pulmonary artery so SVC flow bypasses the right atrium and flows directly to the lungs. The procedure is usually done at 3 to 6 months of age to relieve cyanosis and reduce the volume load on the right ventricle. The final repair is a modified Fontan procedure (see Tricuspid Atresia, Box 42-3).



Transplantation—Heart transplantation in the newborn period is another option for these infants. Problems include the shortage of newborn organ donors, risk for rejection, long-term problems with chronic immunosuppression, and infection (see Heart Transplantation, p. 1351).

Prognosis—For the first-stage repair, survival rates vary widely in different centers. Much progress has been made, and some experienced centers are reporting mortality rates of about 10% (Tweddell, Hoffman, Mussatto, et al., 2002), but a large multicenter series reports a mortality rate of about 30% (Jacobs, Mavroudis, Jacobs, et al., 2004). Long-term problems with repair include worsening ventricular function, tricuspid regurgitation, recurrent aortic arch narrowing, dysrhythmias, and developmental delays. There is a risk for mortality between surgical procedures. The mortality for the later two operations is less than 5%.

ASD, Atrial septal defect; *HF,* heart failure; *IVC,* inferior vena cava; *PDA,* patent ductus arteriosus; *PS,* pulmonic stenosis; *SVC,* superior vena cava; *TAPVC,* total anomalous pulmonary venous connection; *TGA,* transposition of the great arteries; *VSD,* ventricular septal defect.

signs of HF. Some defects, such as transposition of the great arteries, cause severe cyanosis in the first days of life and later cause HF. Others, such as truncus arteriosus, cause severe HF in the first weeks of life and mild desaturation.

CLINICAL CONSEQUENCES OF CONGENITAL HEART DISEASE

Heart Failure

HF is the inability of the heart to pump an adequate amount of blood to the systemic circulation at normal filling pressures to meet the body's metabolic demands. In children, HF most frequently occurs secondary to structural abnormalities (e.g., septal defects) that result in increased blood volume and pressure within the heart. It can also result from myocardial failure in which the contractility of the ventricle is impaired. This can occur with cardiomyopathy, dysrhythmias, or severe electrolyte disturbances. HF can also occur because of excessive demands on a normal heart muscle, such as sepsis or severe anemia.

Pathophysiology

Heart failure is often separated into two categories—right-sided failure and left-sided failure. In right-sided failure, the right ventricle is unable to pump blood effectively into the pulmonary artery, resulting in increased pressure in the right atrium and systemic venous circulation. Systemic venous hypertension causes hepatosplenomegaly and occasionally edema. In left-sided failure, the left ventricle is unable to pump blood into the systemic circulation, resulting in increased pressure in the left atrium and pulmonary veins. The lungs become congested with blood, causing elevated pulmonary pressures and pulmonary edema.

Although each type of HF produces different signs and symptoms, clinically, it is unusual to observe solely right- or left-sided failure in children. Because each side of the heart depends on adequate function of the other side, failure of one chamber causes a reciprocal change in the opposite chamber.

If the abnormalities precipitating HF are not corrected, the heart muscle becomes damaged. Despite compensatory mechanisms, the heart is unable to maintain an adequate cardiac output. Decreased blood flow to the kidneys continues to stimulate sodium and water reabsorption, leading to fluid overload, increased workload on the heart, and congestion in the pulmonary and systemic circulations (Fig. 42-6).

Clinical Manifestations

The signs and symptoms of HF can be divided into three groups: (1) impaired myocardial function, (2) pulmonary congestion, and

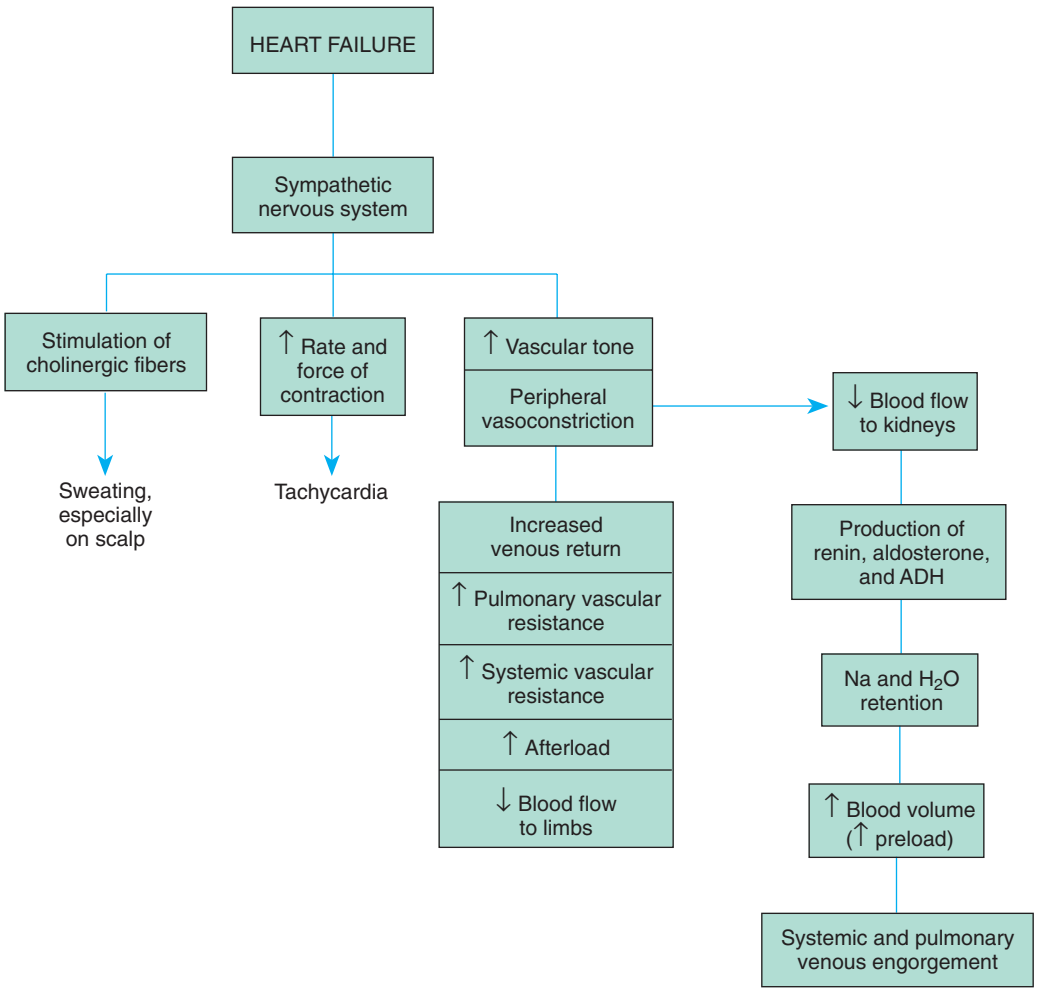


FIG 42-6 Pathophysiology of heart failure. *ADH,* Antidiuretic hormone; *Na,* sodium.

BOX 42-5 CLINICAL MANIFESTATIONS OF HEART FAILURE

Impaired Myocardial Function
- Tachycardia
- Sweating (inappropriate)
- Decreased urinary output
- Fatigue
- Weakness
- Restlessness
- Anorexia
- Pale, cool extremities
- Weak peripheral pulses
- Decreased blood pressure
- Gallop rhythm
- Cardiomegaly

Pulmonary Congestion
- Tachypnea
- Dyspnea
- Retractions (infants)
- Flaring nares
- Exercise intolerance
- Orthopnea
- Cough, hoarseness
- Cyanosis
- Wheezing
- Grunting

Systemic Venous Congestion
- Weight gain
- Hepatomegaly
- Peripheral edema, especially periorbital
- Ascites
- Neck vein distention (children)

(3) systemic venous congestion (Box 42-5). Because these hemodynamic changes occur from different causes and at differing times, the clinical presentation may vary among children.

Diagnostic Evaluation

Diagnosis is made on the basis of clinical symptoms such as tachypnea and tachycardia at rest, dyspnea, retractions, activity intolerance (especially during feeding in infants), weight gain caused by fluid retention, and hepatomegaly. Chest radiography demonstrates cardiomegaly and increased pulmonary blood flow. Ventricular hypertrophy appears on the ECG. An echocardiogram is done to determine the cause of HF such as a congenital heart defect or poor ventricular function.

Therapeutic Management

The goals of treatment are to (1) improve cardiac function (increase contractility and decrease afterload), (2) remove accumulated fluid and sodium (decrease preload), (3) decrease cardiac demands, and (4) improve tissue oxygenation and decrease oxygen consumption. For most infants diagnosed with HF, the cause is CHD. Infants are stabilized on medical therapy and then referred for surgical repair. Today many children are being surgically repaired in the neonatal and early infancy stages before the onset of HF symptoms (Margossian, 2008). For children newly diagnosed with HF, the cause may be worsening ventricular function following a previous cardiac repair, cardiomyopathy, dysrhythmia, or other conditions. In addition to management of HF, the underlying cause is treated if possible.

Improve Cardiac Function. Two groups of drugs are used to enhance myocardial function in HF: (1) digitalis glycosides (digoxin), which improve contractility; and (2) angiotensin-converting enzyme (ACE) inhibitors, which reduce the afterload on the heart and thus make it easier for the heart to pump. Myocardial efficiency is improved through administration of digitalis glycosides. The beneficial effects are increased cardiac output, decreased heart size, decreased venous pressure, and relief of edema. In children, digoxin (Lanoxin) is used almost exclusively because of its more rapid onset. It is available as an elixir (0.05 mg/mL) for oral administration. For infants, the dose is calculated in micrograms (1000 mcg = 1 mg).

Treatment consists of (1) a digitalizing dosage, given orally or intravenously in divided doses over 24 hours to produce optimal cardiac effects, and (2) a maintenance dosage, given orally twice a day to maintain blood levels. During digitalization, the child is monitored by means of an ECG to observe for the desired effects (prolonged PR interval and reduced ventricular rate) and detect side effects, especially dysrhythmias.

Another group of drugs used in the treatment of HF, the ACE inhibitors, inhibit the normal function of the renin-angiotensin system in the kidney. The ACE inhibitors block the conversion of angiotensin I to angiotensin II so that, instead of vasoconstriction, vasodilation occurs. Vasodilation results in decreased pulmonary and systemic vascular resistance, decreased BP, and a reduction in afterload. It also reduces the secretion of aldosterone, which reduces preload by preventing volume expansion from fluid retention and decreases the risk for hypokalemia. Common medications used in children are captopril (Capoten), enalapril (Vasotec), and lisinopril. The principal side effects of ACE inhibitors are hypotension, cough, and renal dysfunction.

β-Blockers, specifically metoprolol and carvedilol (Coreg), are the newest medications to be added to the treatment of some children with chronic HF. The α- and β-adrenergic receptors are blocked, causing decreased heart rate, decreased BP, and vasodilation. It has been shown to decrease morbidity and mortality in some adults with HF and is being used selectively in children. Side effects included dizziness, headache, and hypotension.

Cardiac resynchronization therapy (CRT) using biventricular pacing is an effective treatment in adult patients with HF and is beginning to be applied in the pediatric population. With pharmacologic therapies just described, CRT has the potential to improve cardiac function in this group of patients, including those with a single ventricle (Cecchin, Frangini, Brown, et al., 2009; Dubin, Janousek, Rhee, et al., 2005).

SAFETY ALERT

Because ACE inhibitors also block the action of aldosterone, the addition of potassium supplements or spironolactone (Aldactone) to the drug regimen of patients taking diuretics is usually not needed and may cause hyperkalemia.

Remove Accumulated Fluid and Sodium. Treatment consists of diuretics, possible fluid restriction, and possible sodium restriction. Diuretics are the mainstay of therapy to eliminate excess water and salt to prevent reaccumulation. The most frequently used agents are listed in Table 42-1. Because furosemide and the thiazides are potassium-losing diuretics, potassium supplements may be prescribed and rich dietary sources of the electrolyte are encouraged.

SAFETY ALERT

A fall in the serum potassium level enhances the effects of digitalis, increasing the risk for digoxin toxicity. Increased serum potassium levels diminish digoxin's effect. Therefore serum potassium levels must be carefully monitored.

Fluid restriction may be required in the acute stages of HF and must be carefully calculated to avoid dehydrating the child, especially if cyanotic CHD and significant polycythemia are present.

TABLE 42-1 DIURETICS USED IN HEART FAILURE

ACTIONS	COMMENTS	NURSING CARE MANAGEMENT
Furosemide (Lasix)—Blocks reabsorption of sodium and water in proximal renal tubule and interferes with reabsorption of sodium	Drug of choice in severe HF Causes excretion of chloride and potassium (hypokalemia may precipitate digitalis toxicity)	Begin to record output as soon as drug is given. Observe for dehydration caused by profound diuresis. Observe for side effects (nausea and vomiting, diarrhea, ototoxicity, hypokalemia, dermatitis, postural hypotension). Encourage foods high in potassium, or give potassium supplements. Monitor chloride and acid-base balance with long-term therapy. Observe for signs of digoxin toxicity.
Chlorothiazide (Diuril)—Acts directly on distal tubules to decrease sodium, water, potassium, chloride, and bicarbonate absorption	Less frequently used drug Causes hypokalemia, acidosis from large doses	Observe for side effects (nausea, weakness, dizziness, paresthesia, muscle cramps, skin eruptions, hypokalemia, acidosis). Encourage foods high in potassium, or give potassium supplements.
Spironolactone (Aldactone)—Blocks action of aldosterone, which promotes retention of sodium and excretion of potassium	Weak diuretic Has potassium-sparing effect; frequently used with thiazides, furosemide Poorly absorbed from GI tract Takes several days to achieve maximum actions	Observe for side effects (skin rash, drowsiness, ataxia, hyperkalemia). Do not administer potassium supplements.

GI, Gastrointestinal; *HF,* heart failure.

Infants rarely need fluid restrictions because HF makes feeding so difficult that they struggle to take maintenance fluids.

Sodium-restricted diets are used less often in children than in adults to control HF because of their potential negative effects on the child's appetite and ultimate growth. If salt intake is restricted, additional table salt and highly salted foods are avoided.

Decrease Cardiac Demands. To lessen the workload on the heart, metabolic needs are minimized by (1) providing a neutral thermal environment to prevent cold stress in infants, (2) treating any existing infections, (3) reducing the effort of breathing (by placement in semi-Fowler position), (4) using medication to sedate an irritable child, and (5) providing for rest and decreasing environmental stimuli.

Improve Tissue Oxygenation. The preceding measures serve to increase tissue oxygenation, either by improving myocardial function or by lessening tissue oxygen demands. In addition, supplemental cool humidified oxygen may be administered to increase the amount of available oxygen during inspiration. Oxygen administration is especially helpful in patients with pulmonary edema, intercurrent respiratory tract infections, and increased pulmonary vascular resistance (oxygen is a vasodilator that decreases pulmonary vascular resistance).

MEDICATION ALERT

Oxygen is a drug and is administered only with an appropriate order. There are some uncommon circumstances in patients with complex hemodynamics in which oxygen can be detrimental.

An oxygen hood, nasal cannula, or face tent is used to deliver oxygen. Nasal cannulas are ideal for long-term oxygen administration because the child can be ambulatory and can easily eat and drink. Cool humidification is necessary to counteract the drying effect of oxygen. The amount of cool humidity is carefully regulated to prevent chilling.

CARE MANAGEMENT

The infant or child with HF may be acutely ill, and some may require intensive care until the symptoms improve. Expert nursing care is essential to reduce the cardiac demands that strain the failing heart muscle. During this time, the child and family require emotional support. Although the objectives of nursing care are the same, interventions differ depending on the child's age (see Nursing Care Plan).

Assist in Measures to Improve Cardiac Function. The nurse's responsibility in administering digoxin includes calculating and administering the correct dosage, observing for signs of toxicity, and instituting parental teaching regarding drug administration at home. The child's apical pulse is always checked before administering digoxin. As a general rule, the drug is not given if the pulse is below 90 to 110 beats/min in infants and young children or below 70 beats/min in older children (the cutoff point for adults is 60 beats/min). However, because the pulse rate varies in children in different age-groups, the written drug order should specify at what heart rate the drug is withheld. The nurse should also use judgment in evaluating the pulse rate. If it is significantly lower than the previous recording, the dose should be withheld until the health care practitioner is notified.

The apical rate is taken because a pulse deficit (radial pulse rate lower than apical) may be present with decreased cardiac output. It is auscultated for 1 full minute to evaluate alterations in rhythm. If the child is monitored by means of an ECG, a rhythm strip is obtained and attached to the chart for rate and rhythm analysis, such as abnormal lengthening of the PR interval (>50% increase over predigitalization interval) and dysrhythmias.

Digoxin is a potentially dangerous drug because of its narrow margin of safety of therapeutic, toxic, and lethal doses. Many toxic responses are extensions of its therapeutic effects. Therefore the nurse must maintain a high index of suspicion for signs of toxicity when administering digoxin (Box 42-6).

Because digoxin toxicity can occur from accidental overdose, great care must be taken in properly calculating and measuring the dosage. When converting milligrams to micrograms to milliliters,

the nurse carefully checks the placement of the decimal point because an error causes a significant change in dosage. For example, 0.1 mg is 10 times the dosage of 0.01 mg.

MEDICATION ALERT

Infants rarely receive more than 1 mL (50 mcg or 0.05 mg) of digoxin in one dose; a higher dose is an immediate warning of a dosage error. To ensure safety, compare the calculation with another staff member's calculation before giving the drug.

These same principles are taught to parents in preparation for discharge, although the correct dose in milliliters is usually specified on the container, thus reducing potential errors in calculation. The nurse watches the parent measure the elixir in the dropper and stresses the level mark as the meniscus of the fluid that is observed at eye level.

Parents are also advised of the signs of toxicity. According to the health care practitioner's preference, they may be taught to take the pulse before giving the drug. A return demonstration of the procedure from the parents or another principal caregiver is included as part of the teaching plan. Their level of anxiety in counting the pulse is assessed because overconcern about the heart rate may result in excessive withholding of the drug.

Monitor Afterload Reduction. For patients receiving ACE inhibitors for afterload reduction, the nurse should carefully monitor BP before and after dose administration, observe for symptoms of hypotension, and notify the health care practitioner if BP is low. Numerous medications affecting the kidney can potentiate renal dysfunction, so children taking multiple diuretics and an ACE inhibitor require careful assessment of serum electrolytes and renal function.

NURSING CARE PLAN

The Child with Heart Failure

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
Decreased Cardiac Output related to structural defect, myocardial dysfunction, altered hemodynamics	Child will have adequate cardiac output as evidenced by: • Heart rate within acceptable range (state specific range) • Respiratory rate within acceptable range (state specific range) • Skin warm to touch • Strong and equal peripheral pulses • Blood pressure normal for age • Brisk capillary refill within 2 or 3 seconds • Lack of distended neck veins • Normal sinus rhythm • Lack of edema • Adequate urinary output (state specific; 1-2 mL/kg/hr) • Age-appropriate weight gain on standardized growth curve • Successful feeding	Assess and record heart rate, respiratory rate, blood pressure, and any signs or symptoms of decreased cardiac output (listed under Defining Characteristics) every 2 to 4 hr and as necessary	To detect change in vital signs and child's physical status that reflect altered cardiac output
Child's or Family's Defining Characteristics *(Subjective and Objective Data)* Tachycardia Tachypnea Ineffective peripheral circulation, cool extremities Hypotension Rapid, weak peripheral pulses Prolonged capillary refill, longer than 2 or 3 seconds Narrow pulse pressure Distended neck veins in older children Cardiomegaly revealed on chest radiograph Gallop rhythm Edema Rapid weight gain Feeding difficulty Irritability		Administer cardiac drugs on schedule; assess and record any side effects or any signs and symptoms of toxicity; follow hospital protocol for administration	To avoid dangers inherent in failure to administer cardiac drugs as prescribed and to perform careful assessment before administration
		Keep accurate record of intake and output	To detect HF, which causes decreased urinary output
		Weigh child or infant on same scale at same time of day as previously; document results and compare with previous weight	To monitor for weight increases, which may indicate excess fluid accumulation
		Administer diuretics on schedule; assess and record effectiveness and any side effects noted	To eliminate excess water and salt because fluid retention commonly occurs with HF
		Elevate head of bed at a 30- to 45-degree angle	To promote maximum chest expansion
		Offer small, frequent feedings to infant's or child's tolerance	To increase caloric intake and compensate for fatigue during feeding and increased metabolic rate because of poor cardiac function
		Organize nursing care to allow child or infant uninterrupted rest	To allow adequate rest because poor cardiac output decreases energy level and lowers tolerance to activity
	Child or family will be able to state at least four characteristics of heart failure such as: • Rapid heart rate • Fast breathing • Cool extremities • Puffiness (edema) • Fussiness • Decreased appetite	Educate child and family about characteristics of HF; assess and record teaching session	To promote measures to improve cardiac function and decrease demands
	Child or family will be able to state knowledge of care regarding: • Medication administration • Head elevated positioning • Sufficient rest periods • Monitoring of intake and output • When to contact health care provider	Educate child and family about care such as medication administration; assess and record results and family's participation in care	To promote safety and minimize medication side effects

NURSING CARE PLAN

The Child with Heart Failure—cont'd

NURSING DIAGNOSIS	EXPECTED OUTCOMES	NURSING INTERVENTIONS	RATIONALES
Ineffective Breathing Pattern related to pulmonary congestion, decreased cardiac output **Child's or Family's Defining Characteristics *(Subjective and Objective Data)*** Tachypnea Dyspnea Retractions Crackles Shortness of breath Cyanosis Pallor Mottling Nasal flaring Grunting Head bobbing Cough Use of accessory muscles Activity intolerance	Child will have effective breathing pattern as evidenced by: • Respiratory rate within acceptable range (state specific range) • Clear and equal breath sounds bilaterally anteriorly and posteriorly • Pink or tan color • Absence of nasal flaring, retractions, cough, and head bobbing • Unlabored breath sounds • Tolerance of activities appropriate for age Child or family will be able to state four characteristics of ineffective breathing pattern such as: • Color change from pink or tan to pale, dusky, or blue • Fast breathing • Change in amount or characteristics of secretions • Retractions, head bobbing • Ineffective cough • Decreased or altered activity level Child or family will be able to state knowledge of care regarding: • Positioning to facilitate respiratory effort • Oxygen administration • When to contact health care provider	Assess and record respiratory rate, breath sounds, and any signs or symptoms of ineffective pattern (listed under Defining Characteristics) every 2 to 4 hr and as needed Administer humidified oxygen in correct amount and route of delivery Record percent of oxygen and route of delivery Assess and record child's response to therapy Keep head of bed elevated at a 30- to 45-degree angle Suction if child has ineffective cough or is unable to manage secretions; assess and record amount and characteristics of secretions Assess and record oxygen saturation every 2 to 4 hr and as needed Educate child and family about characteristics of ineffective breathing pattern; assess and record results Educate child and family about care; assess and record results and family participation in care	To detect indicators of worsening HF To reduce respiratory distress by easing respiratory effort To promote maximum chest expansion To maintain patent airway to promote respiratory expansion To evaluate pulmonary effectiveness To promote measures to improve breathing effort

BOX 42-6 COMMON SIGNS OF DIGOXIN TOXICITY IN CHILDREN

Gastrointestinal	Cardiac
• Nausea	• Bradycardia
• Vomiting	• Dysrhythmias
• Anorexia	

Decrease Cardiac Demands. The infant requires rest and conservation of energy for feeding. Every effort is made to organize nursing activities to allow for uninterrupted periods of sleep. Whenever possible, parents are encouraged to stay with their infant to provide the holding, rocking, and cuddling that help children sleep more soundly. To minimize disturbing the infant, changing bed linens and complete bathing are done only when necessary. Feeding is planned to accommodate the infant's sleep and wake patterns. The child is fed at the first sign of hunger, such as when sucking on fists, rather than waiting until he or she cries for a bottle because the stress of crying exhausts the limited energy supply. Because infants with HF tire easily and may sleep through feedings, smaller feedings every 3 hours may be helpful. Gavage feedings may be instituted to provide adequate nutrition and allow the infant to rest.

Every effort is made to minimize unnecessary stress. Older children need an explanation of what is happening to them to decrease anxiety about their illness and necessary treatments such as cardiac monitoring, oxygen administration, and medications. Outlining a plan for the day, preparing the child for tests and procedures, providing quiet activities, and providing adequate rest periods are all helpful interventions with older children. Some infants and children require sedation during the acute phase of illness to allow them to rest.

Temperature is carefully monitored because hyperthermia or hypothermia increases the need for oxygen. Febrile states are reported to the physician because infection must be promptly treated. Maintaining body temperature is of special importance in children who are receiving cool, humidified oxygen and in infants, who tend to be diaphoretic and lose heat by way of evaporation.

Skin breakdown from edema is prevented with a change of position every 2 hours (from side to side while in semi-Fowler position) and use of a pressure-relieving mattress or bed. The skin, especially over the sacrum, is checked for evidence of redness from pressure.

Reduce Respiratory Distress. Careful assessment, positioning, and oxygen administration can reduce respiratory distress. Respirations are counted for 1 full minute during a resting state. Any evidence of increased respiratory distress is reported because this may indicate worsening HF.

Infants are positioned to encourage maximum chest expansion, with the head of the bed elevated; they should sit up in an infant seat or be held at a 45-degree angle. Children prefer to sleep on several pillows and remain in a semi-Fowler or high-Fowler position during waking hours. Safety restraints, such as those used with

infant seats, are applied low on the abdomen and loosely enough to provide both safety and maximum expansion.

The infant or child is often given humidified supplemental oxygen via oxygen hood or tent, nasal cannula, or mask. The child's response to oxygen therapy is carefully evaluated by noting respiratory rate, ease of respiration, color, and especially oxygen saturation as measured by oximetry.

Respiratory tract infections can exacerbate HF and should be appropriately treated and prevented if possible. The child should be protected from persons with respiratory tract infections and have a noninfectious roommate. Good hand washing is practiced before and after caring for any hospitalized child. Antibiotics may be given to combat respiratory tract infection. The nurse ensures that the drug is given at equally divided times over a 24-hour schedule to maintain high blood levels of the antibiotic.

Maintain Nutritional Status. Meeting the nutritional needs of infants with HF or serious cardiac defects is a nursing challenge. The metabolic rate of these infants is greater because of poor cardiac function and increased heart and respiratory rates. Their caloric needs are greater than those of the average infant because of their increased metabolic rate, yet their ability to take in adequate calories is hampered by their fatigue. Feeding for a fragile infant with serious CHD is similar to exercising for an adult, and these infants often do not have the energy or cardiac reserve to do extra work. The nurse seeks measures to enable the infant to feed easily without excess fatigue and to increase the caloric density of the formula.

The infant should be well rested before feeding and fed soon after awakening so as not to expend energy on crying. A 3-hour feeding schedule works well for many infants. (Feeding every 2 hours does not provide enough rest between feedings, and a 4-hour schedule requires an increased volume of feeding, which many infants are unable to take.) The feeding schedule should be individualized to the infant's needs. A feeding goal of 150 mL/kg/day and at least 120 kcal/kg/day is common for newborns with significant heart disease (Stetzler, Rudd, and Pick, 2005). A soft preemie nipple or a slit in a regular nipple to enlarge the opening decreases the infant's energy expenditure while sucking. Infants should be well supported and fed in a semiupright position. Infants may need to rest frequently and may need to have the jaw and cheeks stroked to encourage sucking. Generally, giving an infant about a half-hour to complete a feeding is reasonable. Prolonging the feeding time can exhaust the infant and decrease the rest period between feedings.

Infants with feeding difficulties are often gavage-fed using a nasogastric tube to supplement their oral intake and ensure adequate calories. If they are very stressed and fatigued, in respiratory distress, or tachypneic to 80 to 100 breaths/min, oral feedings may be withheld and all nutrition given by gavage feedings. Gavage feedings are usually a temporary measure until the infant's medical status improves and nutritional needs can be met through oral feedings. Some infants with severe HF, neurologic deficits, or significant gastroesophageal reflux may need placement of a gastrostomy tube to allow adequate nutrition.

The caloric density of formulas is frequently increased by concentration and then adding Polycose, medium-chain triglyceride oil, or corn oil. Infant formulas provide 20 kcal/oz, and the use of additives can increase the calories to 30 kcal/oz or more. This allows the infant to obtain more calories despite a smaller volume intake of formula. The caloric density of the formula needs to be increased slowly (by 2 kcal/oz/day) to prevent diarrhea or formula intolerance. Breastfeeding mothers are encouraged to provide the infant with alternating feedings of breast milk and high-calorie formulas. Some lactating mothers prefer to feed the child expressed breast milk that has been fortified with Similac or Enfamil powder, Polycose, or corn oil to increase caloric intake. A diet plan specific to the individual infant's needs is calculated and prescribed by the nutritionist in collaboration with the other health care personnel. The nurse needs to reinforce this information with the parents as necessary.

Assist in Measures to Promote Fluid Loss. When diuretics are given, the nurse records fluid intake and output and monitors body weight at the same time each day to evaluate benefit from the drug. Because profound diuresis may cause dehydration and electrolyte imbalance (loss of sodium, potassium, chloride, bicarbonate), the nurse observes for signs indicating either complication, as well as signs and symptoms suggesting reactions to the drugs. Diuretics should be given early in the day to children who are toilet trained to avoid the need to urinate at night. If potassium-losing diuretics are given, the nurse encourages foods high in potassium, such as bananas, oranges, whole grains, legumes, and leafy vegetables and administers prescribed supplements. Serum potassium levels are checked frequently.

MEDICATION ALERT

Mix the elixir with fruit juice (red punch or grape juice works well) to disguise the bitter taste and to prevent intestinal irritation from a concentrated solution.

Fluid restriction is rarely necessary in infants because of their difficulty in feeding. However, if fluids are restricted, the nurse plans fluid intake schedules for a 24-hour period, allowing for most fluids during waking hours. Toddlers and preschoolers should be given small amounts of liquid in small cups so the containers appear full. Older children's cooperation is gained by placing them in charge of recording their fluid intake.

If salt is limited, the nurse discusses food sources of sodium with the family and discourages their bringing salt-containing treats to the child. At mealtimes, the child's tray is checked to make sure the appropriate diet is given.

Support Child and Family. HF is a serious complication of heart disease. Parents and older children are usually acutely aware of the critical nature of the condition. Because stress places additional demands on cardiac function, the nurse should focus on reducing anxiety through anticipatory preparation, frequent communication with the parent regarding the child's progress, and constant reassurance that everything possible is being done.

The nurse teaches the family about the medications that need to be administered and alerts them to the signs of worsening HF that require medical attention, such as increased sweating, decreased urinary output (noted in fewer wet diapers or infrequent use of the toilet), or poor feeding. Every effort is made to improve the family's adherence to the medication schedule by adapting the schedule to their usual home routines, avoiding medications during the night, making it as simple as possible, and using charts or visual aids to remember when to give medications. Written instructions regarding correct administration of digoxin are essential.

Hypoxemia

Hypoxemia refers to an arterial oxygen tension (or pressure, Pao_2) that is less than normal and can be identified by a decreased arterial saturation or a decreased Pao_2. Hypoxia is a reduction in tissue oxygenation that results from low oxygen saturations and Pao_2 and results in impaired cellular processes. Cyanosis is a blue discoloration in the mucous membranes, skin, and nail beds of the child

with reduced oxygen saturation. It results from the presence of deoxygenated hemoglobin (hemoglobin not bound to oxygen) in a concentration of 5 g/dL of blood. Cyanosis is usually apparent when arterial oxygen saturations are 80% to 85%. Determination of cyanosis is subjective. It can vary depending on skin pigment, quality of light, color of the room, or clothing worn by the child. The presence of cyanosis may not accurately reflect arterial hypoxemia because both oxygen saturation and the amount of circulating hemoglobin are involved. Children with severe anemia may not be cyanotic despite severe hypoxemia because the hemoglobin level may be too low to produce the characteristic blue color. Conversely, patients with polycythemia may appear cyanotic despite a near-normal Pao_2. Heart defects that cause hypoxemia and cyanosis result from desaturated venous blood (blue blood) entering the systemic circulation without passing through the lungs.

Clinical Manifestations

Over time, two physiologic changes occur in the body in response to chronic hypoxemia—polycythemia and clubbing. **Polycythemia,** an increased number of red blood cells, increases the oxygen-carrying capacity of the blood. However, anemia may result if iron is not readily available for the formation of hemoglobin. Polycythemia increases the viscosity of the blood and increases the risk for blood clot formation. Clubbing, a thickening and flattening of the tips of the fingers and toes, is thought to occur because of chronic tissue hypoxemia and polycythemia (Fig. 42-7). Infants with mild hypoxemia may be asymptomatic except for cyanosis and exhibit near-normal growth and development. Those with more severe hypoxemia may exhibit fatigue with feeding, poor weight gain, tachypnea, and dyspnea. Severe hypoxemia resulting in tissue hypoxia is manifested by clinical deterioration and signs of poor perfusion.

Hypercyanotic spells, also referred to as blue spells or tet spells because they are often seen in infants with tetralogy of Fallot, may occur in any child whose heart defect includes obstruction to pulmonary blood flow and communication between the ventricles. The infant becomes acutely cyanotic and hyperpneic because sudden infundibular spasm decreases pulmonary blood flow and increases right-to-left shunting (the proposed mechanism in tetralogy of Fallot). Spells, rarely seen before 2 months of age, occur most frequently in the first year of life. They occur more often in the morning and may be preceded by feeding, crying, defecation, or stressful procedures. Because profound hypoxemia causes cerebral hypoxia, hypercyanotic spells require prompt assessment and treatment to prevent brain damage or possibly death.

FIG 42-7 Clubbing of the fingers.

Persistent cyanosis as a result of cyanotic heart defects places the child at risk for significant neurologic complications. Cerebrovascular accident (CVA, stroke), brain abscess, and developmental delays (especially in motor and cognitive development) may result from chronic hypoxia.

Diagnostic Evaluation

Cyanosis in a newborn can be the result of cardiac, pulmonary, metabolic, or hematologic disease, although cardiac and pulmonary causes occur most often. To distinguish between the two, a hyperoxia test is helpful. The infant is placed in a 100% oxygen environment, and blood parameters are monitored. A Pao_2 of 100 mm Hg or higher suggests lung disease, and a Pao_2 lower than 100 mm Hg suggests cardiac disease (Park, 2008). An accurate history, a chest radiograph, and especially an echocardiogram contribute to the diagnosis of cyanotic heart disease.

Therapeutic Management

Newborns generally exhibit cyanosis within the first few days of life as the ductus arteriosus, which provided pulmonary blood flow, begins to close. Prostaglandin E_1, which causes vasodilation and smooth muscle relaxation, thus increasing dilation and patency of the ductus arteriosus, is administered intravenously to reestablish pulmonary blood flow. The use of prostaglandins has been lifesaving for infants with ductus-dependent cardiac defects. The increase in oxygenation allows the infant to be stabilized and have a complete diagnostic evaluation performed before further treatment is needed.

Hypercyanotic spells occur suddenly, and prompt recognition and treatment are essential. In the hospital setting, spells are often seen during blood drawing or IV insertion, when the child is highly agitated, or after cardiac catheterization. Treatment of a hypercyanotic spell is outlined in the Guidelines box. Morphine, administered subcutaneously or through an existing IV line, helps reduce infundibular spasm. A spell indicates the need for prompt surgical treatment if possible. In infants with defects not amenable to surgical repair, a shunt may be created surgically to increase blood flow to the lungs. Several commonly used shunt procedures are described in Table 42-2 and Fig. 42-8.

The cyanotic infant and child are well hydrated to keep the hematocrit and blood viscosity within acceptable limits to reduce the risk for CVAs. The infant is monitored closely for anemia because of the risk for CVAs and the reduced arterial oxygen-carrying capacity that occurs. Iron supplementation and possibly blood transfusion are used as needed.

Respiratory tract infections or reduced pulmonary function from any cause can worsen hypoxemia in the cyanotic child. Aggressive pulmonary hygiene, chest physical therapy, administration of antibiotics, and use of oxygen to improve arterial saturations are important interventions.

CARE MANAGEMENT

The general appearance of infants and children with significant cyanosis poses unique concerns. Blue lips and fingernails are obvious signs of their hidden cardiac defect. Clubbing and small, thin stature in older children further indicate severe heart disease. Adolescents are especially concerned about their body image; children with cyanosis are often teased about their appearance and singled out as different. Many children, when asked what surgery will do, reply, "Make me pink." Their joy and excitement after surgery are evident when they see their pink fingers. Parents are often fearful of their child's bluish color because cyanosis is usually associated with lack

TABLE 42-2 SELECTED SHUNT PROCEDURES FOR CHILDREN WITH CARDIAC DEFECTS

SHUNT TYPE	COMMENTS
Modified Blalock-Taussig shunt—Subclavian artery to pulmonary artery using GORE-TEX or IMPRA tube graft	Shunt flow sometimes excessive, requiring use of diuretics Possibility of thrombosis; aspirin usually prescribed postoperatively Easy to ligate at time of definitive correction Shunt size fixed and may become too small as child grows
Sano Modification—Right ventricular to pulmonary artery using GORE-TEX	Prevents diastolic runoff of systemic blood into the pulmonary arteries Provides a higher diastolic blood pressure and seemingly better coronary perfusion Used in place of the modified Blalock-Taussig shunt in the Norwood procedure
Central shunt—Ascending aorta to main pulmonary artery using GORE-TEX graft	Length of shunt acts to restrict blood flow; possibility of symptoms of HF; diuretic therapy sometimes required Uncommon; used when modified Blalock-Taussig shunt cannot be used Easy to insert and remove at time of repair Possibility of thrombosis; aspirin usually prescribed postoperatively
Biderectional Glenn shunt (cavopulmonary anastomosis)—SVC to side of right pulmonary artery; blood flow to both lungs	Done as a second shunt; often used as a staging step to a Fontan procedure Can be incorporated into eventual modified Fontan procedure Relieves severe cyanosis and decreases volume overload on ventricle Carries risk for embolic events (mixing defect); aspirin often prescribed Pulmonary arteriovenous fistulas may occur months or years later, causing desaturation (uncommon finding)

HF, Heart failure; *SVC,* superior vena cava.

GUIDELINES

Treating Hypercyanotic Spells

- Place infant in knee-chest position (Fig. 42-9).
- Use a calm, comforting approach.
- Administer 100% oxygen by blow-by.
- Give morphine subcutaneously or through an existing IV line.
- Begin IV fluid replacement and volume expansion if needed.
- Repeat morphine administration.

IV, Intravenous.

of oxygen and severe illness. They also must deal with comments from relatives, friends, and strangers about their child's abnormal color. They need a simple explanation of hypoxemia and cyanosis and reassurance that cyanosis does not imply a lack of oxygen to the brain. Their questions and fears need to be addressed in a calm, supportive manner, and positive aspects of their child's growth and development are emphasized. They are taught the treatment for hypercyanotic spells (see Guidelines box).

Dehydration must be prevented in children with hypoxemia because it potentiates the risk for CVAs. Fluid status is carefully monitored, with accurate intake and output and daily weight measurements. Maintenance fluid therapy is the minimum requirement, supplemental fluids should be readily available, and gavage feeding or IV hydration is given to children unable to take adequate oral fluids. Fever, vomiting, and diarrhea can cause dehydration and require prompt treatment. Parents are instructed in the importance of adequate fluid intake and measures to prevent dehydration. An oral electrolyte solution should be available at home in the event that the infant is unable to tolerate the usual formula. The health care practitioner should be notified of fever, vomiting, diarrhea, or other problems.

Preventive measures and accurate assessment of respiratory infection are important nursing considerations. Any compromise in pulmonary function will increase the infant's hypoxemia. Good hand washing and protection from individuals with an obvious respiratory tract infection are important. Aggressive pulmonary

hygiene, treatment with antibiotics or antiviral agents as indicated, and supplemental oxygen to decrease hypoxemia are necessary measures. Infants may need to be gavage fed or given parenteral hydration if respiratory distress prevents oral feeding.

! NURSING ALERT

Intracardiac shunting of blood from the right side (desaturated) to the left side of the heart allows air in the venous system to go directly to the brain, resulting in an air embolism. Therefore all IV lines should have filters in place to prevent air from entering the system, the entire tubing should be checked for air, all connections should be taped securely, and any air should be removed.

NURSING CARE OF THE FAMILY AND CHILD WITH CONGENITAL HEART DISEASE

When a child is born with a severe cardiac anomaly, the parents are faced with the immense psychologic and physical tasks of adjusting to the birth of a child with special needs. The following discussion is directed primarily (1) toward the family of an infant who has a serious heart defect and requires home care before definitive repair and (2) toward preparation and care of the child and family when invasive procedures (catheterization and surgery) are performed. For nursing care related to the child with hypoxemia and HF, the reader should refer to earlier discussions of these topics.

Nursing care of the child with a congenital heart defect begins as soon as the diagnosis is suspected. Prenatal diagnosis of congenital heart defects is becoming increasingly frequent. New demands are being placed on nurses to counsel and support families as they prepare for the birth of these infants.

Help the Family Adjust to the Disorder

When parents learn of the heart defect, they are initially in a period of shock followed by high anxiety and fear that the child will die. The family needs time to grieve before they can assimilate the meaning of the defect. Unfortunately, the demands for medical treatment may not allow this, instead necessitating that the parents immediately give informed consent for diagnostic-therapeutic procedures. The nurse can be instrumental in supporting parents in their loss, assessing their level of understanding, supplying information as needed, and helping other members of the health care team understand the parents' reactions (see Family-Centered Care box).

The effect of a child with a serious heart defect on the family is complex. No member, regardless of the degree of positive adjustment, is unaffected. Mothers frequently feel inadequate in their mothering ability because of the more complex care infants with congenital heart defects require. They often feel exhausted from the pressures of caring for these children and the other family members. Fathers and siblings may feel neglected and resentful, a reaction similar to the feelings toward family members with other chronic conditions (see Chapter 36). Often, parents do not feel confident leaving the child in another person's care. This often sets up a trap for parents, especially mothers, who become locked into the child's care with no relief. Although the fears are justified, they can be minimized by gradually teaching someone (a reliable relative or neighbor) how to care for the child.

The need to maintain discipline and set consistent limits can be difficult for parents. Using behavior modification techniques, in the form of either concrete awards (e.g., a favorite activity) or social reinforcement (e.g., approval), can be effective. However, it is most beneficial if used *before* the child learns to control the family. To prevent later problems, it is necessary to begin discussions with parents while the child is in infancy regarding the need for discipline as the child gets older.

Another issue that may develop within family relationships is the child's overdependency. This is often the result of parental fear that the child may die. Parents need guidance to recognize the eventual hazards of continuing dependency and protectiveness as the child grows older, and the nurse can assist parents in learning ways to foster optimum development. Unless parents are shown what activities the child can do, they may focus on physical limitations and encourage dependency.

The child also needs opportunities for normal social interaction with peers. These children do not need to be prevented from playing with other children because of concern regarding overexertion. Children usually limit their activities if allowed to set their own pace. A child with CHD may constitute a long-term family crisis. Frequently, the continuing unremitting stresses of care—physical exhaustion, financial costs, emotional upset, fear of death, and concern for the child's future—are not fully appreciated by those caring for the family. Even when the child's condition is stabilized or corrected, the family may need to make adjustments in their lifestyle. Introducing them to other families with similarly affected children can help them adjust to the daily stresses.

Educate the Family About the Disorder

When parents are ready to hear about the heart condition, they require a clear explanation based on their level of understanding. A review of the basic structure and function of the heart is helpful before describing the defect. A simple diagram, pictures, or a model of the heart can help parents visualize the heart and the congenital defect. Parents appreciate receiving written information about the specific condition.* Health care professionals should take advantage

FAMILY-CENTERED CARE

Diagnosis of Heart Disease

Remember, we don't have your experience. We don't see children every day who have heart disease. We would have been upset finding out our child had to have his tonsils out. How could we ever be prepared for this? Please remember, we only know people who have trivial heart murmurs. How could we ever expect this to happen? And to us, this is the worst problem we've ever heard of.

We still fear most what we don't know and understand. Be honest with us. If you don't know either, tell us. But at least don't leave us wondering about what you know and we don't. Not knowing anything really can be worse than knowing something bad. Be honest but don't strip us of hope …

Please, remember we are trying to learn complex information in a moment of time. And trying to learn it in a context of great pain and emotional investment. This is our lives you're talking about. Please be thorough but keep it simple. Tell us again, maybe even again and again, when we can hear better.

From Schrey C, Schrey M: A parent's perspective: our needs and our message, *Crit Care Nurs Clin North Am* 6(1):113-119, 1994.

of subsequent encounters to assess parental understanding of the condition and clarify information as needed.

Increasingly, families are using the Internet as a source of information about heart disease in children. They are also finding support through contacts with other parents and parent groups.* It is important for parents to realize that not all websites offer medically accurate information and that information from other parents might not be applicable to their own situation. Some children with rare, complex heart defects require individualized treatment plans, and general information on the Internet or in books may not apply to their child. Parents should use their health care team, in particular their cardiologist, to discuss information they have received from other sources.

Information given to the child must be tailored to the child's developmental age. As the child matures, the level of information is revised to meet the child's new cognitive level. Preschoolers need basic information about what they will experience more than what is actually occurring physiologically. School-age children benefit from a concrete explanation of the defect. Preadolescents and adolescents often appreciate a more detailed description of how the defect affects their heart. Children of all ages need to express their feelings concerning the diagnosis.

Help the Family Manage the Illness at Home

Parents are the child's principal caregivers and need to develop a positive, supportive working relationship with the health care team. Because most children spend the majority of their time at home with episodic trips to the hospital, parents manage their child's illness on a daily basis. They monitor for signs of illness, give medications and treatments, bring their child to appointments, work with a variety of caregivers, and alert the team about problems. Successful relationships are partnerships between parents and caregivers that is built on mutual trust and respect. Good communication among the family, the cardiology specialists, and the primary care practitioner is essential. As children reach adolescence, they begin to take a larger role in managing their illness and making decisions about their care.

Parents should be aware of the symptoms of their child's cardiac condition and signs of worsening clinical status. Parents of children who may develop HF should be familiar with the symptoms (see Box 42-5) and know when to contact the health care practitioner. Parents of children with cyanosis should be informed about fluid management and hypercyanotic spells (see p. 1337). Parents should have an information sheet with their child's diagnosis, significant treatments such as surgical procedures, allergies, other health care problems, current medications, and health care providers' contact numbers available in case of emergencies and to share with other caregivers such as teachers, babysitters, and day care providers.

The family also needs to be knowledgeable regarding the therapeutic management of the disorder and the role that surgery, other procedures, medications, and a healthy lifestyle plays in maintaining good health. Medications play a critical role in managing some cardiac conditions such as dysrhythmias, severe HF, anticoagulation for artificial valves, and antirejection medications after heart transplantation. Some patients must take multiple medications daily for their lifetime. Many medications can be dangerous if taken incorrectly and require close monitoring. Parents are taught the correct procedure for giving medications and cautioned to keep them in a safe area to prevent accidental ingestion.

Another area of parental concern is the child's level of physical activity. Most children do not need to restrict activity, and the best approach is to treat the child normally and allow self-limited activity. Exceptions to self-determined activity primarily involve strenuous recreational and competitive sports in children with specific cardiac problems. Activities and exercise restrictions should be discussed with the child's cardiologist. Deliberately attempting to prevent crying should be avoided because it can establish a maladaptive parental pattern of relating to the infant.

Infants and children with CHD require good nutrition. Breastfeeding should be possible for many infants with CHD. Providing adequate nutrition to infants with HF or complex congenital defects is especially difficult because of their high caloric requirements and inability to suck effectively because of fatigue and tachypnea. Instructing parents in feeding methods that decrease the infant's work and giving high-calorie formula are important interventions (see p. 1336 for a discussion on feeding the infant with HF). Children with severe cardiac defects are often anorexic. Encouraging them to eat can be a tremendous challenge. Consultation with a dietitian is often helpful. The child should be given a choice of available high-nutrient foods.

Infants with heart disease should be immunized according to the current guidelines. Immunization schedules may need to be modified around times of acute illness or surgical procedures (Smith, 2001). Infants and children younger than 2 years with unrepaired heart defects, cyanotic lesions, pulmonary hypertension, or history of prematurity should receive the vaccine for respiratory syncytial virus (RSV) monthly during RSV season (November to April in North America) for a total of five doses (American Academy of Pediatrics [AAP] Committee on Infectious Diseases, 2009).

Infants and children who have serious heart disease are at risk for developmental delays. Multiple factors can influence neurodevelopmental outcomes, including genetics (chromosomal abnormalities and microdeletions), family background (parental intelligence quotient [IQ] and socioeconomic status), preoperative factors (including prematurity, cyanosis, shock), intraoperative factors (use of cardiopulmonary bypass, deep hypothermic circulatory arrest), and postoperative factors (hemodynamic instability, hypoxia, acidosis, cardiac arrest, stroke, ischemic events).

Research in the past decade has begun to identify specific risk factors and common developmental concerns for CHD. Bellinger, Wypij, duPlessis, et al. (2003) found an association between longer periods of deep hypothermic circulatory arrest and the presence of postoperative seizures, delayed motor development, and a downward trend in full-scale IQ. At 8 years of age, more than one third of the study patients had received remedial services in school. Shillingford, Glanzman, Ittenbach, et al. (2008) also found that a significant proportion of children with complex CHD were at risk for inattention and hyperactivity and nearly half were using remedial school services. In another longitudinal study, Limperopoulos, Majnemer, Shevell, et al. (2002) found that preoperative and early postoperative neurologic status, microcephaly, type of cardiac lesions, length of deep hypothermic circulatory arrest, age at surgery, and length of ICU stay were predictors of developmental delay.

Recent efforts to limit the time of deep hypothermic circulatory arrest and provide better neuroprotection during infant surgery may improve outcomes in the future. Although most children with serious heart disease are within the normal range for IQ, there is a higher incidence of neurodevelopmental deficits in children after

Many major medical centers that perform pediatric heart surgery also have information on their websites.

heart surgery than in the normal population, specifically in speech and language, fine motor skills, and cognitive processes (Majnemer and Limperopoulos, 1999). Severe neurologic problems such as cerebral palsy, epilepsy, and intellectual disability are uncommon.

Prepare the Child and Family for Invasive Procedures

Chapter 39 provides an extensive discussion of the principles for preparing children for invasive procedures. The American Heart Association published a scientific statement "Recommendations for Preparing Children and Adolescents for Invasive Cardiac Procedures" (LeRoy, Elixson, O'Brien, et al., 2003), which addresses issues specific to the child with heart disease. The following discussion highlights some important aspects of preparation for cardiac catheterization and cardiac surgery.

The expected outcomes for preprocedure preparation include reducing anxiety, improving patient cooperation with procedures, enhancing recovery, developing trust with caregivers, and improving long-term emotional and behavioral adjustments after procedures (LeRoy, Elixson, O'Brien, et al., 2003). Important factors to consider in planning preparation strategies are the child's cognitive development, previous hospital experiences, the child's temperament and coping style, the timing of preparation, and the involvement of the parents. The most beneficial preparation strategies usually combine information giving and coping-skills training such as conscious breathing exercises, distraction techniques, guided imagery, or other behavioral interventions.

Outpatient preoperative and precatheterization workups are common for most elective procedures. Children are then admitted on the morning of the procedure. Preprocedure teaching is often done in the clinic setting or at home and may include a tour of the ICU and inpatient facilities. Children of different ages and developmental levels require different amounts of information and different approaches. Whereas young children should be prepared close in time to the event, older children and adolescents may benefit from teaching several weeks in advance. Parents should be included in the preparation session to support their child and learn about upcoming events.

Topics to include in preoperative or precatheterization preparation include information on the environment, equipment, and procedures that the child will encounter during and after the procedure. Many information-giving techniques can be used such as verbal and written information, hospital tours, preoperative classes, picture books, or videos. Information about what the child will see, hear, and feel should be included, especially for older children and adolescents. Some of the sensory experiences of being in an ICU or catheterization laboratory include sights (monitors, many people, much equipment), sounds (beeping noises, alarms, voices), and sensations (lines and dressings, tape, discomfort, thirst). Familiar aspects of the environment, such as BP cuffs, stethoscopes, or oximeter probes, are reviewed, and new equipment, such as monitors, IV lines, and oxygen masks, is described. Comforting aspects of the environment, such as play areas, chairs for parents, and televisions, are emphasized. Many patients who will be sedated during catheterization or receiving narcotic pain relievers after surgery will have minimal recall of that period and will not need detailed information about the equipment or procedures used. Information should be specific to the planned procedure for each patient.

A discussion of ways the child can cope with the experience should be included. For a young child, bringing a familiar stuffed animal or comfort object will help relieve anxiety, and advising an older child to bring headphones and favorite music to the catheterization laboratory will help distract him or her during the procedure. Recovery topics after catheterization include lying still to prevent bleeding at the catheter site, advancing diet, controlling pain, and monitoring. After surgery, the nurse reviews the importance of ambulation, coughing, deep breathing, drinking, and eating and describes pain management and monitoring routines. Simple coping strategies for use during painful procedures should be reviewed; these include distraction techniques such as counting, blowing, singing, and telling stories.

Children and their families should have a choice about an ICU tour. Exposure to the ICU environment can actually increase anxiety in some children, particularly young children, those with previous hospital experiences, and those who are highly anxious (LeRoy, Elixson, O'Brien, et al., 2003). Usually the day before the procedure is ample time to allow the child to ask questions and to prevent undue fantasizing about the experience. The child should be protected from the frightening sights in the unit; equipment not in view postoperatively, such as equipment located behind or below the bed, needs less attention. The child and parents are encouraged to ask questions or to explore further any equipment in the room, but they should not be pushed to assimilate more information than they are able.

Preoperative physical care differs little, if any, from that for any other surgery and is discussed in Chapter 39. The child should be assured that the parents will be there when the child wakes up; parents should be allowed to accompany their child as far as possible to the operating suite (see Surgical Procedures, p. 1136). After all of the equipment and procedures have been explained, it is important to talk about "getting well" and going home.

Provide Postoperative Care

Immediate postoperative care is usually provided by specially trained nurses in ICUs. Many of the procedures, such as arterial pressure and central venous pressure (CVP) monitoring, and the observations related to vital functions require advanced educational training (readers should refer to critical care texts for further information). However, nurses caring for the child before surgery and during the convalescent period need to be familiar with the major principles of care. Selected complications that may occur postoperatively are described in Box 42-7.

Observe Vital Signs

Vital signs and BP are recorded frequently until stable. Heart rate and respirations are counted for 1 full minute, compared with the ECG monitor, and recorded with activity. The heart rate is normally increased after surgery. The nurse observes cardiac rhythm and notifies the health care practitioner of any changes in regularity. Dysrhythmias may occur postoperatively secondary to anesthetics, acid-base and electrolyte imbalance, hypoxia, surgical intervention, or trauma to conduction pathways (p. 1347).

At least hourly, the lungs are auscultated for breath sounds. Diminished or absent sounds may indicate an area of atelectasis or a pleural effusion or pneumothorax, which necessitates further medical assessment. Temperature changes are typical during the early postoperative period, Hypothermia is expected immediately after surgery from hypothermia procedures, effects of anesthesia, and loss of body heat to the cool environment. During this period, the child is kept warm to prevent additional heat loss. Infants may be placed under radiant heat warmers. During the next 24 to 48 hours, the body temperature may rise to 37.7° C (100° F) or slightly higher as part of the inflammatory response to tissue trauma. After this period, an elevated temperature is most likely a sign of infection and warrants immediate investigation for probable cause.

BOX 42-7 SELECTED COMPLICATIONS AFTER CARDIAC SURGERY AND TREATMENT APPROACHES

Cardiac

Heart failure—Digoxin, diuretics (see p. 1332)
Low cardiac output—Intravenous inotropes (see Shock, p. 1355)
Dysrhythmias—Identification, drug treatment, possible pacing, cardioversion (see p. 1349)
Tamponade (blood or fluid in the pericardial space constricting the heart)—Prompt removal of fluid by pericardiocentesis

Respiratory

Atelectasis—Chest physical therapy, coughing, deep breathing, ambulation
Pulmonary edema—Diuretics
Pleural effusions—Diuretics, possible chest tube drainage
Pneumothorax—Possible chest tube drainage

Neurologic

Seizures—Assessment, antiepileptic drugs
Cerebrovascular accident (stroke), cerebral edema, neurologic deficits—Assessment and treatment

Infectious Disease

Infections (especially wound, pneumonia, otitis media, and sepsis)—Antibiotics

Hematologic

Anemia—Iron supplementation, possible transfusion
Postoperative bleeding—Initially, clotting factors, blood products; may need repeat surgery to locate and ligate source of bleeding

Other

Postpericardiotomy syndrome (syndrome of fever, leukocytosis, friction rub, pericardial and pleural effusions, and lethargy seen about 7 to 21 days after cardiac surgery; possible viral or autoimmune etiologies)—Antipyretics, diuretics, antiinflammatory medications

Intraarterial monitoring of BP is commonly done after open-heart surgery. A catheter is passed into the radial artery or other artery, and the other end is attached to an electronic monitoring system, which provides a continuous recording of the BP. The intra-arterial line is maintained with a low-rate, constant infusion of heparinized saline to prevent clotting.

Several IV lines are inserted preoperatively, including a peripheral IV line to give fluids and medications and a central venous line, usually in a large vessel in the neck, to measure CVP. Additional intracardiac monitoring lines are sometimes placed intraoperatively in the right atrium, left atrium, or pulmonary artery. Intracardiac lines allow assessment of pressures inside the cardiac chambers, providing vital information about volume status, cardiac output, and ventricular function. All lines must be cared for using strict aseptic technique, and patients must be carefully assessed for bleeding at the time of line removal.

Maintain Respiratory Status

Infants usually require mechanical ventilation in the immediate postoperative period. Early extubation in the operating room or early postoperative period is becoming more common. Children, especially those not requiring cardiopulmonary bypass, may be extubated in the operating room or in the first few postoperative hours. Suctioning is performed only as needed and performed carefully to avoid vagal stimulation (which can trigger cardiac dysrhythmias) and laryngospasm, especially in infants. Suctioning is intermittent and maintained for no more than 5 seconds at a time to avoid depleting the oxygen supply. Supplemental oxygen is administered with a manual resuscitation bag before and after the procedure to prevent hypoxia. The heart rate is monitored after suctioning to detect changes in rhythm or rate, especially bradycardia. The child should always be positioned facing the nurse to permit assessment of the child's color and tolerance of the procedure.

When weaning and extubation are completed, humidified oxygen is delivered by mask, hood, or nasal cannula to prevent drying of mucosa. The child is encouraged to turn and deep breathe at least hourly. Measures are used to enhance ventilation and decrease pain, such as splinting of the operative site and use of analgesics. Chest tubes are inserted into the pleural or mediastinal space during surgery or in the immediate postoperative period to remove secretions and air to allow reexpansion of the lung. Drainage is checked hourly for color and quantity. Immediately after surgery, the drainage may be bright red, but afterward, it should be serous. The largest volume of drainage occurs in the first 12 to 24 hours and is greater in extensive heart surgery.

! NURSING ALERT

Chest tube drainage greater than 3 mL/kg/hr for more than 3 consecutive hours or 5 to 10 mL/kg in any 1 hour is excessive and may indicate postoperative hemorrhage. The surgeon should be notified immediately because cardiac tamponade can develop rapidly and is life threatening.

Chest tubes are usually removed on the first to third postoperative day. Removal of chest tubes is a painful, frightening experience. Analgesics such as morphine sulfate, often combined with midazolam (Versed), should be given before the procedure. Older children are forewarned that they will feel a sharp, momentary pain. After the suture is cut, the tubes are quickly pulled out at the end of full inspiration in the extubated patient to prevent intake of air into the pleural cavity. (In the intubated patient, the tubes are pulled out on inspiration because the lungs are stented open with the positive-pressure ventilation.) A purse-string suture (placed when the tubes were inserted) is pulled tight to close the opening. A petrolatum-covered gauze dressing is immediately applied over the wound and securely taped on all four sides to the skin so that an airtight seal is formed. It is left on for 1 or 2 days. Breath sounds are checked to assess for a pneumothorax—a possible complication of chest tube removal. A chest radiograph is usually obtained after removal to evaluate for possible pneumothorax or pleural effusion.

Monitor Fluids

Intake and output of all fluids must be accurately calculated. Intake is primarily IV fluids; however, a record of fluid used to flush the arterial and CVP lines or to dilute medications is also kept. Output includes hourly recordings of urine (usually a Foley catheter is inserted and attached to a closed collecting device), drainage from chest and nasogastric tubes, and blood drawn for analysis. Renal failure is a potential risk from a transient period of low cardiac output.

! NURSING ALERT

The signs of renal failure are decreased urinary output (<1 mL/kg/hr) and elevated levels of blood urea nitrogen and serum creatinine.

Fluids are restricted during the immediate postoperative period to prevent hypervolemia, which places additional demands on the myocardium, predisposing the patient to cardiac failure. If the child is to be extubated within the first 24 to 48 hours, fluids are provided primarily intravenously. If the child is to be intubated longer, fluids may be given via a nasogastric or nasojejunal tube to optimize nutrition and gut motility. Approximately 4 hours after extubation, enteral fluids may be reinitiated in the setting of a stable hemodynamic and respiratory status. To monitor fluid retention, the child is weighed daily, and the same scale is used at approximately the same time each day to avoid errors in measurement. Fluid restriction may be imposed even when oral fluids are given. The nurse calculates the distribution over a 24-hour period based on the child's preoperative weight and drinking habits. The distribution should allow for most fluid to be given during the child's most wakeful and active periods.

Provide Rest and Progressive Activity

After heart surgery, rest should be provided to decrease the workload of the heart and promote healing. The simplest way to ensure individualized, efficient, high-quality care is to plan at the beginning of the shift the nursing procedures to be done, with periods of rest identified. The schedule should be shared with parents to allow them to visit at the most advantageous times, such as after a rest period when no special treatments are anticipated.

A progressive schedule of ambulation and activity is planned, based on the child's preoperative activity patterns and postoperative cardiovascular and pulmonary function. Ambulation is initiated early, usually by the second postoperative day, when chest tubes, arterial lines, and assisted ventilatory equipment have been removed. Activity progresses from sitting on the edge of the bed and dangling the legs to standing up and sitting in a chair. Heart rate and respirations are carefully monitored to assess the degree of cardiac demand imposed by each activity. Tachycardia, dyspnea, cyanosis, desaturation, progressive fatigue, and dysrhythmias indicate the need to limit further energy expenditure.

Provide Comfort and Emotional Support

Heart surgery is both painful and frightening for children, and comfort is a primary nursing concern. Several types of incisions are used by the cardiac surgeon. A median sternotomy is most common, following the sternum down the center of the chest. A ministernotomy opens the lower sternum. A thoracotomy incision is most uncomfortable because it goes through muscle tissue. It allows access to the side of the chest through an incision from under the arm around the back to the scapula.

Most patients need IV analgesics for pain control during the immediate postoperative period. Patient-controlled analgesia may be used with children old enough to understand the concept. Nonsteroidal antiinflammatory drugs (NSAIDs) such as ketorolac (Toradol) may be used intravenously. Paralyzing agents may also be used with the analgesics for children who are hemodynamically unstable.

After extubation and removal of lines and tubes, pain can be satisfactorily controlled with oral medications such as ibuprofen, codeine with acetaminophen (Tylenol No. 3), or oxycodone and acetaminophen. Acetaminophen alone provides adequate pain relief for most children at discharge. Sternotomy incisions are usually well tolerated, with some discomfort when walking and coughing. Thoracotomy incisions are usually more painful because the incision is through muscle; a more aggressive pain management plan with around-the-clock medications for several days is often necessary to allow for adequate rest, ambulation, and pulmonary hygiene.

In addition to pharmacologic pain control, every effort is made to minimize the discomfort of procedures, such as using a firm pillow or favorite stuffed animal placed against the chest incision during movement and performing treatments *after* pain medication is given, preferably at a time that coincides with the drug's peak effect. Nonpharmacologic measures are used to lessen the perception of pain, and parents are encouraged to comfort their child as much as possible. (See also Pain Assessment; Pain Management, Chapter 30.)

Children may become depressed after surgery. This is thought to be caused by preoperative anxiety, postoperative psychologic and physiologic stress, and sensory overstimulation. Typically, the child's disposition improves on leaving the ICU.

Children may also be angry and uncooperative after surgery as a response to the physical pain and to the loss of control imposed by the surgery and treatments. They need an opportunity to express feelings, either verbally or through activity. Children often regress in their behavior during the stress of surgery and hospitalization. They also may express feelings of anger or rejection toward their parents. The nurse can support the parents by being available for information and explaining all of the procedures to them. The first few postoperative days are particularly difficult because parents see their child in pain and realize the potential risks from surgery. They often are overwhelmed by the physical environment of the ICU and feel useless because they can do so little for their child. The nurse can minimize such feelings by including parents in caregiving activities and comfort and play activities, providing information about the child's condition, and being sensitive to their emotional and physical needs. The importance of their presence in making the child feel more secure is stressed even if they do not provide physical care.

Plan for Discharge and Home Care

Ideally, discharge planning begins on admission for cardiac surgery and includes an assessment of the parents' adjustment to the child's altered state of health. Neonates need additional screening tests (e.g., newborn metabolic screen and hearing tests) and may need immunizations before discharge (Dodds and Merle, 2005). The family will need both verbal and written instructions on medication, nutrition, activity restrictions, subacute bacterial endocarditis (SBE), return to school, wound care, and signs and symptoms of infection or complications (see Family-Centered Care box). Referrals to community agencies may be warranted to assist parents in the transition from the hospital to home and to reinforce the teaching.

The parents will also need clear instructions on when to seek medical care for complications and how to contact the health care provider. Follow-up with the cardiologist and primary care provider is also arranged before discharge. Parents should have a summary, including their child's medical condition, medications, and health care providers available for emergencies. Appropriate identification, such as a MedicAlert device, is indicated for children with a pacemaker or a heart transplant and for those receiving anticoagulation therapy or antidysrhythmic medication.

Although surgical correction of heart defects has improved dramatically, it is still not possible to completely repair many of the complex anomalies. For many children, repeat procedures are

FAMILY-CENTERED CARE

Topics to Include in Discharge Teaching After Cardiac Surgery

- Medication teaching
- Activity restrictions
- Diet and nutrition
- Wound care (including dressings, if any; suture removal; bathing)
- Bacterial (infective) endocarditis prophylaxis (see Box 42-9)
- Follow-up appointments (cardiologist, primary care provider)
- Community agencies as needed (visiting nurse service, early developmental intervention)
- When to call health care practitioner; signs and symptoms of postoperative problems
- Review of cardiac defect and surgical repair

required to replace conduits or grafts or to manage complications such as restenosis. Consequently, the long-term prognosis is uncertain and full recovery is not always possible. For these families, medical follow-up and continued emotional support are essential. The nurse can often serve as an important primary health care professional and as a resource for referrals when needed.

ACQUIRED CARDIOVASCULAR DISORDERS

Bacterial (Infective) Endocarditis

Bacterial endocarditis (BE), or subacute bacterial endocarditis (SBE), is now commonly referred to as infective endocarditis (IE). IE is an infection of the inner lining of the heart (endocardium), generally involving the valves. Although it can occur without underlying heart disease, it is most often a sequela of bacteremia in children with acquired or congenital anomalies of the heart or great vessels. It especially affects children with valvular abnormalities, prosthetic valves, shunts, recent cardiac surgery with invasive lines, and rheumatic heart disease with valve involvement. The most common causative agents are *Staphylococcus aureus* and *Streptococcus viridans;* other causative agents include gram-negative bacteria and fungi such as *Candida albicans.*

Pathophysiology

Organisms may enter the bloodstream from any site of localized infection. In the past, endocarditis was believed to be highly associated with invasive procedures; however, endocarditis is most likely to occur from routine exposure to bacteremia associated with usual daily activities, although it can also occur after procedures such as dental work (*S. viridans*); after invasive procedures involving the gastrointestinal and genitourinary tracts; after cardiac surgery, especially if synthetic material is used (valves, patches, conduits); or from long-term indwelling catheters. The microorganisms grow on the endocardium, forming vegetations (verrucae), deposits of fibrin, and platelet thrombi. The lesion may invade adjacent tissues, such as the aortic and mitral valves, and may break off and embolize elsewhere, especially in the spleen, kidney, and central nervous system (CNS).

Diagnostic Evaluation

The diagnosis of IE is suspected on the basis of clinical manifestations (Box 42-8). The most commonly used guidelines for diagnosis use the revised Duke criteria, which outline major and minor criteria consistent with IE (Li, Sexton, Mick, et al., 2000). Several

BOX 42-8 CLINICAL MANIFESTATIONS OF INFECTIVE ENDOCARDITIS

- Onset usually insidious
- Unexplained fever (low grade and intermittent)
- Anorexia
- Malaise
- Weight loss
- Characteristic findings caused by extracardiac emboli formation:
  - Splinter hemorrhages (thin black lines) under the nails
  - Osler nodes (red, painful intradermal nodes found on pads of phalanges)
  - Janeway lesions (painless hemorrhagic areas on palms and soles)
  - Petechiae on oral mucous membranes
- May be present:
  - Heart failure
  - Cardiac dysrhythmias
  - New murmur or change in previously existing one

laboratory findings may suggest IE (e.g., ECG changes [prolonged PR interval], radiographic evidence of cardiomegaly, anemia, elevated erythrocyte sedimentation rate [ESR], leukocytosis, microscopic hematuria). Vegetations on the valve and abnormal valve function can often be visualized by echocardiography. Definitive diagnosis rests on growth and identification of the causative agent in the blood. A diagnosis of culture-negative IE is made when the patient has echocardiographic or clinical evidence of IE but no organism can be cultured (Ferrieri, 2002).

Therapeutic Management

Treatment should be instituted immediately and consists of administration of high doses of appropriate antibiotics intravenously for 2 to 8 weeks. Blood cultures are taken periodically to evaluate the response to antibiotic therapy.

Prevention involves administration of prophylactic antibiotic therapy 1 hour before certain procedures that are associated with the risk for entry of organisms in very high risk patients. Recent guidelines recommend prophylaxis only in patients with the highest risk for poor outcome if they develop endocarditis (Box 42-9). Drugs of choice for prophylaxis include amoxicillin, ampicillin, clindamycin, cephalexin, cefadroxil, azithromycin, and clarithromycin.

CARE MANAGEMENT

Ideally, the objective of nursing care is to counsel parents of high risk children concerning the signs and symptoms of endocarditis and, in certain cases, the need for prophylactic antibiotic therapy before procedures such as dental work. The family's dentist should be advised of the child's cardiac diagnosis as an added precaution to ensure preventive treatment. SBE prophylaxis is now reserved for very high risk patients. Many patients who met criteria established in the past may not require prophylaxis under the new guidelines (Wilson, Taubert, Gewitz, et al., 2007) (see Box 42-9). Parents should be counseled regarding the rationale for discontinuing prophylaxis and should be educated as to the fact that their child is still at higher risk for IE than the general population. It is important that all children with congenital or acquired heart disease maintain the highest level of oral health to reduce the chance of bacteremia from oral infections.

BOX 42-9 CARDIAC CONDITIONS ASSOCIATED WITH THE HIGHEST RISK FOR ADVERSE OUTCOME FROM ENDOCARDITIS

- Prophylaxis with dental procedures recommended for*:
  - Previous episode of infective endocarditis
  - Prosthetic cardiac valve
- CHD, including only:
  - Unrepaired cyanotic CHD, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplantation recipients who develop cardiac valvulopathy

Adapted from Wilson W, Taubert K, Gewitz M, et al: Prevention of infective endocarditis: guidelines from the American Heart Association, *Circulation* 116(15):1736-1754, 2007.
CHD, Congenital heart disease.
*Except for the conditions listed, antibiotic prophylaxis is no longer recommended for any other form of CHD.

Parents should also have a high index of suspicion regarding potential infections. Without unduly alarming them, the nurse stresses that any unexplained fever, weight loss, or change in behavior (lethargy, malaise, anorexia) must be brought to the health care practitioner's attention. Such symptoms should not be self-diagnosed as a cold or flu. Early diagnosis and treatment are important in preventing further cardiac damage, embolic complications, and growth of resistant organisms.

Treatment of endocarditis requires long-term parenteral drug therapy. In many cases, IV antibiotics may be administered at home with nursing supervision. Nursing goals during this period are (1) preparation of the child for IV infusion, usually with an intermittent-infusion device and several venipunctures for blood cultures; (2) observation for side effects of antibiotics, especially inflammation along venipuncture sites; (3) observation for complications, including embolism and HF; and (4) education regarding the importance of follow-up visits for cardiac evaluation, echocardiographic monitoring, and blood cultures.

Rheumatic Fever

Rheumatic fever (RF) is a poorly understood inflammatory disease that occurs after infection with group A β-hemolytic streptococcal (GABHS) pharyngitis. It occurs most often in late school-age children and adolescents and is rare in adults. It is a self-limited illness that involves the joints, skin, brain, serous surfaces, and heart. Cardiac valve damage (referred to as rheumatic heart disease) is the most significant complication of RF. The mitral valve is most often affected. In developed countries, RF and rheumatic heart disease have become uncommon. However, RF remains a devastating problem in developing countries.

Etiology

Strong evidence supports a relationship between upper respiratory tract infection with GABHS and subsequent development of RF (usually within 2 to 6 weeks). In almost all cases of RF, a previous infection with GABHS can be documented by laboratory evidence of rising antibody titers. Prevention or treatment of GABHS infection prevents RF.

Diagnostic Evaluation

Diagnosis continues to be based on a set of guidelines known as the *modified Jones criteria* (Guidelines for the diagnosis of rheumatic fever, 1992). These guidelines were reviewed and again endorsed by the American Heart Association in 2002 and continue to be used to this date (Ferrieri, 2002). The updated Jones criteria suggest that the presence of two major manifestations or one major and two minor manifestations, with supportive evidence of recent streptococcal infection, indicates a high probability of RF.

Children suspected of having RF are tested for streptococcal antibodies. The most reliable and best standardized test is an elevated or rising antistreptolysin O (ASO or ASLO) titer, which occurs in 80% of children with RF. Additional antistreptococcal antibody titers may be sent if ASO titers are negative. Acute-phase reactants, ESR, and C-reactive protein (CRP) are usually elevated as well.

Therapeutic Management

The goals of medical management are (1) eradication of hemolytic streptococci, (2) prevention of permanent cardiac damage, (3) palliation of the other symptoms, and (4) prevention of recurrences of RF. Penicillin is the drug of choice or an alternative in penicillin-sensitive children (Gerber, Baltimore, Eaton, et al., 2009). Salicylates are used to control the inflammatory process, especially in the joints, and reduce the fever and discomfort. Bed rest is recommended during the acute febrile phase but need not be strict.

Children who have had acute RF are susceptible to recurrent RF for the rest of their lives and should be followed medically because repeated infections are likely to result in rheumatic heart disease.

Prophylactic treatment against recurrence of RF (secondary prevention) is started after the acute therapy and involves monthly intramuscular injections of benzathine penicillin G (1.2 million units), two daily oral doses of penicillin (200,000 units), or one daily dose of sulfadiazine (1 g). The current American Heart Association guidelines recommend secondary prophylaxis for all patients diagnosed with RF. The exact length of secondary prophylaxis is based on whether or not a patient has residual heart disease. In RF with carditis, prophylaxis is recommended for 5 years or until age 21 years. In the setting of carditis, prophylaxis is recommended for 10 years or until 21 years old. In the setting of RF with carditis and residual heart disease, prophylaxis can continue until the age of 40 years and may be indicated indefinitely depending on the individual's risk (Gerber, Baltimore, Eaton, et al., 2009).

CARE MANAGEMENT

The objectives of nursing care for the child with RF are to (1) encourage compliance with drug regimens, (2) facilitate recovery from the illness, (3) provide emotional support, and (4) prevent the disease. Because compliance is a major concern in long-term drug therapy, every effort is made to encourage adherence to the therapeutic plan (see Compliance, Chapter 39). When compliance is poor, monthly injections may be substituted for daily oral administration of antibiotics and children need preparation for this often-dreaded procedure.

Interventions during home care are concerned primarily with providing rest and adequate nutrition. Usually, after the febrile stage is over, children can resume moderate activity and their appetite improves. If carditis is present, the family must be aware of any

activity restrictions and may need help in choosing less strenuous activities for the child.

One of the most disturbing and frustrating manifestations of the disease is chorea. The onset is gradual and may occur weeks to months after the illness; it sometimes even occurs in children who have not been diagnosed with RF. It may be mistaken for nervousness, clumsiness, behavioral changes, inattentiveness, and learning disability. It is usually a source of great frustration to the child because the movements, incoordination, and weakness severely limit physical ability. Of utmost importance is stressing to parents and schoolteachers the involuntary, sudden nature of the movements; that the chorea is transitory; and that all manifestations eventually disappear.

Nurses also have a role in prevention, primarily in screening school-age children for sore throats caused by GABHS. This may involve actively participating in throat culture screening programs or in referring children with a possible streptococcal infection for testing.

Hyperlipidemia (Hypercholesterolemia)

Hyperlipidemia is a general term for excessive lipids (fat and fatlike substances); hypercholesterolemia refers to excessive cholesterol in the blood. Dyslipidemia is a term used to describe all abnormalities in lipid metabolism, including low levels of high-density lipoprotein (HDL) or "good" cholesterol. High lipid or cholesterol levels play an important role in producing atherosclerosis (fatty plaque on the arteries), which eventually can lead to coronary artery disease—a primary cause of morbidity and mortality in the adult population. A presymptomatic phase of atherosclerosis can begin in childhood. Preventive cardiology focuses on the screening and management of lipid levels in childhood. The goal is to identify children at high risk and intervene early.

Cholesterol is part of the lipoprotein complex in plasma that is essential for cellular metabolism. Triglycerides, natural fats synthesized from carbohydrates, are used for energy. Both are major lipids transported on lipoproteins, a combination of lipids and proteins, which include:

- Low-density lipoproteins (LDLs)—These contain low concentrations of triglycerides, high levels of cholesterol, and moderate levels of protein. LDL is the major carrier of cholesterol to the cells. Cells use cholesterol for synthesis of membranes and steroid production. Elevated circulating LDL is a strong risk factor in cardiovascular disease.
- High-density lipoproteins (HDLs)—These contain very low concentrations of triglycerides, relatively little cholesterol, and high levels of protein. They transport free cholesterol to the liver for excretion in the bile. High levels of HDL are thought to protect against cardiovascular disease.

Diagnostic Evaluation

Hyperlipidemia is diagnosed on the basis of analysis of blood for a full lipid profile, drawn after a 12-hour fast. Hyperlipidemia can have a genetic basis or a lifestyle component or can be caused by secondary problems, such as hypothyroidism. In children with elevated cholesterol levels, a screening thyroid-stimulating hormone is also measured once to rule out hypothyroidism as a cause of secondary hypercholesterolemia. Additional blood work is individualized based on other risk factors. In overweight children, a fasting glucose level may be obtained to assess for risk factors associated with metabolic syndrome, which is a combination of multiple symptoms that are associated with increased cardiovascular risk in adults. Blood samples should be collected after having the child sit for 5 minutes, and the tourniquet should be applied immediately before the needle puncture because posture and vascular stasis may affect results. Diagnostic values for acceptable, borderline, and high total cholesterol and LDL cholesterol levels are listed in Table 42-3.

TABLE 42-3 CLASSIFICATION OF CHOLESTEROL LEVELS IN CHILDREN FROM FAMILIES WITH A HISTORY OF HEART DISEASE

CATEGORY	TOTAL CHOLESTEROL (MG/DL)	LDL CHOLESTEROL (MG/DL)
Acceptable	<170	<110
Borderline	170-199	110-129
High	≥200	≥130

From Daniels SR, Greer FR, Committee on Nutrition: Lipid screening and cardiovascular health in childhood, *Pediatrics* 122(1):198-208, 2008.
LDL, Low-density lipoprotein.

The National Heart, Lung, and Blood Institute (NHLBI) (NHLBI, 2011) recently issued a recommendation for universal lipid (nonfasting or fasting) screening of all children and adolescents between the ages of 9 and 11 years and again between the ages of 17 and 21 years. LDL cholesterol–lowering drug therapy is recommended for children and adolescents 10 years of age and older whose LDL remains elevated after 6 months to 1 year on a restricted fat diet, lifestyle modification (exercise), and weight management (NHLBI, 2011). Additional information and practice guidelines for monitoring cholesterol levels and initiation of cholesterol-lowering medication as well as specific dietary modifications are found in the 2011 NHLBI summary report at www.nhlbi.nih.gov/guidelines/cvd_ped/summary.htm#chap5.

Therapeutic Management

The first step in the treatment of high cholesterol is oriented to lifestyle modification. The American Academy of Pediatrics (AAP) (Daniels, Greer, and Committee on Nutrition, 2008) guidelines continue to advocate the benefits of a heart-healthy diet for all children. Children with known elevated cholesterol should have individual nutritional counseling by a nutritionist with expertise in pediatric lipids.

Research continues to support the benefit of diets low in saturated fats. Current thinking favors a "Mediterranean"-type diet. Whole grains, fruits, and vegetables form the foundation of this diet. In addition, this diet allows the use of monounsaturated fats, such as olive oil and canola oil, which have beneficial effects on HDL cholesterol values. The use of these fats also makes the diet more realistic. Patients who have elevated triglycerides, especially in the setting of an elevated body mass index (BMI), should receive targeted counseling related to decreasing their intake of simple carbohydrates. Aerobic exercise of at least 60 minutes a day 5 days a week is also recommended for children with high cholesterol. In addition, patients and parents should be counseled regarding the negative effects of smoking (both firsthand and secondhand).

For children with severe hypercholesterolemia who fail to respond to dietary modifications, drug therapy may be necessary. Pharmacologic therapy is recommended for children older than 8

years who have LDL cholesterol greater than 190 mg/dL without other risk factors or over 160 mg/dL in patients with two or more other risk factors. In young people with other risk factors, such as diabetes, medication can be considered when LDL values are greater than 130 mg/dL. The use of medication in young people needs to be a cooperative decision with the parents. Parents should understand what data are available about statin use in young people because long-term evidence-based practice is not practical or available for this population. In the past, bile acid–binding resins were the only class of drugs recommended for treatment of younger children. This class of drug acts by binding bile acids in the intestinal lumen. Because they are not absorbed by the intestine, resin binders do not produce systemic toxicity and are safe for children. Both cholestyramine (Questran) and colestipol (Colestid) are powders that are mixed with water or juice just before ingestion. Unfortunately, the vast majority of patients do not get adequate reduction in LDL cholesterol from bile acid–binding resins. Many cannot tolerate the medication because of the taste; gritty texture; and side effects, the most significant being constipation, abdominal pain, gastrointestinal bloating, flatulence, and nausea. The most recent guidelines on lipid abnormalities in children give the option for treatment with statins if pharmacologic therapy is indicated using the previously outlined guidelines for treatment (Daniels, Greer, and Committee on Nutrition, 2008; McCrindle, Urbina, Dennison, et al., 2007). Statins are much more effective than other drugs at lowering LDL cholesterol. To a lesser degree, they also help lower triglycerides levels and can raise HDL cholesterol. Statins work by inhibiting the enzyme necessary for cholesterol synthesis. Statins are most effective when taken in the evening and are started at the lowest possible dose in young people. Blood work should be followed closely in children and adolescents and usually includes a fasting lipid profile, liver function tests, and creatinine kinase repeated at 4- and 8-week intervals initially and with dosage changes.

Patients beginning therapy with a statin should be counseled regarding rare but potentially serious side effects such as rhabdomyolysis, elevated transaminases, and elevated creatinine kinase. Patients should discontinue their medication and contact their practitioner if they develop dark urine or new muscle aches. Last, statin medications are not safe during pregnancy; therefore sexually active adolescents need to take adequate birth control measures. Very long–term studies are unlikely to be available over decades; however, in the shorter-term studies that have been completed, statins seem to have a similar safety profile for children as they do for adults (McCrindle, Urbina, Dennison, et al., 2007).

CARE MANAGEMENT

Nurses play an important role in the screening, education, and support of children with lipid abnormalities and their families. When a child is referred to a preventive cardiology clinic, it is essential that the family be adequately prepared for the first visit. Generally, the parents will be asked to keep a dietary history of the child before this visit. Sometimes they will need to complete a questionnaire regarding the child's normal dietary habits during the preceding year. Families should be instructed to keep their child fasting for at least 12 hours before screening. Last, parents should be aware that lipids should not be drawn within 3 weeks of a febrile illness because doing so can affect cholesterol values. It is important to schedule the blood test early in the morning and to arrange for nourishment immediately thereafter. At the visit, a full family history should be taken, including the health of both parents and all first-degree relatives. Specific questions should be asked regarding early heart disease, hypertension, strokes (CVAs), sudden death, hyperlipidemia, diabetes, and endocrine abnormalities.

Parents and extended families should be educated about cholesterol and lipid abnormalities. This education should include a brief introduction of the different lipoprotein categories, including cholesterol, HDL, LDL, and triglycerides. Also, behavioral risk factors for heart disease, such as smoking and exercise, should be reviewed. For management to be effective, parents and patients need to understand that the rationale for dietary or pharmacologic intervention is prevention of future cardiovascular disease.

Stringent dietary guidelines may become an issue of control and a source of great stress for many families. A child with a lipid disorder should not be viewed as having a disease. Rather, the positive aspects of healthy eating, regularly exercising, and avoiding smoking should be emphasized. Basic dietary changes should be encouraged for the whole family so the affected child is not singled out. Cultural differences must be considered and recommendations individualized. Substitution rather than elimination needs to be emphasized. Visual aids (e.g., test tubes depicting the amount of fat in a hot dog or the number or packs of sugar in a glass of juice) are often helpful, especially for children. Diets should be flexible and individually tailored by a nutritionist who is experienced in lipid disorders. Dietary recommendations need to meet the nutritional demands of growing children while providing benefit to the overall profile. Parents are encouraged to participate in dietary and educational sessions, ask questions, and share ideas and experiences.

Parents often feel guilty about the hereditary component of hyperlipidemia. Many also believe they have failed if the diet alone is not making a significant difference in their child's lipid profile. They need to be reassured that a dietary approach alone is often not sufficient, especially for children with significantly elevated values.

Parents of children who require pharmacologic therapy need to understand the purpose, dosage, and possible side effects of the various drugs. Medication schedules should remain flexible and should not interfere with the child's daily activities. Follow-up phone calls by the nurse between visits allow parents to discuss their concerns and ask any questions that have arisen (see Evidence-Based Practice box).

Cardiac Dysrhythmias

Dysrhythmias, or abnormal heart rhythms, can occur in children with structurally normal hearts, as features of some congenital heart defects, and in patients after surgical repair of congenital heart defects. They are also seen in patients with cardiomyopathy and with cardiac tumors. They can occur secondary to metabolic and electrolyte imbalances. They can be classified in several ways, including by heart rate characteristics (bradycardia and tachycardia) and by the origin of the dysrhythmia in the atria or ventricles. Some dysrhythmias are well tolerated and self-limiting. Others may cause decreased cardiac output with associated symptoms. Some dysrhythmias can cause sudden death. Treatment depends on the cause of the dysrhythmia and its severity.

Many advances have been made in the diagnosis and treatment of pediatric dysrhythmias in the past decade. Improvements in technology have allowed better diagnosis, the development of ablation techniques, and the expansion of pacemaker capabilities. New antidysrhythmic medications have proven safe and effective in children. Radiofrequency ablation has offered a cure for some dysrhythmias. Pediatric electrophysiology has become a highly specialized field, and students should consult more detailed sources for an in-depth discussion. The following sections address diagnostic studies and

EVIDENCE-BASED PRACTICE

Cholesterol Screening for Children

Ask the Question

Should cholesterol screening be performed in children?

Search for the Evidence

Search Strategies

The literature was searched to locate clinical research studies related to this issue. Selection criteria included English-language publications, research-based articles (level 3 or lower), and infant and child populations.

Databases Used

PubMed, Cochrane Collaboration, MD Consult, Joanna Briggs Institute, National Guidelines Clearinghouse (AHRQ), TRIP Database Plus, PedsCCM, BestBETs

Critically Analyze the Evidence

- In late 2011, an expert panel of the National Heart, Lung, and Blood Institute (NHLBI) made a recommendation that lipid screening be performed on all children ages 9 to 11 years; this recommendation was based on evidence that as many as 30% to 60% of children with dyslipidemia might be missed when screening is performed by family history alone (National Heart, Lung, and Blood Institute, 2011). The expert panel's guidelines also include comprehensive screening and treatment guidelines for children with cardiovascular disease risk factors.
- Diagnosis of obesity is paramount in enhancing care of obese pediatric patients. Current laboratory (cholesterol or glucose) screening rates (10%) are inadequate in the outpatient setting (Patel, Madsen, Maselli, et al., 2010).
- Testing for cardiovascular risk factors: HDL cholesterol, LDL cholesterol, fasting glucose, blood pressure, OGTT, thyrotropin, and ALT should be considered in pediatric patients with increased waist circumference and even normal BMI (l'Allemand-Jander, 2010).
- In obese children, LDL cholesterol, HDL cholesterol, total cholesterol, and triglycerides are significantly different from those of subjects who are not obese (Simsek, Balta, Balta, et al., 2010).
- Serum triglyceride levels are a predictive risk factor of carotid intima-media thickness (Simsek, Balta, Balta, et al., 2010).
- In children and adolescents (12-19 years old) fasting non-HDL cholesterol levels were strongly associated with metabolic syndrome. A non-HDL cholesterol threshold of 120 mg/dL indicated borderline risk for metabolic syndrome, and a threshold of 145 mg/dL indicated high metabolic syndrome risk (Li, Ford, McBride, et al., 2011).
- Cholesterol levels in childhood are a major population predictor for adult cholesterol levels (Daniels, Greer, Committee on Nutrition, 2008).
- Precursors of atherosclerosis are present in young people. The atherosclerotic process begins early in life with early phases characterized by the development of fatty streaks in the vessels (PDAY study) (Enos, Holmes, Beyer, 1953; Strong, Malcom, McMahan, et al., 1999).
- Atherosclerosis is related to the presence and degree of cardiovascular risk factors in adults (Berenson, Srinivasan, Bao, et al., 1998).
- Most severely affected children come from families with a high incidence of early heart disease. Children whose genetic family history is unknown should also be screened (AAP Committee on Nutrition, 1998).
- Universal cholesterol screening in children would identify all individuals with dyslipidemia. Using solely the family history to identify subjects for cholesterol screening missed individuals with moderate dyslipidemia and those with potentially genetic dyslipidemia (Ritchie, Murphy, Ice, et al., 2010).

Apply the Evidence: Nursing Implications

There are strong recommendations (Guyatt, Oxman, Vist, et al., 2008) that lipid screening should be performed on all children 9 to 11 years of age. The NHLBI guidelines have been endorsed by the American Academy of Pediatrics (AAP, 2011).

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Describe use of cholesterol screening in children.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by using cholesterol screening in children.

Attitudes

Value the concept of evidence-based practice as integral to determining best clinical practice.

Appreciate strengths and weakness of evidence for using cholesterol screening in children.

provide a general discussion of the most common tachycardia (**supraventricular tachycardia [SVT]**) and the most common bradycardia (complete heart block) that require treatment in the pediatric population.

Diagnostic Evaluation

Nurses must be familiar with the standards of normal heart rate for the particular age-group (see Appendix C). An initial nursing responsibility is recognition of an abnormal heartbeat, either in rate or rhythm. When a dysrhythmia is suspected, the apical rate is counted for 1 full minute and compared with the radial rate, which may be lower because not all of the apical beats are felt. Consistently high or low heart rates should be regarded as suspicious. The patient should be placed on a cardiac monitor with recording capabilities. A 12-lead ECG yields more information than the monitor recording and should be done as soon as possible.

The basic diagnostic procedure is the ECG, including 24-hour Holter monitoring. Electrophysiologic cardiac catheterization allows for identification of the conduction disturbance and immediate investigation of drugs that may control the dysrhythmia. Another procedure that may be used is transesophageal recording. An electrode catheter is passed to the lower esophagus and, when in position at a point proximal to the heart, is used to stimulate and record dysrhythmias.

Dysrhythmias can be classified according to various criteria, such as effect on heart rate and rhythm, as follows:

- **Bradydysrhythmias—**Abnormally slow rate
- **Tachydysrhythmias—**Abnormally rapid rate
- **Conduction disturbances—**Irregular heart rate

Bradydysrhythmias. Sinus bradycardia (slower than normal rate) in children can be attributed to the influence of the autonomic nervous system, as with hypervagal tone, or in response to hypoxia and hypotension. Sinus bradycardias are also known to develop after some complex cardiac surgical repairs involving extensive atrial suture lines such as atrial baffle repairs (Mustard and Senning repairs) and the Fontan procedure.

Complete atrioventricular (AV) block is also referred to as complete heart block. This can be either congenital (occurring in children with structurally normal hearts) or acquired after surgery to repair cardiac defects. AV blocks are most often related to edema around the conduction system and resolve without treatment. Temporary epicardial wires are placed in most patients at surgery; if a rhythm disturbance occurs, temporary pacing can be used. Several days after surgery, the health care practitioner removes the wires by pulling slowly and deliberately down on them from the site of insertion.

Some children may need a permanent pacemaker. The pacemaker takes over or assists in the heart's conduction function. The implantation of a pacemaker, in the operating room or possibly the catheterization laboratory, is usually a low risk procedure. The pacemaker is made up of two basic parts, the pulse generator and the lead. The pulse generator is composed of the battery and the electronic circuitry. The lead is an insulated, flexible wire that conducts the electrical impulse from the pulse generator to the heart. Two types of leads are available—transvenous and epicardial. After the lead has been attached to the heart, a small incision is made and a pocket is formed under the muscle to house and protect the generator. Continuous ECG monitoring is necessary during the recovery phase to assess pacemaker function. The nurse should be aware of the programmed rate and expected individual generator variations. The pacemaker insertion site is monitored for signs of infection. Analgesics are given for pain.

Pacemaker functions have become more sophisticated, and some models can adjust the heart rate to activity demands or be programmed for overdrive pacing or cardioversion.

Discharge teaching includes information about the signs and symptoms of infection, general wound care, and activity restrictions. Parents, and patients if they are old enough, should be taught to take a pulse and know the settings of the pacemaker. If the patient's low rate is set at 80 beats/min and the heart rate is only 68 beats/min, there is a possible problem with the pacemaker that needs to be investigated. Instructions for telephone transmission of ECG readings are also given. Telephone transmission can be used to transmit ECG strips and to monitor battery life and pacemaker function. The pacemaker generator will have to be replaced periodically because of battery depletion. Children with pacemakers should wear a MedicAlert device, and their parents should have a paper identification card with specific pacer data in case of an emergency. Cardiopulmonary resuscitation (CPR) instruction is suggested for parents.

Tachydysrhythmias. Sinus tachycardia (an abnormally fast heart rate) secondary to fever, anxiety, pain, anemia, dehydration, or any other etiologic factor requiring increased cardiac output should be ruled out before diagnosing an increased heart rate as pathologic. SVT is the most common tachydysrhythmia found in children and refers to a rapid regular heart rate of 200 to 300 beats/min. As many as one in 250 children experience SVT (Schlente, Boramanand, and Funk, 2008). The onset of SVT is often sudden, the duration is variable, and the rhythm may end abruptly and convert back to a normal sinus rhythm. Clinical signs in infants and young children are poor feeding, extreme irritability, and pallor. Children may experience palpitations, dizziness, chest pain, and diaphoresis. If SVT is sustained, signs of HF may be seen.

The treatment of SVT depends on the degree of compromise imposed by the dysrhythmia (see Critical Thinking Case Study). In some cases, vagal maneuvers, such as applying ice to the face, massaging the carotid artery (on one side of the neck only), or having an older child perform a Valsalva maneuver (e.g., exhaling against a closed glottis, blowing on a thumb as if it were a trumpet for 30 to 60 seconds), have terminated SVT. If vagal maneuvers fail or the child is hemodynamically unstable, adenosine (a drug that impairs AV conduction) may be used. Adenosine is given by rapid IV push with a saline bolus immediately after the drug because of its very short half-life. If this is unsuccessful or cardiac output is compromised, esophageal overdrive pacing or synchronized cardioversion (delivering an electrical shock to the heart) can be used in the intensive care setting. Sedation is needed for both procedures. Cardioversion should never be done in a conscious patient. More long-term pharmacologic treatment includes digoxin or possibly propranolol (Inderal) or amiodarone for severe or recurrent SVT.

A primary focus of nursing care is education of the family regarding the symptoms of SVT and its treatment. SVT may occur again despite therapy. Parents should be taught to take a radial pulse for a full minute. If medication is prescribed, instructions regarding accurate dosage and the importance of administering the correct dose at specified intervals are stressed.

Radiofrequency ablation has become first-line therapy for some types of SVT. The procedure is done in the cardiac catheterization laboratory and begins with mapping of the conduction system to identify the dysrhythmia focus. A catheter delivering radiofrequency current is directed at the site, and the area is heated to destroy the tissue in the area. These are lengthy procedures, often lasting 6 to 8 hours, and sedation or general anesthesia is required. Preparation is similar to that for cardiac catheterization. Another procedure,

CRITICAL THINKING CASE STUDY

Supraventricular Tachycardia

You are working in the emergency department when a father comes through the doors, crying, carrying his 1-month-old infant. The infant is awake and very irritable. The father reports that the infant has not been feeding well for the past 6 hours, and the father has noticed sweating (diaphoresis) with attempted feeds. No history of fever is noted. Further assessment reveals a diaphoretic, crying infant with a respiratory rate of 60 breaths/min, BP of 60/40 mm Hg, and heart rate that is too fast to count by auscultation. When the infant is attached to the cardiorespiratory monitor, the heart rate is 220 beats/min, nonvariable, with an oxygen saturation of 97%. Capillary refill time is slightly prolonged at 3 seconds, and femoral pulses are palpable but weak.

1. Evidence—Is there sufficient evidence to draw conclusions about this infant?
2. Assumptions—Describe an underlying assumption about each of the following:
   a. Symptoms associated with heart failure
   b. An infant younger than 3 months with poor feeding
   c. Tachydysrhythmias in infants
3. What priorities for nursing care should be established?
4. Does the evidence support your nursing interventions?

BP, Blood pressure.

cryoablation, is also used in treatment of SVT. Liquid nitrous oxide is used to cool a catheter to subfreezing temperatures, which then destroys the tissue of target by freezing.

Pulmonary Artery Hypertension

Pulmonary artery hypertension (PAH) describes a group of rare disorders that result in an elevation of pulmonary artery pressure above 25 mm Hg at rest after the neonatal period (Barst, 1999). These disorders are poorly understood, and until recently, there was no treatment beyond supportive care. PAH is a progressive, eventually fatal disease for which there is no known cure. It can be difficult to diagnose in the early stages. Often when patients become symptomatic and a diagnosis is made, their disease is rapidly progressing, treatment is unsuccessful, and death occurs within several years. There is now evidence of a genetic basis for some PAH; some mutations localized to chromosome 2 have been identified in about half of patients with familial PAH (Lane, Machado, Pauciulo, et al., 2000).

Pulmonary artery hypertension affects the small pulmonary arteries and is characterized by vascular narrowing leading to an increase in pulmonary vascular resistance. Generally, these abnormalities result in remodeling of the pulmonary circulation, characterized by occlusion of the lumen in medium and small pulmonary arteries because of cellular proliferation (Michelakis, Wilkins, and Rabinovitch, 2008). Why some children develop the disease and others do not is unclear. There are many possible causes of PAH. Cardiac causes occur primarily in patients with a large left-to-right shunt producing increased pulmonary blood flow. If these defects are not repaired early, the high pulmonary flow will cause changes in the pulmonary artery vessels and the vessels will lose their elasticity. Other causes of PAH include hypoxic lung diseases, thromboembolic diseases causing pulmonary vascular obstruction, collagen vascular diseases, and exposure to toxic substances. Many of the patients have no identifiable cause for PAH and have primary or idiopathic PAH.

Clinical Manifestations

The clinical manifestations include dyspnea with exercise, chest pain, and syncope. Dyspnea is the most common symptom and is caused by impaired oxygen delivery. Chest pain is the result of coronary ischemia in the right ventricle from severe hypertrophy. Syncope reflects a limited cardiac output leading to decreased cerebral blood flow. Right-sided heart dysfunction is steadily progressive, and when symptoms of venous congestion and edema are present, the prognosis is poor.

Therapeutic Management

Although no cure is known, several therapies have shown promise in slowing the progression of the disease and improving quality of life. In general, situations that may exacerbate the disease and cause hypoxia, such as exercise and high altitudes, are avoided. Supplemental oxygen, especially at night while sleeping, is commonly used to relieve hypoxia. Patients are at risk for thromboembolic events leading to pulmonary emboli, so anticoagulation with warfarin (Coumadin) is often prescribed.

Vasodilator therapy (which relaxes vascular smooth muscle and reduces pulmonary artery pressure) can prolong survival of patients with PAH. Oral calcium channel blockers have been successful in some children. Now available for patients who are nonresponders in vasodilator testing is a new oral drug, bosentan, an endothelin-receptor antagonist, that reduces pulmonary artery pressure and resistance and is safe and well tolerated in children (Barst, Ivy, Dingemanse, et al., 2003). It has been used in combination with IV prostacyclin.

Continuous IV prostacyclin has been used with some success in children who did not respond to oral therapy. Both of these therapies, although promising, have been used in only small numbers of patients and are expensive. Lung transplantation may be another treatment option.

Cardiomyopathy

Cardiomyopathy refers to abnormalities of the myocardium in which the cardiac muscle's ability to contract is impaired. Cardiomyopathies are relatively rare in children. Possible etiologic factors include familial or genetic causes, infection, deficiency states, metabolic abnormalities, and collagen vascular diseases. Most cardiomyopathies in children are considered primary or idiopathic, in which the cause is unknown and the cardiac dysfunction is not associated with systemic disease. Some of the known causes of secondary cardiomyopathy are anthracycline toxicity (the antineoplastic agents *doxorubicin* [Adriamycin] and *daunomycin*), hemochromatosis (from excessive iron storage), Duchenne muscular dystrophy, Kawasaki disease (KD), collagen diseases, and thyroid dysfunction.

Cardiomyopathies can be divided into three broad clinical categories according to the type of abnormal structure and dysfunction present: dilated cardiomyopathy, hypertrophic cardiomyopathy, and restrictive cardiomyopathy.

Dilated cardiomyopathy is characterized by ventricular dilation and greatly decreased contractility, resulting in symptoms of HF. This is the most common type of cardiomyopathy in children. Its cause is often unknown. The clinical findings are of HF with tachycardia, dyspnea, hepatosplenomegaly, fatigue, and poor growth. Dysrhythmias may be present and may be more difficult to control with worsening HF.

Hypertrophic cardiomyopathy is characterized by an increase in heart muscle mass without an increase in cavity size, usually occurring in the left ventricle and associated with abnormal diastolic filling. It is a familial autosomal dominant genetic abnormality in

most cases and is probably the most common genetically transmitted cardiovascular disease (Maron, 2001). The expression of clinical disease varies greatly among patients. Clinical symptoms usually appear in the school-age period or adolescence and may include anginal chest pain, dysrhythmias, and syncope. One recent study confirmed that unexplained syncope in the childhood age-group (younger than 18 years) with known hypertrophic cardiomyopathy had a 60% cumulative risk for sudden death within 5 years of the syncopal event (Spirito, Autore, Rapezzi, et al., 2009). Presentation in infancy includes signs of HF and has a poor prognosis. The ECG demonstrates left ventricular hypertrophy, often with ST-T changes. The echocardiogram is most helpful and demonstrates asymmetric septal hypertrophy and an increase in left ventricular wall thickness, with a small left ventricle cavity.

Restrictive cardiomyopathy, which is rare in children, describes a restriction to ventricular filling caused by endocardial or myocardial disease or both. It is characterized by diastolic dysfunction and absence of ventricular dilation or hypertrophy. Symptoms are similar to those of HF (see p. 1331).

Therapeutic Management

Treatment is directed toward correcting the underlying cause whenever feasible. However, in most affected children, this is not possible and treatment is aimed at managing HF (p. 1332) and dysrhythmias. Digoxin, diuretics, and aggressive use of afterload reduction agents have been found to be helpful in managing symptoms in those with dilated cardiomyopathy. Practice guidelines for the management of HF in children have recently been outlined and provide an in-depth review of available therapies (Rosenthal, Chrisant, Edens, et al., 2004). Digoxin and inotropic agents are usually not helpful in the other forms of cardiomyopathy because increasing the force of contraction may exacerbate the muscular obstruction and actually impair ventricular ejection. β-Blockers such as propranolol and calcium channel blockers such as verapamil (Calan) have been used to reduce left ventricular outflow obstruction and improve diastolic filling in those with hypertrophic cardiomyopathy.

Careful monitoring and treatment of dysrhythmias are essential. The placement of an automatic implantable cardioverter defibrillator (AICD) should be considered for patients at high risk for sudden death because of ventricular dysrhythmias. Anticoagulants may be given to reduce the risk for thromboemboli, a complication of the sluggish circulation through the heart. For worsening HF and signs of poor perfusion, IV inotropic or vasodilating drugs may be needed. Severely ill children may require mechanical ventilation, oxygen administration, and IV medications. Heart transplantation may be a treatment option for patients who have worsening symptoms despite maximum medical therapy.

CARE MANAGEMENT

Because of the poor prognosis in many children with cardiomyopathy, nursing care is consistent with that for any child with a life-threatening disorder (see Chapter 36). One of the most difficult adjustments for the child (especially normally active youngsters with hypertrophic cardiomyopathy) may be the realization of failing health and the need for restricted activity. The child should be included in decisions regarding activity and allowed to discuss feelings, particularly if the disease follows a progressively fatal course. After symptoms of HF or dysrhythmias develop, the same nursing interventions are implemented as discussed on p. 1333. If heart transplantation is considered, the needs of the child and family are great in terms of psychologic preparation and postoperative care. The nurse plays an important role in assessing the family's understanding of the procedure and long-term consequences. Children of school age and older should be fully informed to give their assent to the procedure (see Informed Consent, Chapter 39).

HEART TRANSPLANTATION

Heart transplantation has become a treatment option for infants and children with worsening HF and a limited life expectancy despite maximum medical and surgical management. Indications for heart transplantation in children are cardiomyopathy and end-stage CHD. It is also an option for patients with some forms of complex congenital cardiac defects, such as hypoplastic left heart syndrome, for whom conventional surgical approaches have a high mortality rate.

The heart transplant procedure may be orthotopic or heterotopic. Orthotopic heart transplantation refers to removing the recipient's own heart and implanting a new heart from a donor who has had brain death but a healthy heart. The donor and recipient are matched by weight and blood type. Heterotopic heart transplantation refers to leaving the recipient's own heart in place and implanting a new heart to act as an additional pump, or "piggyback" heart; this type of transplant is rarely done in children.

Before transplantation, potential recipients undergo a careful cardiac evaluation to determine if there are any other medical or surgical options to improve the patient's cardiac status. Other organ systems are assessed to identify problems that might increase the risk of or preclude transplantation. A psychosocial evaluation of the patient and family is done to assess family function, support systems, and ability to comply with the complex medical regimen after the transplant. Support services to help the family successfully care for their child are provided when possible. Parents and older adolescents need extensive education about the risks and benefits of transplantation so they can make an informed decision. Patients are listed on a national computer network organized by the United Network for Organ Sharing to match donors and recipients. (See also Organ or Tissue Donation and Autopsy, Chapter 36.)

According to the Scientific Registry of Transplant Recipients, the number of pediatric candidates active on the waiting list was 134 in 2009, (SRTR, 2011). The 1-year graft survival rate for pediatric heart transplants performed in 2008 was 87.5% (SRTR, 2011).

Waiting list mortality remains high, particularly in the smallest children. Recent progress in suitable ventricular assist devices for use in children as a bridge to transplantation has made outcomes to survival for cardiac transplantation more successful (Blume, Naftel, Bastardi, et al., 2006). A multicenter study using the U.S. Scientific Registry of Transplant Recipients was recently conducted (Almond, Thiagarajian, Piercy, et al., 2009). Among 3098 children listed for a heart transplant between 1999 and 2006, the median age was 2 years. Of those children, 60% were listed as a top status (30% ventilated and 18% on supportive measures), and of those children, 17% died, 63% received transplants, 8% recovered, and 12% remained listed. These numbers concluded that waiting time in the United States remains high in the current era and high risk groups in these categories could benefit from emerging cardiac assist devices, such as extracorporeal membrane oxygenation and ventricular assist devices.

The posttransplant course is complex. Although heart function is greatly improved or normal after transplantation, the risk for rejection is serious. The leading cause of death in the first 3 years after heart transplantation is rejection, with the greatest risk in the first 6 months (Blume, 2003). Rejection of the heart is diagnosed

primarily by endomyocardial biopsy in older children. Serial echocardiograms are often used in infants and young children to reduce the need for invasive biopsies. Immunosuppressants must be taken for life and have many systemic side effects. Triple-drug therapy for immunosuppression with a calcineurin inhibitor (cyclosporine or tacrolimus), steroids, and azathioprine is most commonly used in pediatric patients, although mycophenolate mofetil is being used more frequently and replacing azathioprine. Steroids are weaned in the first year and may be discontinued in some patients.

Infection is always a risk. Potential long-term problems that may limit survival include chronic rejection, causing coronary artery disease; renal dysfunction and hypertension resulting from cyclosporine administration; lymphoma; and infection. Coronary artery disease is the leading cause of death among late survivors of heart transplantation (Boucek, Aurora, Edwards, et al., 2007). In the short term, after successful transplantation, children are able to return to full participation in age-appropriate activities and appear to adapt well to their new lifestyle. Transplantation is not a cure because patients must live with the lifetime consequences of chronic immunosuppression.

CARE MANAGEMENT

Successfully caring for a child after a heart transplant requires the expertise and dedication of many members of the health care team. Nurses play vital roles in assessment, coordination of care, psychosocial support, and patient and family education. The heart transplant recipient must be carefully monitored for signs of rejection, infection, and the side effects of the immunosuppressant medications. The patient's and family's psychosocial well-being also need to be assessed to identify issues such as increased family stress, depression, substance abuse, and school problems. Noncompliance with an intense medication regimen, especially during adolescence, can lead to serious medical problems and can be fatal.

The first 6 months to 1 year after the transplant are most intense because the risk for complications is greatest and the patient and family are adjusting to a new lifestyle. Patients are monitored closely by the health care team, with frequent visits and laboratory tests. Care is usually shared between local health care providers and the transplant center. Many patients are able to return to school and other age-appropriate activities within 2 to 3 months after the transplant.

VASCULAR DYSFUNCTION

Systemic Hypertension

Hypertension is defined as the consistent elevation of BP beyond values considered to be the upper limits of normal. The two major categories are essential hypertension (no identifiable cause) and secondary hypertension (subsequent to an identifiable cause). In recent years, there has been increasing interest in this disorder in adolescents and children. Hypertension in children and adolescents is defined as having a systolic or diastolic BP that consistently falls at or over the 95th percentile. This group is further delineated as follows:

- **Stage 1 hypertension** includes patients who have BP readings between the 95th and 99th percentiles.
- **Stage 2 hypertension** includes patients with BP readings over the 99th percentile plus 5 mm Hg.

An additional group includes children and adolescents who have prehypertension (or high-normal BP). This prehypertensive group includes those with BP readings that fall consistently between the 90th and 95th percentiles. The *Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents* outlines in detail the identification, testing, and treatment recommendations for young people with high BP (National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004).

Etiology

Most instances of hypertension observed in young children occur secondary to a structural abnormality or an underlying pathologic process, although this is being challenged by screening programs of relatively healthy children. The most common cause of secondary hypertension is renal disease, followed by cardiovascular, endocrine, and some neurologic disorders. As a rule, the younger the child and the more severe the hypertension, the more likely it is to be secondary.

The causes of essential hypertension are undetermined, but evidence indicates that both genetic and environmental factors play a role. The incidence of hypertension has been shown to be higher in children whose parents are hypertensive. African Americans have a higher incidence of hypertension than Caucasians; in African Americans, it develops earlier, is frequently more severe, and results in death at an earlier age. Environmental factors that contribute to the risk for developing hypertension include obesity, salt ingestion, smoking, and stress.

Diagnostic Evaluation

Because of the increasing numbers of hypertensive or potentially hypertensive children and adolescents being identified, a BP determination should be a routine part of annual assessment in healthy children older than 3 years. BP readings should be done in children younger than 3 years who have high risk family histories or those with individual risk factors, including CHD, kidney disease, malignancy, transplant, certain neurologic problems, or systemic illnesses known to cause hypertension. Although clinical manifestations associated with hypertension depend largely on the underlying cause, some observations can provide clues to the examiner that an elevated BP may be a factor (Box 42-10). In infants and very young children who cannot communicate symptoms, observation of behavior provides clues, although gross behavioral changes may not be apparent until complications are present.

No definitive cutoff values are used in the diagnosis of hypertension in the pediatric patient. The *Fourth Report on the Diagnosis, Evaluation, and Treatment of High Blood Pressure in Children and Adolescents* (National High Blood Pressure Education Program Working Group on High Blood Pressure in Children and Adolescents, 2004) provides normative data for children (see Appendix C). BP tables now include the 50th, 90th, 95th, and 99th percentiles for BP readings based on age, gender, and height percentiles.

BOX 42-10 CLINICAL MANIFESTATIONS OF HYPERTENSION

Adolescents and Older Children	Infants or Young Children
• Frequent headaches	• Irritability
• Dizziness	• Head banging or head rubbing
• Changes in vision	• Waking up screaming in the night

These guidelines are based on auscultatory readings, and therefore this is currently the preferred method of assessment. These charts take into account differences in body height. It is therefore important to note that a child who is large for his or her age may normally have a higher BP than a child of average size. Before a diagnosis is made, BP should be measured on at least three separate occasions. An ambulatory BP monitor may be ordered if "white-coat hypertension" is suspected. These are useful in that they provide BP readings over a 24-hour period. There are different normative values for ambulatory BP readings (Urbina, Alpert, Flynn, et al., 2008).

A careful medical history and family history should be obtained to screen for other relatives with hypertension or other cardiovascular risk factors. In children with suspected hypertension, initial laboratory data include a urinalysis, renal function studies such as creatinine and blood urea nitrogen, a lipid profile, complete blood count, and electrolytes. Depending on the severity of hypertension, additional testing may be indicated. Testing may include a retinal examination, renal ultrasonography to measure kidney size and Doppler flow to detect the possibility of a renal causes, and an ECG and an echocardiogram to evaluate the presence of end-organ involvement such as left ventricular hypertrophy. Further testing for a secondary cause may be indicated based on individual circumstances, especially in children with significant hypertension and normal initial screening test findings.

Therapeutic Management

Therapy for secondary hypertension involves diagnosis and treatment of the underlying cause. Children and adolescents with consistently elevated BP readings from no known cause or those with secondary hypertension not amenable to surgical correction may be treated with a combination of nonpharmacologic and pharmacologic interventions. Dietary practices and lifestyle changes are important in the control of hypertension both for children and for adults. Nonpharmacologic measures, such as weight control in overweight patients, increased exercise, limited salt intake, and avoidance of stress and smoking, carry no risk and should be instituted as first-line therapy except in severe cases in which pharmacologic therapy may be indicated as well.

Drug therapy is instituted with caution in children with significant elevations of BP resistant to nonpharmacologic intervention. The treatment should begin with one drug and should add other drugs if control is not obtained. The oral antihypertensive drugs used in children include the β-blockers, ACE inhibitors, calcium channel blockers, angiotensin-receptor blockers, and diuretics. The goal is to achieve a normotensive state throughout the day without accompanying drug side effects.

CARE MANAGEMENT

Blood pressure measurement should always be a part of the routine assessment of children older than 3 years and patients younger than 3 years who are considered to be at high risk for hypertension. To obtain an accurate reading, care is taken to quiet the child or relax the adolescent while the measurement is recorded to avoid false readings caused by excitement. BP should be measured in the sitting position with the arm at the level of the heart. Initial evaluation should also include four extremity pressures (in the supine position) to rule out coarctation of the aorta. The chief cause of falsely elevated BP readings is the use of improperly fitting, narrow cuffs. Therefore attention to correct measurement technique is essential (see Blood Pressure, Chapter 29).

Home BP measurements can facilitate surveillance in youngsters with chronic hypertension and can document the effectiveness of therapy. A family member can be instructed in how to take and record accurate BP measurements, thus decreasing the number of trips to a health care facility. This individual needs to understand when to contact the health care practitioner regarding elevated values. The school nurse can often be a valuable resource in monitoring BP. The nurse plays an important role in assessing individual families and providing targeted information regarding nonpharmacologic modes of intervention, such as diet, weight loss, smoking cessation, and exercise programs. If extensive dietary counseling is required, the child should be referred to a nutritionist with expertise in working with children and adolescents. Exercise regimens should be individualized but should emphasize the benefits of regular aerobic exercise. Schoolchildren and young adolescents generally prefer team sports rather than individual training, which they may view as a burden rather than an enjoyable activity. If peers and family members can be encouraged to participate in any of the management strategies, the child's compliance is likely to be greater.

If drug therapy is prescribed, the nurse needs to provide information to the family regarding the reasons for it, how the drug works, and possible side effects. General instructions for antihypertensive drugs include:

- Rise slowly from a horizontal position, and avoid sudden position changes.
- Take drugs as prescribed.
- Maintain adequate hydration.
- Notify the health care practitioner if unpleasant side effects occur, but do not discontinue the drug.
- Avoid alcohol, and stay on the prescribed diet.

The need for follow-up is stressed, especially because antihypertensive therapy can sometimes be safely discontinued if BP remains under control over time.

Kawasaki Disease (Mucocutaneous Lymph Node Syndrome)

Kawasaki disease is an acute systemic vasculitis of unknown cause. It is seen in every racial group, and about 75% of the cases occur in children younger than 5 years, with peak incidence in the toddler age-group. The acute disease is self-limited; however, without treatment, approximately 20% of children develop coronary artery dilation or aneurysm formation. Infants younger than 1 year are most seriously affected by KD and are at the greatest risk for heart involvement, although an increased incidence has also been reported in older children, perhaps because of later diagnosis in many.

The etiology of KD is unknown. It is not spread by person-to-person contact; however, several factors support infectious etiologic factors. It is often seen in geographic and seasonal outbreaks, with most cases reported in the late winter and early spring (Newburger, Takahashi, Gerber, et al., 2004).

Pathophysiology

The principal area of concern in KD is the cardiovascular system. During the initial stage of the illness, extensive inflammation of the arterioles, venules, and capillaries occurs, causing many of the clinical symptoms. In addition, segmental damage to the medium-size muscular arteries, mainly the coronary arteries, can occur, resulting in the formation of coronary artery aneurysms in some children. When death occurs, which is very rare (in <0.17% of cases), it is usually the result of myocardial ischemia from coronary thrombosis or, years later, from severe scar formation and stenosis in coronary aneurysms (Wilder, Palinkas, Kao, et al., 2007).

BOX 42-11 DIAGNOSTIC CRITERIA FOR KAWASAKI DISEASE

Child must have fever for more than 5 days along with four of five clinical criteria (diagnosis may be made on day 4 by an experienced clinician if child has all the clinical criteria):

1. Changes in the extremities: in the acute phase, edema, erythema of the palms and soles; in the subacute phase, periungual desquamation (peeling) of the hands and feet
2. Bilateral conjunctival injection (inflammation) without exudation
3. Changes in the oral mucous membranes, such as erythema of the lips, oropharyngeal reddening; or "strawberry tongue" (large papillae are exposed)
4. Polymorphous rash
5. Cervical lymphadenopathy (one lymph node >1.5 cm)

NOTE: Kawasaki disease can be diagnosed with fewer clinical criteria when coronary artery changes are noted.

Clinical Manifestations

Because no specific diagnostic test exists for KD, the diagnosis is established on the basis of clinical findings and associated laboratory results (Box 42-11). These criteria should be used as guidelines. It is important to note that many children with KD do not fulfill standard diagnostic criteria and infants often have an incomplete presentation. It is therefore important to consider KD as a possible diagnosis in any infant or child with prolonged elevated temperature that is unresponsive to antibiotics and is not attributable to another cause.

Kawasaki disease manifests in three phases: acute, subacute, and convalescent. The acute phase begins with the abrupt onset of a high fever that is unresponsive to antibiotics and antipyretics. The child then develops the remaining diagnostic symptoms. Symptoms may come and go and are not always present simultaneously, although the fever is persistent throughout. During this stage, the child is typically *very* irritable. The subacute phase begins with resolution of the fever and lasts until all clinical signs of KD have disappeared. During this phase, the child is at greatest risk for the development of coronary artery aneurysms. Echocardiograms are used to monitor myocardial and coronary artery status. A baseline echocardiogram should be obtained at the time of diagnosis for comparison with future studies. Irritability persists during this phase. In the convalescent phase, all of the clinical signs of KD have resolved but the laboratory values have not returned to normal. This phase is complete when all blood values are normal (6-8 weeks after onset). At the end of this stage, the child has regained his or her usual temperament, energy, and appetite.

Cardiac Involvement. Long-term complications of KD include the development of coronary artery aneurysms, disrupting blood flow. Children with larger aneurysms have the potential for myocardial infarction, which can result from thrombotic occlusion of a coronary aneurysm. Affected coronary arteries dilate progressively, reaching their maximum diameter approximately 1 month from the onset of fever. Over time, as the damaged vessel tries to heal, stenosis of the aneurysm may develop and may lead to myocardial ischemia. Most of the morbidity and mortality occur in children affected with the largest aneurysms (giant aneurysms >8 mm or z-score >10). Symptoms of acute myocardial infarction in children are often confusing and may include abdominal pain, vomiting, restlessness, inconsolable crying, pallor, and shock, as well as chest pain or pressure (noted less in younger children). In the initial phase of the illness, children with KD may have signs or symptoms related to inflammation of the myocardium, including myocarditis, valvulitis, or dysrhythmias.

Therapeutic Management

The current treatment of children with KD includes high-dose IV gamma globulin (IVGG) along with salicylate therapy. IVIG has been demonstrated to be effective at reducing the incidence of coronary artery abnormalities when given within the first 10 days of the illness and ideally in the first 7 days of illness. A single, large infusion of 2 g/kg over 10 to 12 hours is recommended. Retreatment with IV gamma globulin is indicated in patients who continue with fever after treatment.

Aspirin is given initially in an antiinflammatory dose (80-100 mg/kg/day in divided doses every 6 hours) to control fever and symptoms of inflammation. After fever has subsided, aspirin is continued at an antiplatelet dose (3-5 mg/kg/day). Low-dose aspirin is continued in patients without echocardiographic evidence of coronary abnormalities until the platelet count has returned to normal (6-8 weeks). If the child develops coronary abnormalities, salicylate therapy is continued indefinitely. Additional anticoagulation (e.g., clopidogrel [Plavix], enoxaparin [Lovenox], or warfarin) may be indicated in children who have medium-size or giant coronary artery aneurysms.

Prognosis. Most children with KD recover fully after treatment. However, when cardiovascular complications occur, serious morbidity may result. The prognosis for patients is strongly related to the extent of coronary damage, with patients who have giant aneurysms being at the highest risk for complications.

CARE MANAGEMENT

In the initial phase, the nurse must monitor the child's cardiac status carefully. Intake and output and daily weight measurements are recorded. Although the child may be reluctant to eat and therefore may be partially dehydrated, fluids need to be administered with care because of the usual finding of myocarditis. The child should be assessed frequently for signs of HF, including decreased urinary output, gallop rhythm (an additional heart sound), tachycardia, and respiratory distress.

Administration of IVIG should follow the same guidelines as for any blood product, with frequent monitoring of vital signs. Patients must be watched for allergic reactions. Cardiac status must be monitored because of the large volume being administered to patients who may have diminished left ventricular function.

The majority of nursing care focuses on symptomatic relief. To minimize skin discomfort, cool cloths, unscented lotions, and soft, loose clothing are helpful. During the acute phase, mouth care, including lubricating ointment to the lips, is important for mucosal inflammation. Clear liquids and soft foods can be offered.

Patient irritability is perhaps the most challenging problem. These children need a quiet environment that promotes adequate rest. Their parents need to be supported in their efforts to comfort an often inconsolable child. They may need time away from their child, and nurses can often provide respite care for the family. Parents need to understand that irritability is a hallmark of KD and that they need not feel guilty or embarrassed about their child's behavior.

Discharge Teaching. Parents need accurate information about the progression of KD, including the importance of follow-up monitoring and when they should contact their health care practitioner. Irritability is likely to persist for up to 2 months after the

onset of symptoms. Periungual desquamation (peeling of the hands and feet) begins in the second and third weeks. Usually the fingers peel first, followed by the feet. The peeling is painless, but the new skin may be tender. Arthritis, especially of the larger weight-bearing joints, may occur and persist for several weeks, although it is temporary. Children are typically most stiff in the mornings, during cold weather, and after naps. Passive range-of-motion exercises in the bathtub are often helpful in increasing flexibility. Any live immunizations (e.g., measles, mumps, and rubella; varicella) should be deferred for 11 months after the administration of gamma globulin because the body might not produce the appropriate amount of antibodies to provide lifelong immunity. The decision to give the varicella (chickenpox) vaccine while the child is receiving aspirin therapy is made individually by the health care practitioner. Temperature should be recorded after discharge, and the occurrence of fever should be communicated to the health care provider.

Parents of children with large aneurysms should be educated as to the unlikely but real possibility of myocardial infarction, as well as the signs and symptoms of cardiac ischemia in a child. At discharge, the ultimate cardiac sequelae are generally not fully known because vessels do not reach their maximum diameter until 4 to 6 weeks after the onset of KD. CPR should be taught to parents of children with known severe coronary artery sequelae.

Long-Term Follow-up. The frequency and type of follow-up are based on the presence or absence of coronary damage. The long-term outlook for children without aneurysms is promising. After more than 30 years of follow-up, an increased incidence of early heart disease is not being seen in this population. However, the literature regarding subtle effects of inflammation on the vessels is conflicting, and it is recommended that these children be screened and treated for the presence of coronary risk factors as they grow older. They should have a cholesterol screen performed, BP monitored, and education recommending a heart-healthy lifestyle, including exercise, a heart-healthy diet, and avoidance of smoking. This group of patients is seen at infrequent intervals—approximately every 5 years depending on the institution. In patients with aneurysms, follow-up focuses on the prevention and early detection of coronary ischemia in patients. Noninvasive modalities of coronary imaging, such as cardiac computed tomography angiography, magnetic resonance imaging, echocardiography, and stress testing, are used as much as possible. Patients with coronary aneurysms may require long-term antiplatelet or anticoagulation and possibly β-blocker therapy or other therapies, depending on the severity of coronary involvement.

Shock

Shock, or circulatory failure, is a complex clinical syndrome characterized by inadequate tissue perfusion to meet the metabolic demands of the body, resulting in cellular dysfunction and eventual organ failure. Although the causes are different, the physiologic consequences are the same and include hypotension, tissue hypoxia, and metabolic acidosis. Circulatory failure in children is a result of hypovolemia, altered peripheral vascular resistance, or pump failure. Types of shock are listed in Box 42-12.

Pathophysiology

A healthy child's circulatory system is able to transport oxygen and metabolic substrates to body tissues, which require a constant source for these essential needs. The cardiac output and distribution to the various body tissues can change rapidly in response to intrinsic (myocardial and intravascular) or extrinsic (neuronal) control mechanisms. In shock states, these mechanisms are altered or challenged.

Reduced blood flow, as in hypovolemic shock, causes diminished venous return to the heart, low CVP, low cardiac output, and hypotension. Vasomotor centers in the medulla are signaled, causing a compensatory increase in the force and rate of cardiac contraction and constriction of arterioles and veins, thereby increasing peripheral vascular resistance. Simultaneously, the lowered blood volume leads to the release of large amounts of catecholamines, antidiuretic hormone, adrenocorticosteroids, and aldosterone in an effort to conserve body fluids. This causes reduced blood flow to the skin, kidneys, muscles, and viscera to shunt the available blood to the brain and heart. Consequently, the skin feels cold and clammy, there

BOX 42-12 TYPES OF SHOCK

Hypovolemic

Characteristics

- Reduction in size of vascular compartment
- Falling blood pressure
- Poor capillary filling
- Low CVP

Most Frequent Causes

- Blood loss (hemorrhagic shock)—Trauma, gastrointestinal bleeding, intracranial hemorrhage
- Plasma loss—Increased capillary permeability associated with sepsis and acidosis, hypoproteinemia, burns, peritonitis
- Extracellular fluid loss—Vomiting, diarrhea, glycosuric diuresis, sunstroke

Distributive

Characteristics

- Reduction in peripheral vascular resistance
- Profound inadequacies in tissue perfusion
- Increased venous capacity and pooling
- Acute reduction in return blood flow to the heart
- Diminished cardiac output

Most Frequent Causes

- Anaphylaxis (anaphylactic shock)—Extreme allergy or hypersensitivity to a foreign substance
- Sepsis (septic shock, bacteremic shock, endotoxic shock)—Overwhelming sepsis and circulating bacterial toxins
- Loss of neuronal control (neurogenic shock)—Interruption of neuronal transmission (spinal cord injury)
- Myocardial depression and peripheral dilation—Exposure to anesthesia or ingestion of barbiturates, tranquilizers, opioids, antihypertensive agents, or ganglionic blocking agents

Cardiogenic

Characteristic

- Decreased cardiac output

Most Frequent Causes

- After surgery for congenital heart disease
- Primary pump failure—Myocarditis, myocardial trauma, biochemical derangements, heart failure
- Dysrhythmias—Supraventricular tachycardia, atrioventricular block, and ventricular dysrhythmias; secondary to myocarditis or biochemical abnormalities (occasionally)

CVP, Central venous pressure.

is poor capillary filling, and glomerular filtration rate and urinary output are significantly reduced.

As a result of impaired perfusion, oxygen is depleted in the tissue cells, causing them to revert to anaerobic metabolism, producing lactic acidosis. The acidosis places an extra burden on the lungs as they attempt to compensate for the metabolic acidosis by increasing the respiratory rate to remove excess carbon dioxide. Prolonged vasoconstriction results in fatigue and atony of the peripheral arterioles, which leads to vessel dilation. Venules, which are less sensitive to vasodilator substances, remain constricted for a time, causing massive pooling in the capillary and venular beds, which further depletes blood volume.

Complications of shock create further hazards. CNS hypoperfusion may eventually lead to cerebral edema, cortical infarction, or intraventricular hemorrhage. Renal hypoperfusion causes renal ischemia with possible tubular or glomerular necrosis and renal vein thrombosis. Reduced blood flow to the lungs can interfere with surfactant secretion and result in acute respiratory distress syndrome, which is characterized by sudden pulmonary congestion and atelectasis with formation of a hyaline membrane. Gastrointestinal tract bleeding and perforation are always possibilities after splanchnic ischemia and necrosis of intestinal mucosa. Metabolic complications of shock may include hypoglycemia, hypocalcemia, and other electrolyte disturbances.

Diagnostic Evaluation

The etiology of shock can be discerned from the history and the physical examination. The severity of the shock is determined by measurements of vital signs, including CVP and capillary filling (Box 42-13). Shock can be regarded as a form of compensation for circulatory failure. Because of the progressive nature of shock, it can be divided into the following three stages or phases:

1. **Compensated shock**—Vital organ function is maintained by intrinsic compensatory mechanisms; blood flow is usually normal or increased but generally uneven or maldistributed in the microcirculation.
2. **Decompensated shock**—Efficiency of the cardiovascular system gradually diminishes until perfusion in the microcirculation becomes marginal despite compensatory adjustments. The outcomes of circulatory failure that progress beyond the limits of compensation are tissue hypoxia, metabolic acidosis, and eventual dysfunction of all organ systems.
3. **Irreversible, or terminal, shock**—Damage to vital organs, such as the heart or brain, is of such magnitude that the entire organism will be disrupted regardless of therapeutic intervention. Death occurs even if cardiovascular measurements return to normal levels with therapy.

At all stages, the principal differentiating signs are observed in the (1) degree of tachycardia and perfusion to the extremities, (2) level of consciousness, and (3) BP. Additional signs or modifications of these more universal signs may be present depending on the type and cause of the shock. Initially, the child's ability to compensate is effective; therefore early signs are subtle. As the shock state advances, signs are more obvious and indicate early decompensation.

Additional signs may be present, depending on the type and cause of the shock. In early septic shock, there are chills, fever, and vasodilation, with increased cardiac output that results in warm, flushed skin (hyperdynamic, or "hot," shock). A later and ominous development is disseminated intravascular coagulation (DIC) (see Chapter 43)—the major hematologic complication of septic shock. Anaphylactic shock is frequently accompanied by urticaria and angioneurotic edema, which is life threatening when it involves the respiratory passages (see Anaphylaxis, below).

Laboratory tests that assist in assessment are blood gas measurements, pH, and sometimes liver function tests. Coagulation tests are evaluated when there is evidence of bleeding, such as oozing from a venipuncture site, bleeding from any orifice, or petechiae. Cultures of blood and other sites are indicated when there is a high suspicion of sepsis. Renal function tests are performed when impaired renal function is evident.

BOX 42-13 CLINICAL MANIFESTATIONS OF SHOCK

Compensated
- Apprehensiveness
- Irritability
- Unexplained tachycardia
- Normal blood pressure
- Narrowing pulse pressure
- Thirst
- Pallor
- Diminished urinary output
- Reduced perfusion of extremities

Decompensated
- Confusion and somnolence
- Tachypnea
- Moderate metabolic acidosis
- Oliguria
- Cool, pale extremities
- Decreased skin turgor
- Poor capillary filling

Irreversible
- Thready, weak pulse
- Hypotension
- Periodic breathing or apnea
- Anuria
- Stupor or coma

Therapeutic Management

Treatment of shock consists of three major interventions: (1) ventilation, (2) fluid administration, and (3) improvement of the pumping action of the heart (vasopressor support). The first priority is to establish an airway and administer oxygen. After the airway is ensured, circulatory stabilization is the major concern. Establishment of adequate IV access, ideally with multilumen central lines, is essential to deliver fluids and medications.

Ventilatory Support. The lung is the organ that is most sensitive to shock. Decreased distribution or redistribution of blood flow to respiratory muscles plus the increased work of breathing can rapidly lead to respiratory failure. Critically ill patients are unable to maintain an adequate airway. To place the lung at rest and improve ventilation, tracheal intubation is initiated early with positive-pressure ventilation. Supplemental oxygen is always given as soon as possible. Blood gases and pH are monitored frequently.

Increased extravascular lung water caused by edema contributes to the development of respiratory complications. Therapy is directed toward maintaining normal arterial blood gas measurements, normal acid-base balance, and circulation. Efforts are made to remove fluid and prevent its accumulation with the use of diuretics.

Cardiovascular Support. In most cases, rapid restoration of blood volume is all that is needed for resuscitation of the child in shock. An isotonic crystalloid solution (normal saline or lactated Ringer's) is the fluid of choice; colloids such as albumin are also used. Successful resuscitation is reflected by an increase in BP and a reduction in heart rate; increased cardiac output results in improved capillary circulation and skin color. CVP measurements of right atrial pressure help guide fluid therapy, and urinary output measurement is an important indicator of adequacy of circulation.

Correction of acidosis, hypoxemia, hypoglycemia, hypothermia, and any metabolic derangements is mandatory.

Temporary pharmacologic support may be required to enhance myocardial contractility, reverse metabolic or respiratory acidosis, and maintain arterial pressure. The principal agents used to improve cardiac output and circulation are catecholamines, such as dopamine (Intropin) and epinephrine (Adrenalin). Vasodilators that are sometimes used include nitroprusside (Nipride) and milrinone.

CARE MANAGEMENT

The child who is in shock requires intensive observation and care. *The initial action is to ensure adequate tissue oxygenation.* The nurse should be prepared to administer oxygen by the appropriate route and to assist with any intubation and ventilatory procedures indicated. Other procedures and activities that require immediate attention are establishing an IV line, weighing the child, obtaining baseline vital signs, placing an indwelling catheter, obtaining blood gases and other measurements, and administering medications as indicated. The child is best positioned flat with the legs elevated.

! NURSING ALERT

Early clinical signs of shock include apprehension, irritability, normal BP, narrowing pulse pressure (difference between diastolic and systolic BP), thirst, pallor, diminished urinary output, unexplained mild tachycardia, and decreased perfusion of the hands and feet.

The nurse's responsibilities are to monitor the IV infusion, intake and output, vital signs (including CVP), and general systems assessments on a routine basis. IV medications are titrated according to patient responses, and vital signs are taken every 15 minutes during the critical periods and thereafter as needed. Urinary output is measured hourly; blood gases, hematocrit, pH, and electrolytes are monitored frequently to assess the child's status and the efficacy of therapy. An apnea and cardiac monitor is attached and monitored continuously. In the initial stages of acute shock, more than one nurse is often needed to manage all of the necessary activities that must be carried out simultaneously (see Emergency box).

Throughout the intense activity, support for the family must not be overlooked. Someone should contact family members at frequent intervals to inform them about what is being done and whether there is any progress. Ideally, someone should remain with the parents to serve as a liaison between them and the intensive care team. However, this is not always feasible in such a critical situation. As soon as possible, the family should be allowed to see the child. A member of the clergy or a social worker may be called to help provide comfort and support.

EMERGENCY

Shock

Ventilation
- Establish airway; be prepared for intubation.
- Administer oxygen, usually 100% by mask.

Fluid Administration
- Restore fluid volume as ordered.

Cardiovascular Support
- Administer vasopressors (epinephrine 1:1000, 0.01 mg/kg subcutaneously; maximum dose of 0.5 mg; may repeat if needed).

General Support
- Keep child flat with legs raised above level of heart.
- Keep child warm and calm.

Anaphylaxis

Anaphylaxis is the acute clinical syndrome resulting from the interaction of an allergen and a patient who is hypersensitive to that allergen. When the antigen enters the circulatory system, a generalized reaction rapidly takes place. Vasoactive amines (principally histamine or a histamine-like substance) are released and cause vasodilation, bronchoconstriction, and increased capillary permeability.

Severe reactions are immediate in onset; are often life threatening; and frequently involve multiple systems, primarily the cardiovascular, respiratory, gastrointestinal, and integumentary systems. Exposure to the antigen can be by ingestion, inhalation, skin contact, or injection. Examples of common allergens associated with anaphylaxis include drugs (e.g., antibiotics, chemotherapeutic agents, radiologic contrast media), latex, foods, venom from bees or snakes, and biologic agents (antisera, enzymes, hormones, blood products).

SAFETY ALERT

Penicillin allergy is associated with immediate onset (within 1 hour of administration) or accelerated onset (1-72 hours after administration) of skin eruption, especially a urticarial rash, or more serious symptoms such as laryngeal edema or anaphylactic shock.

Clinical Manifestations

The onset of clinical symptoms usually occurs within seconds or minutes of exposure to the antigen, and the rapidity of the reaction is directly related to its intensity: the sooner the onset, the more severe the reaction. The reaction may be preceded by symptoms of uneasiness, restlessness, irritability, severe anxiety, headache, dizziness, paresthesia, and disorientation. The patient may lose consciousness. Cutaneous signs of flushing and urticaria are common early signs, followed by angioedema, most notable in the eyelids, lips, tongue, hands, feet, and genitalia.

Bronchiolar constriction may follow, causing narrowing of the airway; pulmonary edema and hemorrhage also may occur. Laryngeal edema with severe acute upper airway obstruction may be life threatening and requires rapid intervention. Shock occurs as a result of mediator-induced vasodilation, which causes capillary permeability and loss of intravascular fluid into the interstitial space. Sudden hypotension and impaired cardiac output with poor perfusion are seen.

Therapeutic Management

Successful outcome of anaphylactic reactions depends on rapid recognition and institution of treatment. The goals of treatment are to provide ventilation, restore adequate circulation, and prevent further exposure by identifying and removing the cause when possible.

A mild reaction with no evidence of respiratory distress or cardiovascular compromise can be managed with subcutaneous administration of antihistamines, such as diphenhydramine (Benadryl) and epinephrine.

Moderate or severe distress presents a potentially life-threatening emergency. Establishing an airway is the first concern, as with all

shock states. Epinephrine is given subcutaneously or intravenously as an antihistamine and to support the cardiovascular system and increase BP. Other routes for giving epinephrine are intramuscular and via the airway, either nebulized or injected through an endotracheal tube. In severe anaphylaxis, epinephrine by any route is better than none. Fluids are given to restore blood volume. Additional vasopressors may be given to improve cardiac output.

Prevention of a reaction is preferable. Preventing exposure is more easily accomplished in children known to be at risk, including those with (1) a history of previous allergic reaction to a specific antigen; (2) a history of atopy; (3) a history of severe reactions in immediate family members; and (4) a reaction to a skin test, although skin tests are not available for all allergens. Desensitization may be recommended in certain cases.

CARE MANAGEMENT

When an anaphylactic reaction is suspected, both immediate intervention and preparation for medical therapy are nursing responsibilities. Ventilation is ensured by placing the child in a head-elevated position, unless contraindicated by hypotension, to facilitate breathing and administer oxygen. If the child is not breathing, CPR is initiated and emergency medical services are summoned.

If the cause can be determined, measures are implemented to slow the spread of the offending substance. An IV infusion is established immediately. Emergency medications are given intravenously whenever possible; however, epinephrine may be given subcutaneously (see Emergency box). Vital signs and urinary output are monitored frequently. Medications are administered as prescribed, with regular assessment to monitor effectiveness and to detect signs of side effects of medication and fluid overload.

To prevent an anaphylactic reaction, parents are always asked about possible allergic responses to foods, latex, medications, and environmental conditions. These are displayed prominently on the patient's chart. The specific allergen is noted, as are the type and severity of the reaction. Parents are excellent historians, especially when the child has displayed a pronounced reaction to a substance. Drugs, including related drugs (e.g., penicillin, nafcillin), and other items, such as latex, that have produced a reaction previously are *never* used. If the child is allergic to insect venom, the family is instructed to purchase an emergency kit to be kept with the child at all times. Both the family and the child, if the child is old enough, are taught how to use the equipment. The patient should carry medical identification at all times.

Septic Shock

Sepsis and septic shock are caused by an infectious organism (Maar, 2004). Normally, an infection triggers an inflammatory response in a local area, which results in vasodilation, increased capillary permeability, and eventually elimination of the infectious agent. The widespread activation and systemic release of inflammatory mediators is called the systemic inflammatory response syndrome (SIRS). Box 42-14 provides the exact definitions for SIRS, infection, sepsis, and severe sepsis. SIRS can occur in response to both infectious and noninfectious (e.g., trauma, burns) causes. When caused by infection, it is called sepsis. Septic shock is defined as sepsis with organ dysfunction and hypotension.

Most of the physiologic effects of shock occur because the exaggerated immune response triggers more than 30 different mediators that result in diffuse vasodilation, increased capillary permeability, and maldistribution of blood flow. This impairs oxygen and nutrient delivery to the cells, resulting in cellular dysfunction. If the process continues, multiple-organ dysfunction occurs and may result in death. Table 42-4 includes the age-specific vital signs and laboratory values reflective of septic shock in children.

The incidence of septic shock is increasing in adults and children (Arnal and Stein, 2003), possibly as a result of greater numbers of immunosuppressed patients, more widespread use of invasive devices in seriously ill patients, increased awareness of the diagnosis, and a growing number of resistant microorganisms.

Three stages have been identified in septic shock. In early septic shock, the patient has chills, fever, and vasodilation with increased cardiac output, which results in warm, flushed skin that reflects vascular tone abnormalities and hyperdynamic, warm, or hyperdynamic-compensated responses. BP and urinary output are normal. The patient has the best chance for survival in this stage. The second stage—the normodynamic, cool, or hyperdynamic-decompensated stage—lasts only a few hours. The skin is cool, but pulses and BP are still normal. Urinary output diminishes, and the mental state becomes depressed. With advancing disease, certain

BOX 42-14 DEFINITIONS OF SYSTEMIC INFLAMMATORY RESPONSE SYNDROME, INFECTION, SEPSIS, AND SEVERE SEPSIS

SIRS—The presence of at least two of the following four criteria, one of which must be abnormal temperature or leukocyte count:

1. Core temperature of more than 38.5° C (101.3° F) or less than 36° C (96.8° F)
2. *Tachycardia,* defined as a mean heart rate more than 2 SD above normal for age in the absence of external stimulus, chronic drugs, or painful stimuli; or otherwise unexplained persistent elevation over a 0.5- to 4-hour period; or, for children younger than 1 year: *bradycardia,* defined as a mean heart rate less than the 10th percentile for age in the absence of external vagal stimulus, β-blocker drugs, or congenital heart disease; or otherwise unexplained persistent depression over a 0.5-hour period.
3. Mean respiratory rate more than 2 SD above normal for age or mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia.
4. Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or more than 10% immature neutrophils.

Infection—A suspected or proven (by positive culture, tissue stain, or PCR test) infection caused by any pathogen; or a clinical syndrome associated with a high probability of infection. Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, or purpura fulminans).

Sepsis—SIRS in the presence of or as a result of suspected or proven infection.

Severe sepsis—Sepsis plus cardiovascular organ dysfunction or ARDS or two or more other organ dysfunctions.

signs of circulatory decompensation that deteriorate to signs of circulatory collapse are indistinguishable from late shock of any cause. In the hypodynamic, or cold, stage of shock, cardiovascular function progressively deteriorates even with aggressive therapy. The patient has hypothermia, cold extremities, weak pulses, hypotension, and oliguria or anuria. Patients are severely lethargic or comatose. Multiorgan failure is common. This is the most dangerous stage of shock.

Management of septic shock involves measures to provide hemodynamic stability and adequate oxygenation to the tissues and the use of antimicrobials to treat the infectious organism. As with other forms of shock, hemodynamic stability is achieved with fluid volume resuscitation and inotropic agents as needed. Providing adequate oxygenation often requires intubation and mechanical ventilation, supplemental oxygen, sedation, and paralysis to decrease the work of breathing. Septic shock involves activation of complement proteins that promote clumping of the granulocytes in the lung. The granulocytes can release chemicals that can cause direct lung injury to the pulmonary capillary endothelium. This causes a fluid leak into the alveoli, which causes stiff, noncompliant lungs. DIC and multiorgan dysfunction may also occur and require prompt assessment and management.

Newer therapies are being developed to modify the host immune response by attempting to block various mediators, thereby interrupting the inflammatory cascade.

Early identification of the symptoms of septic shock is critical to patient survival. A high index of suspicion is required in all critically ill patients who are at greater risk for sepsis because of multiple invasive lines and devices, poor nutrition, and impaired immune function. Subtle alterations in tissue perfusion and unexplained tachypnea and tachycardia often are early warning signs. Identification of the infectious agent and prompt treatment are also critical to patient survival. Broad-spectrum antibiotics should be given, and the site of infection should be removed if possible (e.g., drain abscesses, remove indwelling lines). Patients should be managed in an ICU in which continuous monitoring and sophisticated cardiac and respiratory support are available. Multidisciplinary collaboration is essential in managing these critically ill patients.

KEY POINTS

- CHD is the most common form of cardiac disease in children.
- Major categories to investigate in the cardiac history are poor weight gain, poor feeding habits, and fatigue during feeding; frequent respiratory tract infections and difficulties; and evidence of exercise intolerance.
- The most common tests used in assessing cardiac function are radiography, ECG, echocardiography, and cardiac catheterization.
- Cardiac catheterization procedures can be divided into three groups: (1) diagnostic procedures, including angiography, that measure pressures and saturations to establish cardiac diagnosis; (2) interventional procedures, in which catheters or balloon devices are used to correct cardiac defects; and (3) electrophysiology studies, in which catheters with electrodes are used to evaluate dysrhythmias.
- Diagnostic cardiac catheterization provides important information about oxygen saturation of blood within the chambers and great vessels, pressure changes, changes in cardiac output or stroke volume, and anatomic abnormalities.
- Several prenatal factors may predispose children to CHD; these include maternal rubella during pregnancy, maternal alcoholism, maternal age older than 40 years, and maternal type 1 diabetes.
- Congenital heart defects can be divided into four main groups, as determined by hemodynamic patterns: (1) defects that result in increased pulmonary blood flow, (2) obstructive defects, (3) defects that result in decreased pulmonary blood flow, and (4) mixed defects.
- Clinical consequences of congenital heart defects include HF and hypoxemia. A child can have both hypoxemia and HF, although usually they occur independently.
- Clinical manifestations of HF are impaired myocardial function (tachycardia, cardiomegaly), pulmonary congestion (dyspnea, tachypnea, orthopnea, cyanosis), and systemic congestion (hepatosplenomegaly, edema, distended veins).
- Nursing measures in the care of a child with HF are to assist in improving cardiac function, decrease cardiac demands, reduce respiratory distress, maintain nutritional status, promote fluid loss, and provide family support.

- Clinical manifestations of hypoxemia are cyanosis, polycythemia, clubbing, and delayed growth and development. The child is at increased risk for hypercyanotic spells, CVAs, brain abscess, and BE.
- Caring for the child with CHD and the family requires helping them adjust to the disorder and cope with the effects of the defect and fostering growth-promoting family relationships.
- Preoperative care of the child with a congenital heart defect involves introducing the child and family to the hospital and preparing them for preoperative and postoperative procedures.
- Providing postoperative care includes observing vital signs and arterial and venous pressures, maintaining respiratory status, allowing maximum rest, providing comfort, monitoring fluids, planning for progressive activities, giving emotional support, observing for complications of surgery, and planning for discharge and home care.
- Acquired cardiovascular disorders include BE, RF, hyperlipidemia (hypercholesterolemia), KD, and cardiac dysrhythmias.
- Prevention of BE in certain children with CHD involves administration of prophylactic antibiotics when specific procedures are performed.
- Acute RF is a systemic inflammatory disease that can damage the cardiac valves and is associated with previous GABHS infection. Its incidence has increased in some areas of the United States.
- Cholesterol screening in children is controversial; currently, children with known risk factors for hyperlipidemia are screened and treated as needed. The influence of childhood cholesterol levels on later development of coronary artery disease is under investigation.
- Common dysrhythmias in children include slow rhythms (bradycardias, heart block) and fast rhythms (sinus tachycardia, SVT).
- Heart transplantation has been extended to infants and children with cardiomyopathy and complex congenital heart defects involving ventricular dysfunction, such as hypoplastic left heart syndrome.
- Education of the child with hypertension and the family focuses on drug therapy, diet control, and appropriate exercise.
- KD is an extensive inflammation of small vessels and capillaries that may progress to involve the coronary arteries, causing aneurysm formation. The administration of gamma globulin is an important aspect of treatment.
- Emergency treatment for shock includes ensuring ventilation; administering vasopressors, fluids, blood, and antibiotics as needed; and providing supportive measures such as correct positioning, warmth, and psychologic reassurance to the child and family.
- Persons at risk for anaphylaxis may be identified by a history of previous allergic reaction, history of atopy, history of severe reactions in family, and positive skin test to the allergen.

CHAPTER

43

Hematologic and Immunologic Dysfunction

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Distinguish among the various categories of anemia.
- Describe the prevention of iron deficiency anemia and the care of the child with iron deficiency anemia.
- Compare sickle cell anemia and β-thalassemia major in relation to pathophysiology and nursing care.
- Describe the mechanisms of inheritance and nursing care of the child with hemophilia.
- Relate the pathophysiology and clinical manifestations of leukemia.
- Demonstrate an understanding of the rationale of therapies for neoplastic disease.
- Outline a care plan for the child with neoplastic disease and the family.
- Contrast the pathophysiology and management of the immunodeficiency disorders.
- List nursing precautions and responsibilities during blood transfusion.
- Describe the types of hematopoietic stem cell transplants.

HEMATOLOGIC DYSFUNCTION

Several tests can be performed to assess hematologic function, including additional procedures to identify the cause of the dysfunction. The following discussion is limited to a description of the most common and one of the most valuable tests, the complete blood cell count (CBC). Other procedures, such as those related to iron, coagulation, and immune status, are discussed throughout the chapter as appropriate. The nurse should be familiar with the significance of the findings from the CBC (Table 43-1) and be aware of normal values for age, which are listed in Appendix B.

As with any disorder, the history and physical examination are essential to identify hematologic dysfunction, and the nurse is often the first person to suspect a problem based on information from these sources. Comments by the parent regarding the child's lack of energy, food diary of poor sources of iron, frequent infections, and bleeding that is difficult to control offer clues to the more common disorders affecting the blood. A careful physical appraisal, especially of the skin, can reveal findings (e.g., pallor, petechiae, bruising) that may indicate minor or serious hematologic conditions. Nurses need to be aware of the clinical manifestations of blood diseases to assist in recognizing symptoms and establishing a diagnosis.

! NURSING ALERT

A common term used in describing an abnormal CBC is *shift to the left,* which refers to the presence of immature neutrophils in the peripheral blood from hyperfunction of the bone marrow, as seen during a bacterial infection.

RED BLOOD CELL DISORDERS

Anemia

The term anemia describes a condition in which the number of red blood cells (RBCs) or the hemoglobin (Hgb or Hb) concentration is reduced below normal values for age. This diminishes the oxygen-carrying capacity of the blood, causing a reduction in the oxygen available to the tissues. Anemia is the most common hematologic disorder of infancy and childhood and is not a disease itself but an indication or manifestation of an underlying pathologic process.

Classification

Anemias are classified in relation to (1) etiology or physiology, manifested by erythrocyte or Hgb depletion, and (2) morphology,

TABLE 43-1 TESTS PERFORMED AS PART OF A COMPLETE BLOOD COUNT

TEST (AVERAGE VALUE)*	DESCRIPTION, COMMENTS
RBC count (4.5-5.5 million/mm^3)	Number of RBCs/mm^3 of blood Indirectly estimates Hgb content of blood Reflects function of bone marrow
Hgb determination (11.5-15.5 g/dL)	Amount of Hgb (g)/dL of whole blood Total blood Hgb depends primarily on number of circulating RBCs but also on amount of Hgb in each cell
Hct (35%-45%)	Percent volume of packed RBCs in whole blood Indirectly measures Hgb content Is approximately 3 times Hgb content
RBC Indices	
MCV (77-95 fL)	Average or mean volume (size) of a single RBC MCV values are expressed as femtoliters (fL) or cubic microns (mm^3)
MCH (25-33 pg/cell)	Average or mean quantity (weight) of Hgb in a single RBC MCH values are expressed as picograms (pg) or micromicrograms (mmcg) Whereas MCV and MCH depend on accurate counts of RBCs, MCHC does not; therefore MCHC is often more reliable All indices depend on average cell measurements and do not show individual RBC variations (anisocytosis)
MCHC (31%-37% Hgb [g]/dL RBC)	Average concentration of Hgb in a single RBC MCHC values are expressed as percent Hgb (g)/cell or Hgb (g)/dL RBC
RBC volume distribution width (13.4% ± 1.2%)	Average size of RBCs Differentiates some types of anemia
Reticulocyte count (0.5%-1.5% erythrocytes)	Percent reticulocytes in RBCs Index of production of mature RBCs by bone marrow Decreased count indicates depressed bone marrow function Increased count indicates erythrogenesis in response to some stimulus When reticulocyte count is extremely high, other forms of immature RBCs (normoblasts, even erythroblasts) may be present Indirectly estimates hypochromic anemia Usually elevated in patients with chronic hemolytic anemia
WBC count (4.5-13.5 × 10^3 cells/mm^3)	Number of WBCs/mm^3 of blood Total number of WBCs less important than differential count
Differential WBC count	Inspection and quantification of WBC types present in peripheral blood Values are expressed as percentages; to obtain absolute number of any type of WBC, multiply its respective percentage by total number of WBCs
Neutrophils (polys) (54%-62%) (3-5.8 × 10^3 cells/mm^3)	Primary defense in bacterial infection; capable of phagocytizing and killing bacteria
Bands (3%-5%) (0.15-0.4 × 10^3 cells/mm^3)	Immature neutrophil Increased numbers in bacterial infection Also capable of phagocytosis and killing
Eosinophils (1%-3%) (0.05-0.25 × 10^3 cells/mm^3)	Named for their staining characteristics with eosin dye Increased in allergic disorders, parasitic diseases, certain neoplasms, and other diseases
Basophils (0.075%) (0.015-0.030 × 10^3 cells/mm^3)	Named for their characteristic basophilic stippling Contain histamine, heparin, and serotonin; believed to cause increased blood flow to injured tissues while preventing excessive clotting
Lymphocytes (25%-33%) (1.5-3.0 × 10^3 cells/mm^3)	Involved in development of antibody and delayed hypersensitivity
Monocytes (3%-7%)	Large phagocytic cells that are involved in early stage of inflammatory reaction
ANC (>1000/mm^3)	Percent neutrophils/bands times WBC count Indicates body's capability to handle bacterial infections
Platelet count (150-400 × 10^3/mm^3)	Number of platelets/mm^3 of blood Cellular fragments that are necessary for clotting to occur
Stained peripheral blood smear	Visual estimation of amount of Hgb in RBCs and overall size, shape, and structure of RBCs Various staining properties of RBC structures may be evidence of immature forms of erythrocytes Shows variation in size and shape of RBCs: microcytic, macrocytic, poikilocytic (variable shapes)

ANC, Absolute neutrophil count; *Hct,* hematocrit; *Hgb,* hemoglobin; *MCH,* mean corpuscular hemoglobin; *MCHC,* mean corpuscular hemoglobin concentration; *MCV,* mean corpuscular volume; *RBC,* red blood cell; *WBC,* white blood cell.
*See Appendix B for normal values according to age.

the characteristic changes in RBC size, shape, or color (Box 43-1). Although the morphologic classification is more useful in terms of laboratory evaluation of anemia, the etiologic approach provides direction for planning nursing care. For example, anemia with reduced Hgb concentration may be caused by a dietary depletion of iron and the principal intervention is replenishing iron stores. The classification of anemias is found in Fig. 43-1.

Consequences of Anemia

The basic physiologic defect caused by anemia is a decrease in the oxygen-carrying capacity of blood and consequently a reduction in the amount of oxygen available to the cells. When the anemia has developed slowly, the child usually adapts to the declining Hgb level.

The effects of anemia on the circulatory system can be profound. Because the viscosity of blood depends almost entirely on the concentration of RBCs, the resulting hemodilution of severe anemia decreases peripheral resistance, causing greater quantities of blood to return to the heart. The increased circulation and turbulence within the heart may produce a murmur. Because the cardiac workload is greatly increased, especially during exercise, infection, or emotional stress, cardiac failure may ensue.

Children seem to have a remarkable ability to function well despite low levels of Hgb. Cyanosis (the result of the quantity of deoxygenated Hgb in arterial blood) is typically not evident. Growth retardation, resulting from decreased cellular metabolism and coexisting anorexia, is a common finding in chronic severe anemia and is frequently accompanied by delayed sexual maturation in the older child.

BOX 43-1 RED BLOOD CELL MORPHOLOGY

Size (Cell Size)

Variation in RBC sizes (anisocytosis)

- Normocytes (normal cell size)
- Microcytes (smaller than normal cell size)
- Macrocytes (larger than normal cell size)

Shape (Cell Shape)

Variation in RBC shapes (poikilocytosis)

- Spherocytes (globular cells)
- Drepanocytes (sickle-shaped cells)
- Numerous other irregularly shaped cells

Color (Cell Staining Characteristics)

Variation in hemoglobin concentration in the RBC

- Normochromic (sufficient or normal amount of hemoglobin per RBC)
- Hypochromic (reduced amount of hemoglobin per RBC)
- Hyperchromic (increased amount of hemoglobin per RBC)

RBC, Red blood cell.

Diagnostic Evaluation

In general, anemia may be suspected based on findings on the history and physical examination, such as a lack of energy, easy fatigability, and pallor, but unless the anemia is severe, the first clue to the disorder may be alterations in the CBC, such as decreased RBCs, and decreased Hgb and hematocrit (Hct) levels (see Fig. 43-1). Although anemia is sometimes defined as an Hgb level below 10 or 11 g/dL, this arbitrary cutoff is inappropriate for all children because Hgb levels normally vary with age (see Table 43-1 and Appendix B).

Other tests specific to a particular type of anemia are used to determine the underlying cause of anemia. These are discussed in relation to the particular disorder.

Therapeutic Management

The objective of medical management is to reverse the anemia by treating the underlying cause and to make up for any deficiency of

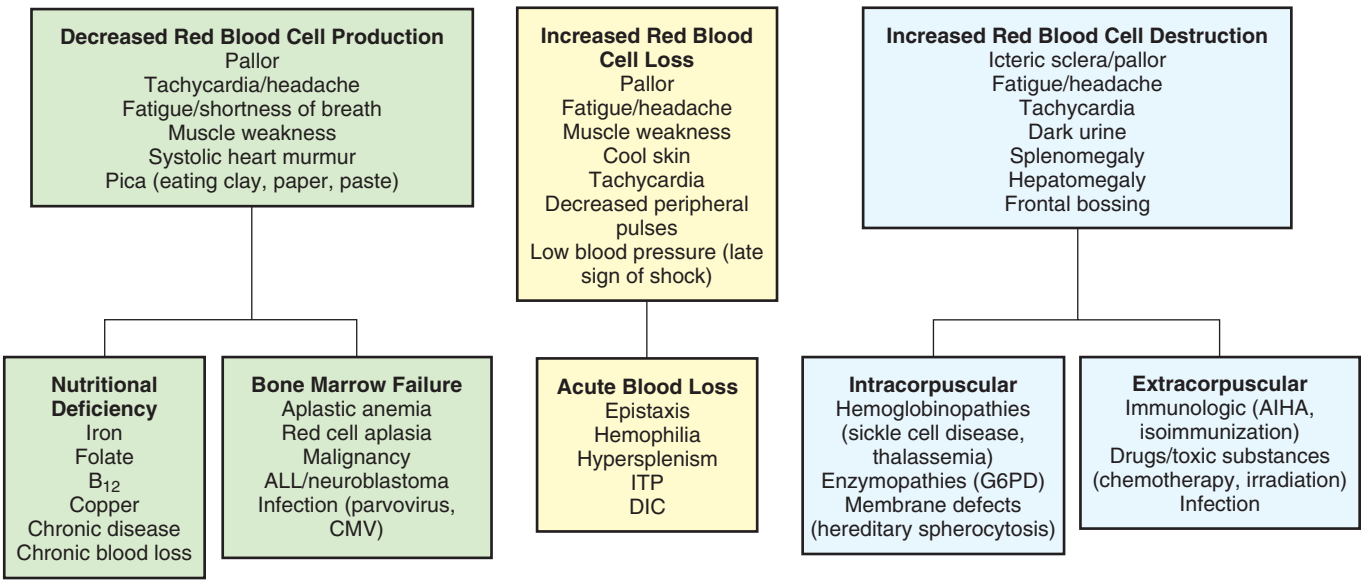

FIG 43-1 Classifications of anemias. *AIHA,* Autoimmune hemolytic anemia; *ALL,* acute lymphoid leukemia; *CMV,* cytomegalovirus; *DIC,* disseminated intravascular coagulation; *G6PD,* glucose-6-phosphate dehydrogenase; *ITP,* idiopathic thrombocytopenic purpura; *RBC,* red blood cell; *SCD,* sickle cell disease.

blood, blood component, or substance the blood needs for normal functioning. For example, blood or blood cells are replaced after hemorrhage; in nutritional anemias, the specific deficiency is replaced.

In patients with severe anemia, supportive medical care may include oxygen therapy, bed rest, and replacement of intravascular volume with intravenous (IV) fluids. The prognosis for anemia depends on the correction of the cause.

CARE MANAGEMENT

The assessment of anemia includes the basic techniques that are applicable to any condition. The age of the infant or child provides some clues regarding the possible etiology of the anemia. For example, iron deficiency anemia occurs more frequently in toddlers between 12 and 36 months of age and during the growth spurt of adolescence.

Racial or ethnic background is significant. For example, the anemias related to abnormal Hgb levels are found in Southeast Asians and persons of African or Mediterranean ancestry. These same groups may be genetically deficient in the enzyme *lactase* after the period of infancy. Affected individuals are unable to tolerate lactose in the diet, with consequent intestinal irritation and chronic blood loss.

Special emphasis is placed on a careful history to elicit any information that might help identify the cause of the anemia. For example, a statement such as: "My child drinks lots of milk" is a frequent finding in toddlers with iron deficiency anemia. An episode of diarrhea may have precipitated temporary lactose intolerance in a young child.

Stool examination for occult (microscopic) blood (Hemoccult test) can identify chronic intestinal bleeding that results from a primary or secondary lactase deficiency. It is also important to understand the significance of various blood tests (see Table 43-1).

Prepare the Child and Family for Laboratory Tests. Usually, several blood tests are ordered, but because they are generally done sequentially rather than at one time, the child is subjected to multiple finger or heel punctures or venipunctures. Laboratory technicians frequently are not aware of the trauma that repeated punctures represent to a child. However, these invasive procedures need not be painful (see Blood Specimens, Chapter 39). For example, the topical application of EMLA (an eutectic mix of lidocaine and prilocaine) or 4% lidocaine (Ela-Max or LMX) before needle punctures can eliminate pain (see Pain Management, Chapter 30). Therefore the nurse is responsible for preparing the child and family for the tests by:

- Explaining the significance of each test, particularly why the tests are not all done at one time
- Encouraging parents or another supportive person to be with the child during the procedure
- Allowing the child to play with the equipment on a doll or participate in the actual procedure (e.g., by cleansing the finger with an alcohol swab)

Older children may appreciate the opportunity to observe the blood cells under a microscope or in photographs. This experience is especially important if a serious blood disorder, such as leukemia, is suspected because it serves as a foundation for explaining the pathophysiology of the disorder.

Bone marrow aspiration is not a routine hematologic test but is essential for definitive diagnosis of the leukemias, lymphomas, and certain anemias.

! NURSING ALERT

The following are suggested explanations for teaching children about blood components:

- **Red blood cells**—Carry the oxygen you breathe from your lungs to all parts of your body
- **White blood cells**—Help keep germs from causing infection
- **Platelets**—Small parts of cells that help make bleeding stop by forming a clot (scab) over the hurt area
- **Plasma**—The liquid portion of blood, which has clotting factors that help make bleeding stop

Decrease Tissue Oxygen Needs. Because the basic pathologic process in anemia is a decrease in oxygen-carrying capacity, an important nursing responsibility is to assess the child's energy level and minimize excess demands. The child's level of tolerance for activities of daily living and play is assessed, and adjustments are made to allow as much self-care as possible without undue exertion. During periods of rest, the nurse takes vital signs and observes behavior to establish a baseline of nonexertion energy expenditure. During periods of activity, the nurse repeats these measurements and observations to compare them with resting values.

! NURSING ALERT

Signs of exertion include tachycardia, palpitations, tachypnea, dyspnea, shortness of breath, hyperpnea, breathlessness, dizziness, lightheadedness, diaphoresis, and change in skin color. The child looks fatigued (sagging, limp posture; slow, strained movements; inability to tolerate additional activity; difficulty sucking in infants).

Prevent Complications. Children who are so severely anemic that they are hospitalized may require oxygen to prevent or reduce tissue hypoxia. Because these children are susceptible to infection, every effort is expended to prevent exposure to infectious agents. All of the usual precautions are taken to prevent infection, such as practicing thorough hand washing, selecting an appropriate room in a noninfectious area, restricting visitors or hospital personnel with active infection, and maintaining adequate nutrition. The nurse also observes for signs of infection, particularly temperature elevation and leukocytosis.

Iron Deficiency Anemia

Anemia caused by an inadequate supply of dietary iron is the most prevalent nutritional disorder in the United States and the most preventable mineral disturbance. The prevalence of iron deficiency anemia has decreased during infancy in the United States, probably in part because of families' participation in the Women, Infants, and Children (WIC) program, which provides iron-fortified formula for the first year of life and routine screening of Hgb levels during early childhood (Baker, Greer, and Committee on Nutrition American Academy of Pediatrics [AAP], 2010; Cusick, Mei, Freedman, et al., 2008). Preterm infants are especially at risk because of their reduced fetal iron supply. Children 12 to 36 months of age are at risk for anemia as a result of primarily cow's milk intake and not eating an adequate amount of iron-containing food (Andrews, Ullrich, and Fleming, 2009; Baker, Greer, and Committee on Nutrition AAP, 2010; Richardson, 2007). Adolescents are also at risk because of their rapid growth rate combined with poor eating habits, menses, obesity, or strenuous activities.

Pathophysiology

Iron deficiency anemia can be caused by any number of factors that decrease the supply of iron, impair its absorption, increase the body's need for iron, or affect the synthesis of Hgb. Although the clinical manifestations and diagnostic evaluation are similar regardless of the cause, the therapeutic and nursing care management depend on the specific reason for the iron deficiency. The following discussion is limited to iron deficiency anemia resulting from inadequate iron in the diet.

During the last trimester of pregnancy, iron is transferred from the mother to the fetus. Most of the iron is stored in the circulating erythrocytes of the fetus, with the remainder stored in the fetal liver, spleen, and bone marrow. These iron stores are usually adequate for the first 5 to 6 months in a full-term infant but for only 2 to 3 months in preterm infants and multiple births. If dietary iron is not supplied to meet the infant's growth demands after the fetal iron stores are depleted, iron deficiency anemia results. Physiologic anemia should not be confused with iron deficiency anemia resulting from nutritional causes.

Although most toddlers with iron deficiency anemia are underweight, many infants are overweight because of excessive milk ingestion (known as milk babies). These children become anemic for two reasons: milk, a poor source of iron, is given almost to the exclusion of solid foods; and 50% of iron deficient infants fed cow's milk have an increased fecal loss of blood.

Therapeutic Management

After the diagnosis of iron deficiency anemia is made, therapeutic management focuses on increasing the amount of supplemental iron the child receives. This is usually done through dietary counseling and the administration of oral iron supplements.

In formula-fed infants, the most convenient and best sources of supplemental iron are iron-fortified commercial formula and iron-fortified infant cereal. Iron-fortified formula provides a relatively constant and predictable amount of iron and is not associated with an increased incidence of gastrointestinal (GI) symptoms, such as colic, diarrhea, or constipation. Infants younger than 12 months should *not* be given fresh cow's milk because it may increase the risk for GI blood loss occurring from exposure to a heat-labile protein in cow's milk or cow's milk–induced GI mucosal damage resulting from a lack of cytochrome iron (heme protein) (Glader, 2007; Richardson, 2007). If GI bleeding is suspected, the child's stool should be guaiac tested on at least four or five occasions to identify any intermittent blood loss.

Dietary addition of iron-rich foods is usually inadequate as the sole treatment of iron deficiency anemia because the iron is poorly absorbed and thus provides insufficient supplemental quantities of iron. If dietary sources of iron cannot replace body stores, oral iron supplements are prescribed for approximately 3 months. Ferrous iron, more readily absorbed than ferric iron, results in higher Hgb levels. Ascorbic acid (vitamin C) appears to facilitate absorption of iron and may be given as vitamin C–enriched foods and juices with the iron preparation.

If the Hgb level fails to rise after 1 month of oral therapy, it is important to assess for persistent bleeding, iron malabsorption, noncompliance, improper iron administration, or other causes of the anemia. Parenteral (IV or intramuscular [IM]) iron administration is safe and effective but painful, expensive, and occasionally associated with regional lymphadenopathy, transient arthralgias, or serious allergic reaction (Andrews, Ullrich, and Fleming, 2009; Glader, 2007; McKenzie, 2004). Therefore parenteral iron is reserved for children who have iron malabsorption or chronic hemoglobinuria. Transfusions are indicated for the most severe anemia and in cases of serious infection, cardiac dysfunction, or surgical emergency when anesthesia is required. Packed RBCs (2-3 mL/kg), not whole blood, are used to minimize the chance of circulatory overload. Supplemental oxygen is administered when tissue hypoxia is severe.

Prognosis. The prognosis for a child with this condition is very good. However, some evidence indicates that if the iron deficiency anemia is severe and longstanding, cognitive, behavioral, and motor impairment may result (Andrews, Ullrich, and Fleming, 2009; Lokeshwar, Mehta, Mehta, et al., 2011; McCann and Ames, 2007).

CARE MANAGEMENT

An essential nursing responsibility is instructing parents in the administration of iron. Oral iron should be given as prescribed in two divided doses between meals, when the presence of free hydrochloric acid is greatest, because more iron is absorbed in the acidic environment of the upper GI tract. A citrus fruit or juice taken with the medication aids in absorption.

MEDICATION ALERT

Cow's milk contains substances that bind the iron and interfere with absorption. Iron supplements should not be administered with milk or milk products (Carley, 2003).

An adequate dosage of oral iron turns the stools a tarry green color. The nurse advises parents of this normally expected change and inquires about its occurrence on follow-up visits. Absence of the greenish black stool may be a clue to poor administration of iron, either in schedule or in dosage. Vomiting or diarrhea can occur with iron therapy. If the parents report these symptoms, the iron can be given with meals and the dosage reduced and then gradually increased until tolerated.

MEDICATION ALERT

Liquid preparations of iron may temporarily stain the teeth. If possible, the medication should be taken through a straw or given through a syringe or medicine dropper placed toward the back of the mouth. Brushing the teeth after administration of the drug lessens the discoloration. Because iron ingestion in excessive quantities is toxic or even fatal, parents should be instructed to keep no more than a month's supply in the home and store it safely away from the reach of children.

If parenteral iron preparations are prescribed, iron dextran must be injected deeply into a large muscle mass using the Z-track method. The injection site is *not* massaged after injection to minimize skin staining and irritation. Because no more than 1 mL should be given in one site, the IV route should be considered to avoid multiple injections. Careful observation is required because of the risk for adverse reactions, such as anaphylaxis, with IV administration. A test dose is recommended before routine use. Recently, a new IV iron preparation (ferumoxytol) was approved in the United States that shows promise in complete replacement of iron with little toxicity (Auerbach, 2011).

Diet. A primary nursing objective is to prevent nutritional anemia through family education. Because breast milk is a low iron source, the nurse must reinforce the importance of administering

iron supplementation to exclusively breastfed infants by 4 months of age (Baker, Greer, and Committee on Nutrition AAP, 2010; Lokeshwar, Mehta, Mehta, et al., 2011). The American Academy of Pediatrics (AAP) recommends preterm, marginally low–birth-weight and low-birth-weight infants or infants with inadequate iron stores at birth receive iron supplements at approximately 2 months of age (Berglund, Westrup, and Domellof, 2010).

In formula-fed infants, the nurse discusses with parents the importance of using iron-fortified formula and introducing solid foods at the appropriate age during the first year of life. Traditionally, cereals are one of the first semisolid foods to be introduced into the infant's diet at approximately 6 months of age (Baker, Greer, and Committee on Nutrition AAP, 2010; Glader, 2007; Lokeshwar, Mehta, Mehta, et al., 2011). The best solid-food source of iron is commercial iron-fortified cereals. It may be difficult at first to teach the infant to accept foods other than milk. The same principles are applied as those for introducing new foods (see Nutrition, Chapter 31), especially feeding the solid food before the milk. Predominantly milk-fed infants rebel against solid foods, and parents are cautioned about this and the need to be firm in not relinquishing control to the child. It may require intense problem solving on the part of both the family and the nurse to overcome the child's resistance.

A difficulty encountered in discouraging the parents from feeding milk to the exclusion of other foods is dispelling the popular myth that milk is a "perfect food." Many parents believe that milk is best for infants and equate weight gain with a "healthy child" and "good mothering." The nurse can also stress that overweight is not synonymous with good health.

Diet education of teenagers is especially difficult, especially because teenage girls are particularly prone to following weight-reduction diets. Emphasizing the effect of anemia on appearance (pallor) and energy level (difficulty maintaining popular activities) may be useful.

Sickle Cell Anemia

Sickle cell anemia (SCA) is one of a group of diseases collectively termed hemoglobinopathies in which normal adult Hgb (Hgb A [HbA]) is partly or completely replaced by abnormal sickle Hgb (HbS). Sickle cell disease (SCD) includes all those hereditary disorders whose clinical, hematologic, and pathologic features are related to the presence of HbS. Even though the term *SCD* is sometimes used to refer to SCA, this use is incorrect. Other correct terms for SCA are SS and homozygous SCD.

The following are the most common forms of SCD in the United States:

- SCA, the homozygous form of the disease (HbSS or SS)
- Sickle cell–C disease, a heterozygous variant of SCD, including both HbS and HbC (SC)
- Sickle cell–hemoglobin E disease, a variant of SCD in which glutamic acid has been substituted for lysine in the number 26 position of the β-chain (SE)
- Sickle thalassemia disease, a combination of sickle cell trait and β-thalassemia trait (Sβthal). β^+ refers to the ability to still produce some normal HbA. β^0 indicates that there is no ability to produce HbA.

Of the SCDs, SCA is the most common form in African-Americans, followed by sickle cell–C disease and sickle thalassemia. Sickle syndromes exist when the HbS is paired with other mutant globins.

Sickle cell disease is one of the most common genetic diseases worldwide. SCD affects approximately 90,000 Americans, primarily African-American, followed by Hispanics, with a lower incidence in the other ethnic groups (Driscoll, 2007). The incidence of the disease varies in different geographic locations. Among African-Americans, the incidence of sickle cell trait is about 9%. In West Africa, the incidence is reported to be as high as 40% among native Africans. The high incidence of sickle cell trait in West Africans is believed by some to be the result of selective protection afforded trait carriers against one type of malaria.

The gene that determines the production of HbS is situated on an autosome and, when present, is always detectable and therefore dominant. Heterozygous persons who have both normal HbA and abnormal HbS are said to have sickle cell trait. Persons who are homozygous have predominantly HbS and have SCA. The inheritance pattern is essentially that of an autosomal recessive disorder. Therefore, when both parents have sickle cell trait, there is a 25% chance with each pregnancy of producing an offspring with SCA.

Although the defect is inherited, the sickling phenomenon is usually not apparent until later in infancy because of the presence of fetal Hbg (HbF). As long as the child has predominantly HbF, sickling does not occur because there is less HbS. Newborns with SCA are generally asymptomatic because of the protective effect of HbF (60%-80% HbF), but this rapidly decreases during the first year, so these children are at risk for sickle cell–related complications (Driscoll, 2007; Heeney and Dover, 2009).

Pathophysiology

The clinical features of SCA are primarily the result of (1) obstruction caused by the sickled RBCs, (2) vascular inflammation, and (3) increased RBC destruction (Fig. 43-2). The abnormal adhesion, entanglement, and enmeshing of rigid sickle-shaped cells accompanied by the inflammatory process intermittently block the microcirculation, causing vasoocclusion (Fig. 43-3). The resultant absence of blood flow to adjacent tissues causes local hypoxia, leading to tissue ischemia and infarction (cellular death). Most of the complications seen in SCA can be traced to this process and its impact on various organs of the body (Box 43-2).

The clinical manifestations of SCA vary greatly in severity and frequency. The most acute symptoms of the disease occur during periods of exacerbation called crises. There are several types of episodic crises, including vasoocclusive, acute splenic sequestration, aplastic, hyperhemolytic, cerebrovascular accident, chest syndrome, and infection. The crises may occur individually or concomitantly with one or more other crises. The vasoocclusive crisis (VOC), preferably called a "painful episode," is characterized by ischemia causing mild to severe pain that may last from minutes to days. Sequestration crisis is a pooling of a large amount of blood—usually in the spleen and infrequently in the liver—that causes a decreased blood volume and ultimately shock. Aplastic crisis is diminished RBC production usually caused by viral infection that may result in profound anemia. Hyperhemolytic crisis is an accelerated rate of RBC destruction characterized by anemia, jaundice, and reticulocytosis.

Another serious complication is acute chest syndrome (ACS), which is clinically similar to pneumonia. It is the presence of a new pulmonary infiltrate and may be associated with chest pain, fever, cough, tachypnea, wheezing, and hypoxia. A cerebrovascular accident (CVA, stroke) is a sudden and severe complication, often with no related illnesses. Sickled cells block the major blood vessels in the brain, resulting in cerebral infarction, which causes variable degrees of neurologic impairment. The current treatment for SCD children who have experienced a stroke is chronic transfusion therapy. Repeat CVAs causing progressively greater brain damage occur in

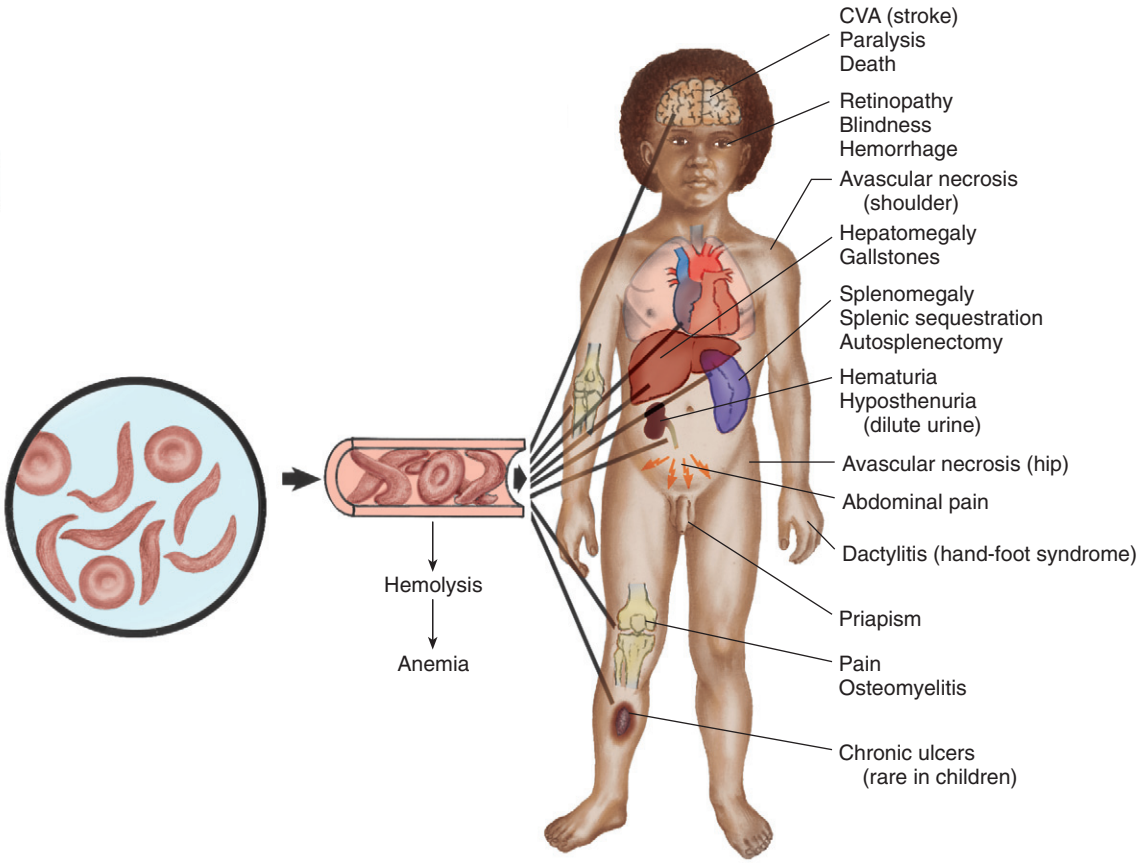

FIG 43-2 Clinical features of sickle cell anemia from red blood cell obstruction and destruction. *CVA,* Cerebrovascular accident.

approximately 70% of untreated children who have experienced one stroke (Heeney and Dover, 2009).

Diagnostic Evaluation

Newborn screening for SCA is mandatory in most of the United States so that infants can be identified before symptoms occur. At birth, infants have up to 80% of HbF, which does not carry the defect. Because levels of HbS are low at birth, Hgb electrophoresis or other tests that measure Hgb concentrations are indicated. Early diagnosis (before 3 months of age) enables initiation of appropriate interventions to minimize complications. The family is taught to administer prophylactic antibiotics and identify early signs of infection and to seek medical therapy as soon as possible.

If SCA is not diagnosed in early infancy, it is likely to manifest symptoms during the toddler and preschool years. SCA is occasionally first diagnosed during a crisis that follows an acute respiratory tract or GI infection. Routine hematologic tests are done to evaluate the anemia. Several specific tests detect the presence of the abnormal Hgb in the heterozygote or the homozygote. For screening purposes, the sickle-turbidity test (Sickledex) is frequently used because it can be performed on blood from a fingerstick and yields accurate results in 3 minutes. However, if the test result is positive, Hgb electrophoresis is necessary to distinguish between children with the trait and those with the disease. Hemoglobin electrophoresis ("fingerprinting" of the protein) is an accurate, rapid, and specific test for detecting the homozygous and heterozygous forms of the disease, as well as the percentages of the various types of Hgb.

Therapeutic Management

The aims of therapy are to (1) prevent the sickling phenomena, which are responsible for the pathologic sequelae, and (2) treat the medical emergencies of sickle cell crisis. The successful achievement of the aims depends on prompt nursing interventions, medical therapies, patient and family preventive measures, and use of innovative treatments.

Medical management of a crisis is usually directed toward supportive and symptomatic treatment. The main objectives are to provide (1) rest to minimize energy expenditure and to improve oxygen utilization; (2) hydration through oral and IV therapy; (3) electrolyte replacement because hypoxia results in metabolic acidosis, which also promotes sickling; (4) analgesia for the severe pain from vasoocclusion; (5) blood replacement to treat anemia and to reduce the viscosity of the sickled blood; and (6) antibiotics to treat any existing infection.

Administration of pneumococcal and meningococcal vaccines is recommended for these children because of their susceptibility to infection as a result of functional asplenia. In addition to routine immunizations, children with SCD should receive a yearly influenza vaccination (see Immunizations, Chapter 31). Oral penicillin prophylaxis is also recommended by 2 months of age to reduce the chance of pneumococcal sepsis (see Evidence-Based Practice box) (AAP Committee on Infectious Diseases, 2009; Hirst and Owusu-Ofori, 2010; National Institutes of Health, 2002; Pack-Mabien and Haynes, 2009).

Oxygen therapy is of little therapeutic value unless the patient has hypoxia (Heeney and Dover, 2009). Severe hypoxia must be

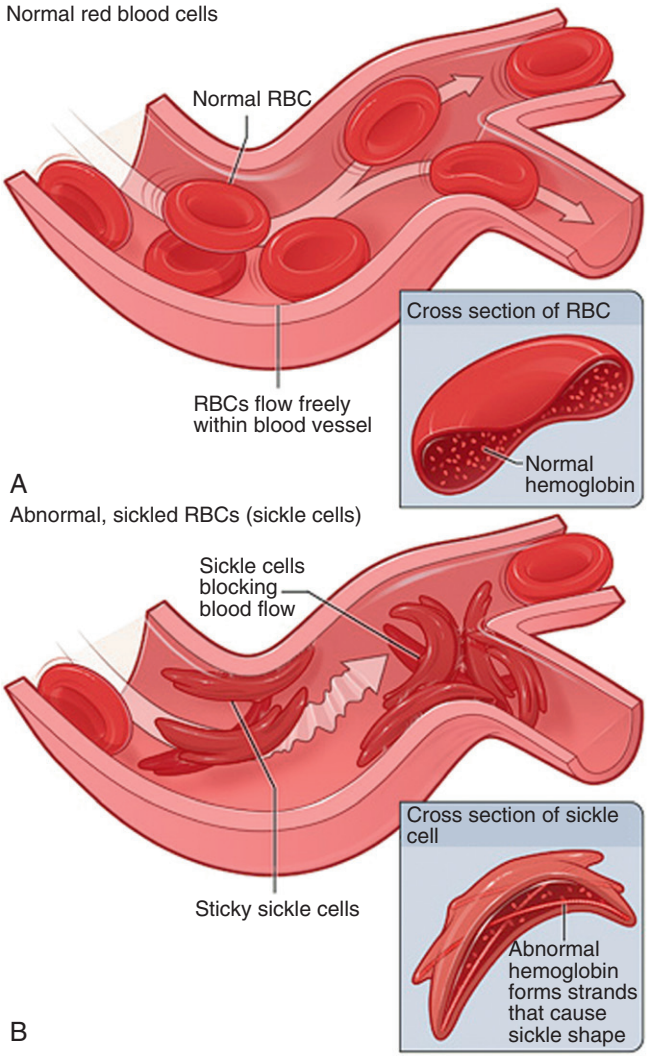

FIG 43-3 A, Normal red blood cells (RBCs) flowing freely in a blood vessel. The *inset* shows a cross section of a normal RBC with normal hemoglobin. **B,** Abnormal, sickled RBCs clumping and blocking blood flow in a blood vessel. (Other cells also may play a role in this clumping process.) The *inset* shows a cross section of a sickle cell with abnormal hemoglobin. (From National Heart, Lung, and Blood Institute: *What is sickle cell anemia?* Bethesda, MD, August 2008, Author.)

BOX 43-2 CLINICAL MANIFESTATIONS OF SICKLE CELL ANEMIA

General
- Possible growth retardation
- Chronic anemia (hemoglobin level of 6-9 g/dL)
- Possible delayed sexual maturation
- Marked susceptibility to sepsis

Vasoocclusive Crisis
- Pain in area(s) of involvement
- Manifestations related to ischemia of involved areas

Extremities—Painful swelling of hands and feet (sickle cell dactylitis, or hand-foot syndrome), painful joints
Abdomen—Severe pain resembling acute surgical condition
Cerebrum—Stroke, visual disturbances
Chest—Symptoms resembling pneumonia, protracted episodes of pulmonary disease
Liver—Obstructive jaundice, hepatic coma
Kidney—Hematuria
Genitalia—Priapism (painful penile erection)

Sequestration Crisis
- Pooling of large amounts of blood
  - Hepatomegaly
  - Splenomegaly
  - Circulatory collapse

Effects of Chronic Vasoocclusive Phenomena
Heart—Cardiomegaly, systolic murmurs
Lungs—Altered pulmonary function, susceptibility to infections, pulmonary insufficiency
Kidneys—Inability to concentrate urine, enuresis, progressive renal failure
Liver—Hepatomegaly, cirrhosis, intrahepatic cholestasis
Spleen—Splenomegaly, susceptibility to infection, functional reduction in splenic activity progressing to autosplenectomy
Eyes—Intraocular abnormalities with visual disturbances; sometimes progressive retinal detachment and blindness
Extremities—Avascular necrosis of hip or shoulder; skeletal deformities, especially lordosis and kyphosis; chronic leg ulcers; susceptibility to osteomyelitis
Central nervous system—Hemiparesis, seizures

EVIDENCE-BASED PRACTICE

Sickle Cell Anemia and Penicillin Prophylaxis

Ask the Question
In children with SCA, does prophylaxis with penicillin reduce the risk for pneumococcal infection?

Critically Analyze the Evidence
- Hirst and Owusu-Ofori (2010) conducted an updated systematic Cochrane review of three trials that showed a reduced rate of infection in children with SCD receiving penicillin preventatively. Two trials looked at whether treatment was effective. The third trial followed from one of the early trials and looked at when it was safe to stop treatment. Adverse drug effects were rare and minor. Penicillin given preventatively reduces the rate of pneumococcal infections in children with SCD younger than 5 years.
- Researchers combined the clinical experiences of three sickle cell programs in the eastern United States in an attempt to determine the age and disease-specific risk for *Streptococcus pneumoniae* bacteremia and meningitis in children with SCD at a time when penicillin prophylaxis was

Continued

EVIDENCE-BASED PRACTICE

Sickle Cell Anemia and Penicillin Prophylaxis—cont'd

routine. Forty-seven pneumococcal infections (44 bacteremia; 3 meningitis) among 40 patients with SCD were observed. Most children in whom infections developed were taking prophylactic penicillin and received Pneumovax at 24 months of age. The observed severe pneumococcal infection rate in HgbSS children younger than 5 years was less than that reported before penicillin prophylaxis in this specific population (Hord, Byrd, Stowe, et al., 2002).

- Administration of oral prophylactic penicillin was compared with the 14-valent pneumococcal vaccine in preventing pneumococcal infection in 242 children between the ages of 6 months and 3 years with HgbSS. In the first 5 years of the trial, there were 11 pneumococcal infections in the pneumococcal vaccine group and higher infection rates in those given the vaccine before 1 year of age. No pneumococcal isolates were found in the group receiving penicillin, although 4 pneumococcal isolates were found in this group within 1 year of stopping the penicillin prophylaxis at age 3 years. This study supported the use of penicillin prophylaxis to prevent pneumococcal infection in children younger than 3 years (John, Ramlal, Jackson, et al., 1984).
- In a multicenter, randomized, double-blind, placebo-controlled clinical trial, 105 children received penicillin twice daily; a control group of 110 children received a placebo twice daily. The trial was terminated 8 months early when an 84% reduction in the incidence of pneumococcal infections was observed in the group treated with penicillin compared with the placebo group. There were no deaths in the penicillin group, but three deaths from infection occurred in the placebo group. Researchers stressed the importance of screening children during the neonatal period and prescribing prophylactic penicillin to decrease the morbidity and mortality associated with pneumococcal infection (Gaston, Verter, Woods, et al., 1986).
- Zarkowsky, Gallagher, Gill, et al. (1986) conducted a retrospective analysis of 178 episodes of bacteremia in children with sickle hemoglobinopathies that occurred during 13,771 patient-years of follow-up ($n = 3451$). The predominant pathogen in patients younger than 6 years was *S. pneumoniae* (66%), and gram-negative organisms were responsible for 50% of the bacteremias in patients 6 years and older. The incidence of pneumococcal bacteremia in children with SCA younger than 3 years was 6.1 events per 100 patient-years. The results of this study supported prophylactic administration of penicillin for prevention of pneumococcal bacteremia in children younger than 3 years.
- A cohort study of 315 patients with HgbSS who lived in Jamaica was conducted between June 1973 and December 1981. The patients were divided into three groups to determine whether interventions such as penicillin prophylaxis, parental education in early diagnosis of acute splenic sequestration, and close monitoring in a sickle cell clinic improved survival. A significant decline in deaths from acute splenic sequestration and pneumococcal septicemia and meningitis was found. The research indicated that early detection of SCD and prophylactic measures could significantly reduce deaths associated with HgbSS (Lee, Thomas, Cupidore, et al., 1995).
- Riddington and Owusu-Ofori (2002) conducted a systematic review of randomized controlled trials evaluating the effectiveness of prophylactic antibiotic administration in preventing pneumococcal infection in children with SCD. The review of published research found that penicillin prophylaxis significantly reduced the risk for pneumococcal infection in children with HgbSS with minimal adverse reactions.

Apply the Evidence: Nursing Implications

There is **good evidence with strong recommendations** (Guyatt, Oxman, Vist, et al., 2008) that demonstrates that penicillin prophylaxis significantly reduces the risk for pneumococcal infection in children with SCA. The epidemiologic studies strongly suggest that all children with SCA should be started on prophylactic penicillin at 2 months of age. Parents and children with SCA should be instructed in the importance of taking the prophylactic penicillin twice daily and seeking medical attention immediately for acute illness, especially if the temperature exceeds 38.3° C (101° F), regardless of the use of prophylaxis.

Quality and Safety Competencies: Evidence-Based Practice*

Knowledge

Differentiate clinical opinion from research and evidence-based summaries.

Summarize the epidemiologic studies that strongly suggest that children with SCA should be started on prophylactic penicillin.

Skills

Base individualized care plan on patient values, clinical expertise, and evidence.

Integrate evidence into practice by making sure infants with SCD are started on penicillin at 2 months of age.

Attitudes

Value the concept of Ebp as integral to determining best clinical practice.

Appreciate strengths and weakness of evidence for preventing pneumococcal infection in children with SCD.

prevented because it causes massive systemic sickling that can be fatal. Oxygen administration is usually not effective in reversing sickling or reducing pain because the oxygen is unable to reach the enmeshed sickled erythrocytes in clogged vessels (Chiocca, 1996). In addition, prolonged administration of oxygen can depress bone marrow, further aggravating the anemia (Khoury and Grimsley, 1995).

Another important component of care is the use of blood transfusions. Exchange RBC transfusion (erythrocytapheresis) is the replacement of sickle cells with normal RBCs. Exchange transfusion is a successful, rapid method of reducing the number of circulating sickle cells and therefore slowing down the vicious circle of hypoxia, thrombosis, tissue ischemia, and injury. The procedure is advocated as a possible technique in preventing reoccurrence of ACS and CVA (Velasquez, Mariscalco, Goldstein, et al., 2009). A transcranial Doppler (TCD) test identifies the child with SCD who is at high risk for developing a CVA by monitoring the intracranial vascular flow (Driscoll, 2007; Kwiatkowski, Yim, Miller, et al., 2011). The TCD test is performed yearly for children from 2 to 16 years of age. The recommended treatment for children with confirmed abnormal TCD is chronic transfusion therapy (Armstrong-Wells, Grimes, Sidney, et al., 2009; Driscoll, 2007; Kwiatkowski, Yim, Miller, et al., 2011). Multiple transfusions carry the risk for transmission of viral infection, hyperviscosity, transfusion reactions, alloimmunization, and hemosiderosis (Driscoll, 2007; Heeney and Dover, 2009). After a CVA, blood transfusions are usually given every 3 to 4 weeks to help prevent a repeat stroke. To reduce iron overload from chronic transfusion therapy, chelation therapy may be started (see p. 1311).

In children with recurrent life-threatening splenic sequestration, splenectomy may be a lifesaving measure. However, the spleen usually atrophies on its own through progressive fibrotic changes (functional asplenia) by 6 years of age in children with SCA. Prophylactic penicillin and pneumococcal vaccines have decreased the incidence of pneumococcal sepsis. Packed RBC transfusions are recommended for treatment of splenic sequestration and stroke and are used preoperatively accompanied with maintenance IV hydration for most surgical procedures in children with SCD.

The most common and debilitating symptom experienced by patients with SCD is VOC, which is accompanied by increasing heath care cost because of prolonged hospitalization associated with pulmonary and GI complications (Driscoll, 2007; Raphael, Mei, Mueller, et al., 2012). The chronic nature of this pain can greatly affect the child's development. A multidisciplinary team (e.g., physician, psychologist, family, nurse, social worker) approach is best for vasoocclusive pain management that includes pharmacologic treatment, hydration, physical therapy, and complementary treatment (e.g., prayer, spiritual healing, massage, herbs, relaxation, acupuncture, and biofeedback) (Brandow, Weisman, and Panepinto, 2011; Redding-Lallinger and Knoll, 2006). When mild to moderate VOC is reported, nonsteroidal antiinflammatory medication (e.g., ibuprofen, ketorolac) or acetaminophen (Tylenol) is used initially. If these drugs are not effective alone, codeine can be added. The dosages of both drugs are titrated (adjusted) to a therapeutic level. Opioids such as immediate- and sustained-release morphine, oxycodone, hydromorphone (Dilaudid), and methadone are administered intravenously or orally for severe pain and are given around the clock. In conjunction with the opioid, IV ketorolac for a maximum of a 5-day course is commonly used to enhance the pain management effect. Patient-controlled analgesia (PCA) has been used successfully for sickle cell–related pain. PCA reinforces the patient's role and responsibility in managing the pain and provides flexibility in dealing with pain, which may vary in severity over time (see Pain Management, Chapter 30).

MEDICATION ALERT

Meperidine (Demerol) is not recommended. Normeperidine, a metabolite of meperidine, is a central nervous system (CNS) stimulant that produces anxiety, tremors, myoclonus, and generalized seizures when it accumulates with repetitive dosing. Patients with SCD are particularly at risk for normeperidine-induced seizures (Howard and Davies, 2007; National Institutes of Health, 2002).

Prognosis. The prognosis varies, but most patients live into the fifth decade. Most of the time, children are without symptoms and participate in normal activities without restrictions. The greatest risk is usually in children younger than 5 years, and the majority of deaths in these children are caused by overwhelming infection. Consequently, SCA is a chronic illness with a potentially terminal outcome. Physical and sexual maturation are delayed in adolescents with SCA. Although adults achieve normal height, weight, and sexual function, the delay may present problems to adolescents (Heeney and Dover, 2009; Redding-Lallinger and Knoll, 2006).

Individuals with SCD who have higher levels of HbF tend to have a milder disease with fewer complications than those with lower levels (Anderson, 2006; Driscoll, 2007). Hydroxyurea is a U.S. Food and Drug Administration–approved medication that increases the production of HbF, reduces endothelial adhesion of sickle cells, improves the sickle cell hydration, increases nitric oxide production (a vasodilator), and lowers leukocyte and **reticulocyte** counts (McGann and Ware, 2011; National Institutes of Health, 2002). Long-term follow-up of patients taking hydroxyurea alone revealed a 40% reduction in mortality and decreased frequency of VOC, ACS, hospital admissions, and need for transfusions, thus making SCD crises milder (Anderson, 2006; Strouse, Lanzkron, Beach, et al., 2008). Pediatric studies have shown that hydroxyurea can be safely used in children (Wang, Ware, Miller, et al., 2011; Zimmerman, Schultz, Davis, et al., 2004).

Hematopoietic stem cell transplantation (HSCT) offers a curative approach for some children with SCD with event-free survival of 95% (Driscoll, 2007; Haining, Duncan, and Lehmann, 2009) (see p. 1389).

CARE MANAGEMENT

Educate the Family and Child. Family education begins with an explanation of the disease and its consequences. After this explanation, the most important issues to teach the family are to (1) seek early intervention for problems, such as fever of 38.5°C (101.3°F) or greater; (2) give penicillin as ordered; (3) recognize signs and symptoms of splenic sequestration, as well as respiratory problems that can lead to hypoxia; and (4) treat the child normally. The nurse tells the family that the child is normal but can get sick in ways that other children cannot.

The nurse emphasizes the importance of adequate hydration to prevent sickling and to delay the adhesion-stasis-thrombosis-ischemia cycle. It is not sufficient to advise parents to "force fluids" or "encourage drinking." They need specific instructions on how many glasses or bottles of fluid are required daily. Many foods are also a source of fluid, particularly soups, flavored ice pops, ice cream, sherbet, gelatin, and puddings.

Increased fluids combined with impaired kidney function result in the problem of enuresis. Parents who are unaware of this fact

FAMILY-CENTERED CARE

Fear of Addiction

Although the pain during a sickle cell crisis is usually severe and opioids are needed, many families fear that their child will become addicted to the narcotic. Unfortunately, misinformed health care professionals may foster this unfounded fear, which results in needless suffering. Extremely few children who receive opioids for severe pain become behaviorally addicted to the drug (American Pain Society, 1999; Howard and Davies, 2007; National Institutes of Health, 2002). Families and older children, especially adolescents, need to be reassured that opioids are medically indicated, high doses may be needed, and children rarely become addicted.

frequently use the usual measures to discourage bedwetting, such as limiting fluids at night, and may resort to punishment and shame to force bladder control. To alleviate parental pressure on the child, enuresis should be considered a complication of the disease just as joint pain or some other symptom is regarded.

Promote Supportive Therapies During Crises. The success of many of the medical therapies relies heavily on nursing implementation. Management of pain is an especially difficult problem and often involves experimenting with various analgesics, including opioids, and schedules before relief is achieved. Unfortunately, these children tend to be undermedicated, resulting in their "clock watching" and demands for additional doses sooner than might be expected. Often this incorrectly raises suspicions of drug addiction, when in fact the problem is one of improper dosage (see Family-Centered Care box). In choosing and scheduling analgesics, the goal should be *prevention* of pain.

NURSING ALERT

Advise parents to be particularly alert to situations in which dehydration may be a possibility, such as hot weather, and to recognize early signs of reduced intake, such as decreased urinary output (e.g., fewer wet diapers) and increased thirst.

Any pain program should be combined with psychologic support to help the child deal with the depression, anxiety, and fear that may accompany the disease. This includes regular visits with the child to discuss any concerns during the hospitalization and positive reinforcement of coping skills, such as successful methods of dealing with the pain and compliance with treatment prescriptions. To reduce the negative connotation associated with the term *crisis,* it is best to say *pain episode.*

If blood transfusions or exchange transfusions are given, the nurse has the responsibility of observing for signs of transfusion reaction. Because hypervolemia from too-rapid transfusion can increase the workload of the heart, the nurse also is alert to signs of cardiac failure.

In splenic sequestration, the size of the spleen is gently measured by abdominal palpation (see Abdomen, Chapter 29). The nurse should be aware of spleen size because increasing splenomegaly is an ominous sign. A decreasing spleen size denotes response to therapy. Vital signs and blood pressure are also closely monitored for impending shock. Anemia is typically not a presenting complication in vasoocclusive crises but is a critical problem in other types of crises. The nurse monitors for evidence of increasing anemia and institutes appropriate nursing interventions. Oxygen is not beneficial in vasoocclusive episodes unless hypoxemia is present (Heeney and Dover, 2009). It does not reverse sickled RBCs, and if used in a nonhypoxic patient, it will decrease erythropoiesis (Vichinsky and Styles, 1996). Because prolonged use of oxygen can aggravate the anemia, signs of lack of therapeutic benefit, such as restlessness, increased pallor, and continued pain, are reported.

Record intake, especially of IV fluids, and output. The child's weight should be taken on admission to serve as a baseline for evaluating hydration. Because diuresis can result in electrolyte loss, the nurse also observes for signs of hypokalemia and should be familiar with normal serum electrolyte values to report changes.

Recognize Other Complications. Nurses also need to be aware of the signs of ACS and CVA, both potentially fatal complications.

NURSING ALERT

Report signs of the following immediately:

- ACS:
  - Severe chest, back, or abdominal pain
  - Fever of 38.5° C (101.3° F) or higher
  - Cough
  - Dyspnea, tachypnea
  - Retractions
  - Declining oxygen saturation (oximetry)
- CVA:
  - Severe, unrelieved headaches
  - Severe vomiting
  - Jerking or twitching of the face, legs, or arms
  - Seizures
  - Strange, abnormal behavior
  - Inability to move an arm or leg
  - Stagger or an unsteady walk
  - Stutter or slurred speech
  - Weakness in the hands, feet, or legs
  - Changes in vision

Support the Family. Families need the opportunity to discuss their feelings regarding transmitting a potentially fatal, chronic illness to their child. Because of the widely publicized prognosis for children with SCA, many parents express their prevalent fear of the child's death. Three manifestations of SCD that may appear in the first 2 years of life (dactylitis, severe anemia, leukocytosis) can be predictors of disease severity (DeBaun and Vichinsky, 2007; Ohls and Christensen, 2007). The nurse should care for the family as for any family with a child who has a chronic and life-threatening illness and consider the siblings' reactions, the stress on the marital relationship, and the childrearing attitudes displayed toward the child. Several resources are available to families with a sickling disorder.*

Guideline for the management of acute and chronic pain in sickle-cell disease is available from the American Pain Society, 4700 W. Lake Ave., Glenview, IL 60025-1485; 847-375-4715; fax: 866-574-2654; e-mail: info@ampainsoc.org; www.ampainsoc.org.

The nurse advises parents to inform all treating personnel of the child's condition. The use of medical identification, such as a bracelet, is another way of ensuring awareness of the disease.

If family members have the SCD trait or SCA, genetic counseling is necessary. A primary consideration in genetic counseling is informing parents of the 25% chance with each pregnancy of having a child with the disease when both parents carry the trait.

β-Thalassemia (Cooley Anemia)

Worldwide, thalassemia is a common genetic disorder, affecting as many as 15 million people (Yaish, 2010). The term thalassemia, which is derived from the Greek word *thalassa,* meaning "sea," is applied to a variety of inherited blood disorders characterized by deficiencies in the rate of production of specific globin chains in Hgb. The name appropriately refers to descendants of or people living near the Mediterranean Sea, who have the highest incidence of the disease, namely Italians, Greeks, and Syrians. Evidence suggests that the high incidence of the disorders among these groups is a result of the selective advantage the trait confers in relation to malaria, as is postulated in SCD. However, the disorder has a wide geographic distribution, probably as a result of genetic migration through intermarriage or possibly as a result of spontaneous mutation.

β-Thalassemia is the most common of the thalassemias and occurs in four forms:

- Two heterozygous forms, thalassemia minor, an asymptomatic silent carrier; and thalassemia trait, which produces a mild microcytic anemia
- Thalassemia intermedia, which is manifested as splenomegaly and moderate to severe anemia
- A homozygous form, thalassemia major (also known as Cooley anemia), which results in a severe anemia that would lead to cardiac failure and death in early childhood without transfusion support

Pathophysiology

Normal postnatal Hgb is composed of two α– and two β–polypeptide chains. In β-thalassemia, there is a partial or complete deficiency in the synthesis of the β-chain of the Hgb molecule. Consequently, there is a compensatory increase in the synthesis of α-chains, and γ-chain production remains activated, resulting in defective Hgb formation. This unbalanced polypeptide unit is very unstable; when it disintegrates, it damages RBCs, causing severe anemia.

To compensate for the hemolytic process, an overabundance of erythrocytes is formed unless the bone marrow is suppressed by transfusion therapy. Excess iron from hemolysis of supplemental RBCs in transfusions and from the rapid destruction of defective cells is stored in various organs (hemosiderosis).

Diagnostic Evaluation

The onset of thalassemia major may be insidious and not recognized until the latter half of infancy. The clinical effects of thalassemia major are primarily attributable to (1) defective synthesis of HbA, (2) structurally impaired RBCs, and (3) shortened life span of erythrocytes (Box 43-3).

Hematologic studies reveal the characteristic changes in RBCs (i.e., microcytosis, hypochromia, anisocytosis, poikilocytosis, target cells, and basophilic stippling of various stages). Low Hgb and Hct levels are seen in severe anemia, although they are typically lower than the reduction in RBC count because of the proliferation of immature erythrocytes. Hgb electrophoresis confirms the diagnosis, and radiographs of involved bones reveal characteristic findings.

BOX 43-3 CLINICAL MANIFESTATIONS OF β-THALASSEMIA

Anemia (Before Diagnosis)
- Pallor
- Unexplained fever
- Poor feeding
- Enlarged spleen or liver

Progressive Anemia
- Signs of chronic hypoxia
  - Headache
  - Precordial and bone pain
  - Decreased exercise tolerance
  - Listlessness
  - Anorexia

Other Features
- Small stature
- Delayed sexual maturation
- Bronzed, freckled complexion (if not receiving chelation therapy)

Bone Changes (Older Children If Untreated)
- Enlarged head
- Prominent frontal and parietal bossing
- Prominent malar eminences
- Flat or depressed bridge of the nose
- Enlarged maxilla
- Protrusion of the lip and upper central incisors and eventual malocclusion
- Generalized osteoporosis

Therapeutic Management

The objectives of supportive therapy are to maintain sufficient Hgb levels to prevent bone marrow expansion and the resulting bony deformities and to provide sufficient RBCs to support normal growth and normal physical activity. Transfusions are the foundation of medical management with the goal of maintaining the Hgb level above 9.5 g/dL, an aim that may require transfusions as often as every 3 to 5 weeks. The advantages of this therapy include (1) improved physical and psychologic well-being because of the ability to participate in normal activities, (2) decreased cardiomegaly and hepatosplenomegaly, (3) fewer bone changes, (4) normal or near-normal growth and development until puberty, and (5) fewer infections.

One of the potential complications of frequent blood transfusions is iron overload (hemosiderosis). Because the body has no effective means of eliminating the excess iron, the mineral is deposited in body tissues. To minimize the development of hemosiderosis, the oral iron chelator *deferasirox* has been shown to be a safe equivalent to deferoxamine (Desferal), a parenteral iron-chelating agent, and more tolerable by patients and families (Cappellini, Porter, El-Beshlawy, et al., 2010; Vichinsky, Bernaudin, Forni, et al., 2011; Vichinsky, Onyekwere, Porter, et al., 2007).

In some children with severe splenomegaly who require repeated transfusions, a splenectomy may be necessary to decrease the disabling effects of abdominal pressure and to increase the life span of supplemental RBCs. Over time, the spleen may accelerate the rate of RBC destruction and thus increase transfusion requirements. After a splenectomy, children generally require fewer transfusions, although the basic defect in Hgb synthesis remains unaffected. A major postsplenectomy complication is severe and overwhelming infection. Therefore these children continue to receive prophylactic antibiotics with close medical supervision for many years and should receive the pneumococcal and meningococcal vaccines in addition to the regularly scheduled immunizations (see Immunizations, Chapter 31).

NURSING ALERT

Ensure that the family and patient understand the need to notify the health care professional of all fevers of 38.5° C (101.3° F) or greater because of the risk for sepsis in a child with asplenia.

Prognosis. Most children treated with blood transfusion and early chelation therapy survive well into adulthood. The most common causes of death are heart disease, postsplenectomy sepsis, and multiple-organ failure secondary to hemochromatosis (Cunningham, Sankaran, Nathan, et al., 2009). A curative treatment for some children is HSCT. Children younger than 16 years who undergo allogeneic HSCT have a high rate of complication-free survival; approximately 80% of these children are cured (Lucarelli and Gaziev, 2008).

CARE MANAGEMENT

The objectives of nursing care are to (1) promote compliance with transfusion and chelation therapy, (2) assist the child in coping with the anxiety-provoking treatments and the effects of the illness, (3) foster the child's and family's adjustment to a chronic illness, and (4) observe for complications of multiple blood transfusions. Basic to each of these goals is explaining to parents and older children the defect responsible for the disorder, its effect on RBCs, and the potential effects of untreated iron overload (e.g., diabetes and heart disease). Because the prevalence of this condition is high among families of Mediterranean descent, the nurse also inquires about the family's previous knowledge about thalassemia. All families with a child with thalassemia should be tested for the trait and referred for genetic counseling.

As with any chronic illness, the family's needs must be met for optimal adjustment to the stresses imposed by the disorder (see Chapter 36). Sources of information for the family include the Cooley's Anemia Foundation* and the Northern California Comprehensive Thalassemia Center.† Genetic counseling for the parents and fertile offspring is mandatory, and both prenatal diagnosis using amniocentesis at 20 weeks' gestation or fetal blood sampling at 10 weeks and screening for thalassemia trait are available.

Aplastic Anemia

Aplastic anemia (AA) refers to a bone marrow failure condition in which the formed elements of the blood are simultaneously depressed. The peripheral blood smear demonstrates **pancytopenia** or the triad of profound anemia, leukopenia, and thrombocytopenia. Hypoplastic anemia is characterized by a profound depression of RBCs but normal or slightly decreased white blood cells (WBCs) and platelets.

Etiology

Aplastic anemia can be primary (congenital, or present at birth) or secondary (acquired). The best-known congenital disorder of which AA is an outstanding feature is Fanconi syndrome, a rare hereditary disorder characterized by pancytopenia, hypoplasia of the bone marrow, and patchy brown discoloration of the skin resulting from the deposit of melanin and associated with multiple congenital anomalies of the musculoskeletal and genitourinary systems. The syndrome appears to be inherited as an autosomal recessive trait with varying penetrance; therefore affected siblings may demonstrate several different combinations of defects.

BOX 43-4 COMMON CAUSES OF ACQUIRED APLASTIC ANEMIA

- Human parvovirus infection, hepatitis, or overwhelming infection
- Irradiation
- Immune disorders such as hypoimmunoglobulinemia and eosinophilic fasciitis
- Drugs such as certain chemotherapeutic agents, anticonvulsants, and antibiotics
- Industrial and household chemicals, including benzene and its derivatives, which are found in petroleum products, dyes, paint remover, shellac, and lacquers
- Infiltration and replacement of myeloid elements, such as in leukemia or the lymphomas
- Idiopathic (In most cases, no identifiable precipitating cause can be found.)

Several etiologic factors contribute to the development of acquired hypoplastic anemia; however, most of the cases are considered idiopathic (Box 43-4). Acquired AA is classified as either *severe acquired AA* or *moderate acquired AA*. The following discussion focuses on severe acquired AA, which carries a poorer prognosis and follows a more rapidly fatal course than the primary types.

Diagnostic Evaluation

The onset of clinical manifestations, which include anemia, leukopenia, and decreased platelet count, is usually insidious. Definitive diagnosis is determined from bone marrow examination, which demonstrates the conversion of red bone marrow to yellow, fatty bone marrow. Severe AA is defined as less than 25% bone marrow cellularity with at least two of the following findings: absolute granulocyte count less than 500/mm^3, platelet count less than 20,000/mm^3, and absolute reticulocyte count less than 40,000/mm^3 (Hord, 2007; Passweg and Marsh, 2010). Moderate AA is defined as more than 25% bone marrow cellularity with the presence of mild or moderate cytopenia (Shimamura and Guinan, 2009).

Therapeutic Management

The objectives of treatment are based on the recognition that the underlying disease process is failure of the bone marrow to carry out its hematopoietic functions. Therefore therapy is directed at restoring function to the marrow and involves two main approaches: (1) immunosuppressive therapy to remove the presumed immunologic functions that prolong aplasia; or (2) replacement of the bone marrow through transplantation. Bone marrow transplantation is the treatment of choice for severe AA when a suitable donor exists (see p. 1389).

Antilymphocyte globulin (ALG) or antithymocyte globulin (ATG) is the principal drug treatment used for AA. The rationale for using ATG is based on the theory that AA may be a result of autoimmunity. ATG and cyclosporine suppress T cell–dependent autoimmune responses but do not cause bone marrow suppression. Cyclosporine is administered orally for several weeks to months. ATG usually is administrated intravenously over 12 to 16 hours for 4 days after a test dose to check for hypersensitivity. A course may

*330 Seventh Ave., No. 200, New York, NY 10001; 800-522-7222; fax: 212-279-5999; www.thalassemia.org.
†747 52nd St., Oakland, CA 94609; 510-428-3885, ext. 5427; http://hemonc.cho.org/thalassemia.

be repeated, depending on the reduction in circulating lymphocytes and the patient's response. Because of the hypersensitivity response associated with ATG (i.e., fever, chills, myalgias), methylprednisolone is given intravenously to prevent these side effects. Colony-stimulating factor (CSF) and granulocyte-macrophage colony-stimulating factor (GM-CSF), given parenterally, may be used to enhance bone marrow production. Androgens may be used with ATG to stimulate erythropoiesis if the AA is unresponsive to initial therapies.

Hematopoietic stem cell transplantation should be considered early in the course of the disease if a compatible donor can be found. Transplantation is more successful when performed before multiple transfusions have sensitized the child to leukocyte and human leukocyte antigens (HLAs). HSCT is associated with an approximately 90% survival rate in patients who receive a bone marrow transplant from an HLA-identical sibling (Hord, 2007; Marsh, 2005; Trigg, 2004).

CARE MANAGEMENT

The care of the child with AA is similar to that of the child with leukemia (see p. 1380) and includes preparing the child and family for the diagnostic and therapeutic procedures, preventing complications from the severe pancytopenia, and emotionally supporting them in the face of a potentially fatal outcome. Information and support are available from the Aplastic Anemia and MDS International Foundation, Inc.*

Because the aspects of nursing care are discussed in the section on leukemia, only the exceptions are presented here. The drug *ATG* is usually administered by way of a central vein. If not, vigilant care must be directed to the IV infusion to prevent extravasation. Meticulous care of the venous access is essential because of the child's susceptibility to infection. CSFs are usually given by subcutaneous injection over several days. Chemotherapeutic agents have been reported in the treatment of relapsed patients with AA after ATG and CSF therapy. Many of the side effects associated with chemotherapy such as nausea and vomiting, **alopecia,** and mucositis are experienced by children receiving treatment for AA. Specialized care is required for children who have HSCT (see p. 1389).

DEFECTS IN HEMOSTASIS

Hemostasis is the process that stops bleeding when a blood vessel is injured. Vascular and plasma clotting factors, as well as platelets, are required. A complex system of clotting, anticlotting, and clot breakdown (fibrinolysis) mechanisms exists in equilibrium to ensure clot formation only in the presence of blood vessel injury and to limit the clotting process to the site of vessel wall injury. Dysfunction in these systems leads to bleeding or abnormal clotting. Although the coagulation process is complex, clotting depends on three factors: (1) vascular influence, (2) platelet role, and (3) clotting factors.

Hemophilia

The term hemophilia refers to a group of bleeding disorders in which there is a deficiency of one of the factors (proteins) necessary for coagulation of the blood. Although the symptomatology is similar regardless of which clotting factor is deficient, the identification of specific factor deficiencies allows definitive treatment with replacement agents.

In about 80% of all cases of hemophilia, the inheritance pattern is demonstrated as X-linked recessive. The two most common forms of the disorder are factor VIII deficiency (hemophilia A, or classic hemophilia) and factor IX deficiency (hemophilia B, or Christmas disease). Von Willebrand disease (vWD) is another hereditary bleeding disorder characterized by a deficiency, abnormality, or absence of the protein called *von Willebrand factor (vWF)* and a deficiency of factor VIII. Unlike hemophilia, vWD affects both males and females. The following discussion is concerned primarily with factor VIII deficiency, which accounts for 80% of all hemophilia cases.

Pathophysiology

The basic defect of hemophilia A is a deficiency of factor VIII (antihemophilic factor [AHF]). AHF is produced by the liver and is necessary for the formation of thromboplastin in phase I of blood coagulation (Fig. 43-4). The less AHF found in the blood, the more severe the disease. Individuals with hemophilia have two of the three factors required for coagulation: vascular influence and platelets. Therefore they may bleed for longer periods but not at a faster rate.

Bleeding into subcutaneous and IM tissue is common. Hemarthrosis, which is bleeding into a joint space, is the most frequent type of internal bleeding. Bony changes and crippling deformities occur after repeated bleeding episodes over several years. Signs of hemarthrosis are swelling, warmth, redness, pain, and loss of movement. Bleeding in the neck, mouth, or thorax is serious because the airway can become obstructed. Intracranial hemorrhage can have fatal consequences and is one of the major causes of death. Hemorrhage anywhere along the GI tract can lead to anemia, and bleeding into the retroperitoneal cavity is especially hazardous because of the large space for blood to accumulate. Hematomas in the spinal cord can cause paralysis.

Diagnostic Evaluation

Overt, prolonged hemorrhage is readily apparent; bleeding into tissues is less apparent (Box 43-5). The diagnosis is usually made from a history of bleeding episodes, evidence of X-linked inheritance (only one third of the cases are new mutations), and laboratory findings. The tests specific for hemophilia plasma depend on specific factors for a reaction to occur, such as the partial thromboplastin time (PTT). Specific determination of factor deficiencies requires assay procedures normally performed in specialized laboratories. Carrier detection is possible in classic hemophilia using DNA testing and is an important consideration in families in whom female offspring may have inherited the trait.

Therapeutic Management

The primary therapy for hemophilia is replacement of the missing clotting factor. The products available are factor VIII concentrates, either produced through genetically engineering (recombinant) or derived from pooled plasma, which are reconstituted with sterile water immediately before use. A synthetic form of vasopressin, 1-deamino-8-D-arginine vasopressin (DDAVP), increases plasma factor VIII activity and is the treatment of choice in mild hemophilia and certain types of vWD if the child shows an appropriate response. DDAVP is not effective in the treatment of severe hemophilia A, severe vWD, or any form of hemophilia B. Aggressive factor concentrate replacement therapy is initiated to prevent chronic crippling effects from joint bleeding.

Other drugs may be included in the therapy plan, depending on the source of the hemorrhage. Corticosteroids are given for

*100 Park Ave., Suite 108, Rockville, MD 20850; 800-747-2820, 301-279-7202; fax: 301-279-7205; e-mail: help@aamds.org; www.aamds.org.

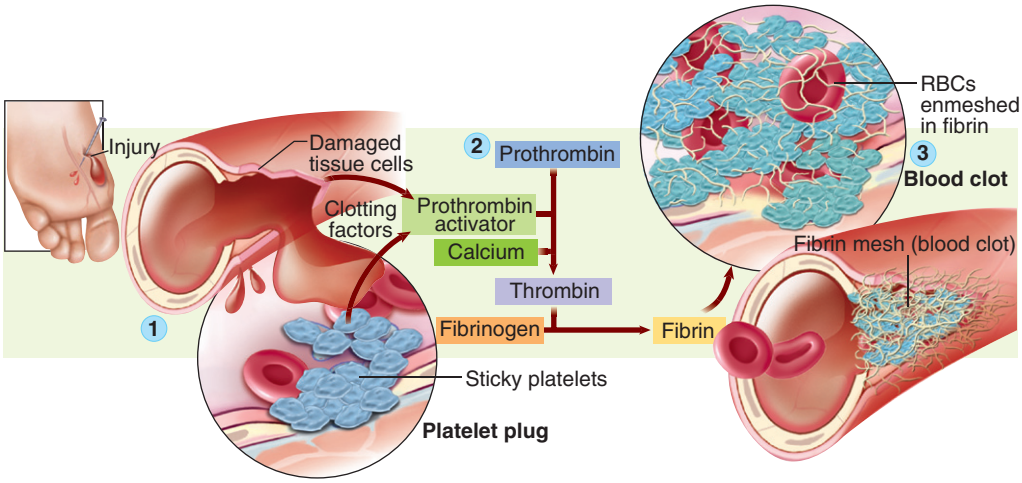

FIG 43-4 Blood clotting. The extremely complex clotting mechanism can be distilled into three basic steps: *(1)* release of clotting factors from both injured tissue cells and sticky platelets at the injury site (which form a temporary platelet plug); *(2)* a series of chemical reactions that eventually result in the formation of thrombin; and *(3)* formation of fibrin and trapping of red blood cells (RBCs) to form a clot. (From Thibodeau GA: *The human body in health and disease,* ed 5, St Louis, Mosby, 2010.)

BOX 43-5 CLINICAL MANIFESTATIONS OF HEMOPHILIA

- Prolonged bleeding anywhere from or in the body
- Hemorrhage from any trauma—loss of deciduous teeth, circumcision, cuts, epistaxis, injections
- Excessive bruising, even from a slight injury, such as a fall
- Subcutaneous and intramuscular hemorrhages
- Hemarthrosis (bleeding into the joint cavities), especially the knees, ankles, and elbows
- Hematomas—pain, swelling, and limited motion
- Spontaneous hematuria

hematuria, acute hemarthrosis, and chronic synovitis. Nonsteroidal antiinflammatory drugs (NSAIDs), such as ibuprofen, are effective in relieving pain caused by synovitis; however, they are occasionally used with caution because they inhibit platelet function (Curry, 2004). Oral administration of ε-aminocaproic acid (Amicar) prevents clot destruction. Its use is limited to mouth or trauma surgery with a dose of factor concentrate given first.

A regular program of exercise and physical therapy is an important aspect of management. Physical activity within reasonable limits strengthens muscles around joints and may decrease the number of spontaneous bleeding episodes.

Treatment without delay results in more rapid recovery and a decreased likelihood of complications; therefore most children are treated at home. The family is taught the technique of venipuncture and to administer the AHF to children older than 2 to 3 years. The child learns the procedure for self-administration at 8 to 12 years of age. Home treatment is highly successful, and the rewards, in addition to the immediacy, are less disruption of family life, fewer school or work days missed, and enhancement of the child's self-esteem and independence.

Primary prophylaxis in hemophilia patients has proved to be effective in preventing bleeding complications by administrating periodic factor replacement. Primary prophylaxis involves the infusion of factor VIII concentrate on a regular basis before the onset of joint damage. Secondary prophylaxis involves the infusion of factor VIII concentrate on a regular basis after the child experiences his or her first joint bleed. The infusions are given 3 times a week. Aggressive or on-demand factor replacement may be a cost-effective alternative to primary prophylaxis, but prophylaxis decreases the development of joint disease compared with on-demand factor replacement treatment (Manco-Johnson, Abshire, Shapiro, et al., 2007). Prompt appropriate treatment of hemorrhage and prophylactic therapy are key to excellent care and prevention of long-term morbidity in patients with hemophilia (Montgomery, Gill, and DiPaola, 2009; Sharathkumar and Pipe, 2008).

Prognosis. Although there is no cure for hemophilia, its symptoms can be controlled and its potentially crippling deformities greatly reduced or even avoided. Today many children with hemophilia function with minimal or no joint damage. They are normal children with an average life expectancy in every respect but one: they have a tendency to bleed, which is a significant inconvenience but not necessarily a life-threatening event.

Gene therapy may prove to be a treatment option in the future. This therapy involves introducing a working copy of the factor VIII gene into a patient who has a flawed copy of the gene. Problems exist with appropriate selection of the **vector,** identification of the cell for gene expression, and control of side effects (Matrai, Chuah, and VandenDriessche, 2010; Montgomery, Gill, and DiPaola, 2009).

CARE MANAGEMENT

The earlier a bleeding episode is recognized, the more effectively it can be treated. Signs that indicate internal bleeding are especially important to recognize. Children are aware of internal bleeding and are reliable in telling the examiner where an internal bleed is. In addition to the manifestations described (see Box 43-5), the nurse maintains a high level of suspicion when a child with hemophilia demonstrates signs such as headache, slurred speech, loss of consciousness (from cerebral bleeding), and black tarry stools (from GI bleeding).

Prevent Bleeding. The goal of prevention of bleeding episodes is directed toward decreasing the risk for injury. Prevention of bleeding episodes is geared mostly toward appropriate exercises to strengthen muscles and joints and to allow age-appropriate activity.

During infancy and toddlerhood, the normal acquisition of motor skills creates innumerable opportunities for falls, bruises, and minor wounds. Restraining the child from mastering motor development can foster more serious long-term problems than allowing the behavior. However, the environment should be made as safe as possible, with close supervision during playtime to minimize incidental injuries.

For older children, the family usually needs assistance in preparing for school. A nurse who knows the family can be instrumental in discussing the situation with the school nurse and in jointly planning an appropriate activity schedule. Because almost all persons with hemophilia are boys, the physical limitations in regard to active sports may be a difficult adjustment and activity restrictions must be tempered with sensitivity to the child's emotional and physical needs. Use of protective equipment, such as padding and helmets, is particularly important, and noncontact sports, especially swimming, walking, jogging, tennis, golf, fishing, and bowling, are encouraged (National Hemophilia Foundation, 2006). However, the use of prophylaxis to prevent joint hemorrhage or overuse during low-impact athletic participation remains unknown (Ross, Goldenberg, Hund, et al., 2009).

To prevent oral bleeding, some readjustment in terms of dental hygiene may be needed to minimize trauma to the gums, such as use of a water irrigating device, softening the toothbrush in warm water before brushing, or using a sponge-tipped disposable toothbrush. A regular toothbrush should be soft bristled and small.

Because any trauma can lead to a bleeding episode, all persons caring for these children must be aware of their disorder. These children should wear medical identification, and older children should be encouraged to recognize situations in which disclosing their condition is important, such as during dental extraction or injections. Health care personnel need to take special precautions to prevent the use of procedures that may cause bleeding, such as IM injections. The subcutaneous route is substituted for IM injections whenever possible. Venipunctures for blood samples are usually preferred for these children. There is usually less bleeding after the venipuncture than after finger or heel punctures. Neither aspirin nor any aspirin-containing compound should be used. Acetaminophen is a suitable aspirin substitute, especially for controlling pain at home.

Recognize and Control Bleeding. As noted, the earlier a bleeding episode is recognized, the more effectively it can be treated. Factor replacement therapy should be instituted according to established medical protocol, and supportive measures may be implemented, such as RICE, which stands for ***r***est, ***i***ce, ***c***ompression, and ***e***levation. When parents and older children are taught such measures beforehand, they can be prepared to initiate immediate treatment. Plastic bags of ice or cold packs should be kept in the freezer for such emergencies. However, such measures do not take the place of factor replacement.

Prevent Crippling Effects of Bleeding. As a result of repeated episodes of hemarthrosis, incompletely absorbed blood in the joints, and limitation of motion, bone and muscle changes occur that result in flexion contractures and joint fixation. During bleeding episodes, the joint is elevated and immobilized. Active range-of-motion exercises are usually instituted after the acute episode. This allows the child to control the degree of exercise and discomfort. If an exercise program is instituted in the home, a physical therapist or home health nurse may need to supervise compliance with the regimen. Rarely, orthopedic intervention, such as casting, application of traction, or aspiration of blood, may be necessary to preserve joint function. Diet is also an important consideration because excessive body weight can increase the strain on affected joints, especially the knees, and predispose the child to hemarthrosis. Consequently, calorie intake should be balanced in accordance with energy requirements.

Support the Family and Prepare for Home Care. Genetic counseling is essential as soon as possible after diagnosis. Unlike many other disorders in which both parents carry the trait, the feeling of responsibility for this condition usually rests with the mother. Without an opportunity to discuss her feelings, the marital relationship can suffer. Technology is now available to identify carriers in approximately 80% of cases and may reduce the anxiety regarding childbearing in women who may be at risk of carrying the defective gene, such as sisters or maternal aunts of an affected boy. Factor concentrates have greatly changed the outlook for these children by minimizing bleeding and allowing the child to live a normal, unrestricted life. Children are taught to take responsibility for their disease at an early age. They learn their limitations, other preventive measures, and self-administration of the prophylactic AHF.

The needs of families who have children with hemophilia are best met through a comprehensive team approach of physicians (pediatrician, hematologist, orthopedist), nurse practitioner, nurse, social worker, and physical therapist. Parent-group discussions are beneficial in meeting the needs that are often best met by similarly affected families. For example, with the improved prognosis for these children, parents and adolescents with hemophilia face vocational and financial problems in addition to concern over future childbearing. After children reach 21 years of age, many insurance companies will no longer carry them. This can be disastrous in terms of the cost of treatment. Financial support is particularly important. A person with severe hemophilia may require factor replacement therapy and other medical treatments that cost in excess of $100,000 a year. The National Hemophilia Foundation* and the Canadian Hemophilia Society† provide numerous services and publications for both health care providers and families.

Children who have become infected with HIV through transfusions and factor replacement products are faced with the consequences of this dreaded disease. Consequently, they need the support of health care professionals, especially in the areas of safe sexual practices to avoid disease transmission and public education regarding acquired immunodeficiency syndrome (AIDS) and ways to deal with public reactions to persons who have AIDS (see p. 1387).

Immune Thrombocytopenia (Idiopathic Thrombocytopenic Purpura)

Idiopathic or immune thrombocytopenic purpura, as a formerly used term because purpura is an infrequent sign at presentation, is now referred to as *immune thrombocytopenia* (ITP) (Rodeghiero, Stasi, Gernsheimer, et al., 2009). ITP is an acquired hemorrhagic disorder characterized by (1) thrombocytopenia, (2) absence or minimal signs of bleeding (easy bruising, mucosal bleeding, petechiae) in most childhood cases, and (3) normal bone marrow with normal or increased number of immature platelets (megakaryocytes) and eosinophils. Although all causes of ITP are not known, it is understood that ITP involves the evolution of antibodies against multiple platelet antigens, leading to reduced platelet survival and impaired platelet production (Consolini, 2011; McCrae, 2011). It is the most frequently occurring thrombocytopenia of

*116 W. 32nd St., 11th Floor, New York, NY 10001; 800-42-HANDI, 212-328-3700; fax: 212-328-3777; e-mail: handi@hemophilia.org; www.hemophilia.org.

BOX 43-6 CLINICAL MANIFESTATIONS OF IMMUNE THROMBOCYTOPENIA (IDIOPATHIC THROMBOCYTOPENIC PURPURA)

- Easy bruising
  - Petechiae
  - Ecchymoses
    - Hematomas over lower extremities
  - Most often over bony prominences
- Bleeding from mucous membranes
  - Epistaxis
  - Bleeding gums
  - Internal hemorrhage evidenced by:
    - Hematuria
    - Hematemesis
    - Melena
    - Hemarthrosis
    - Menorrhagia

childhood. The greatest frequency of occurrence is in children younger than 10 years with the peak incidence at age 2 to 5 years (Consolini, 2011; McCrae, 2011; Wilson, 2009).

The disease occurs in one of two forms: an acute, self-limiting course; or a chronic condition (>12 months' duration). The acute form is most often seen after upper respiratory tract infections; after the childhood diseases *measles, rubella, mumps,* and *chickenpox;* or after infection with parvovirus B19.

Diagnostic Evaluation

The diagnosis is suspected on the basis of clinical manifestations (Box 43-6). In ITP, the platelet count is reduced to below 20,000/mm^3; therefore tests that depend on platelet function, such as the tourniquet test, bleeding time, and clot retraction, have abnormal results. Although there is no definitive test on which to establish a diagnosis of ITP, several tests are usually performed to rule out other disorders in which thrombocytopenia is a manifestation, such as systemic lupus erythematosus, lymphoma, or leukemia.

Therapeutic Management

Management of ITP is primarily supportive because the course of the disease is self-limited in the majority of cases. Activity is restricted at the onset while the platelet count is low and while active bleeding or progression of lesions is occurring. Treatment for acute presentation is symptomatic and has included prednisone, IV immune globulin (IVGG), and anti-D antibody. These are not curative therapies. Anti-D antibody is a relatively new therapy for ITP. Infusion of anti-D antibody causes a transient hemolytic anemia in the patient. Along with the clearance of antibody-coated RBCs, there is prolonged survival of platelets resulting from the blockade of the Fc receptors of the reticuloendothelial cells. The platelet count does not increase until 48 hours after an infusion of anti-D antibody; therefore it is not appropriate therapy for patients who are actively bleeding. The benefits of choosing anti-D antibody therapy over prednisone or IVIG is that anti-D antibody can be given in one dose over 5 to 10 minutes and is significantly less expensive than IVIG. Historically, patients who are treated with prednisone may first undergo a bone marrow examination to rule out leukemia, which is controversial because leukemia rarely manifests with low platelet count alone (Scott and Montgomery, 2007; Wilson, 2009). Therefore the use of anti-D antibody and IVIG alleviates the need for a bone marrow examination. Before receiving the initial dose of anti-D antibody, patients must meet certain criteria (Box 43-7). Premedication with acetaminophen 5 to 10 minutes before the infusion is recommended.

BOX 43-7 CRITERIA FOR ANTI-D ANTIBODY THERAPY

- Age between 1 and 19 years; Rh(D)-positive blood type
- Normal WBC count and hemoglobin level for age; platelet count of 20,000/mm^3
- No active mucosal bleeding
- No history of reaction to plasma products
- No known immunoglobulin A deficiency
- No concurrent infection
- Absence of Evans syndrome (characterized by the combination of idiopathic thrombocytopenic purpura and autoimmune hemolytic anemia)
- No suspicion of lupus erythematosus or other collagen vascular disorder
- No splenectomy

WBC, White blood cell.

! NURSING ALERT

After administration of anti-D antibody, observe the child for a minimum of 1 hour and maintain a patent IV line. Obtain baseline vital signs before the infusion and again 5, 20, and 60 minutes after beginning the infusion. Fever, chills, and headache may occur during or shortly after the infusion. If so, diphenhydramine (Benadryl) and hydrocortisone (Solu-Cortef) should be given and the patient observed for an additional hour.

Splenectomy is for patients who have chronic ITP that is not responsive to pharmacologic management and have increased risk for severe hemorrhage. It is the useful option associated with long-term remission for the majority of these children and reduces the risk for hemorrhage (McCrae, 2011; Scott and Montgomery, 2007; Wilson, 2009). Before splenectomy is considered, waiting until the child is older than 5 years is generally recommended because of the increased risk for bacterial infection. Pneumococcal and meningococcal vaccines are recommended before splenectomy (see Immunizations, Chapter 31). The child also receives penicillin prophylaxis after splenectomy. The length of prophylactic therapy is controversial, but in general, a minimum of 3 years is recommended.

Prognosis. The majority of children have a self-limited course without major complications. Some children may develop chronic ITP and require ongoing therapy. A splenectomy may modify the disease process, and the child will be asymptomatic.

CARE MANAGEMENT

Nursing care is largely supportive and should include teaching regarding possible side effects of therapy and limitation in activities while the child's platelet count is less than 50,000/mm^3 (Consolini, 2011). Children with ITP should not participate in *any* contact sports, bike riding, skateboarding, in-line skating, gymnastics, climbing, or running. Parents are encouraged to engage their children in quiet activities and to prevent any injuries to the child's head. The harmful effects of using aspirin and NSAIDs to control pain are

critical for these children; therefore salicylate substitutes (e.g., acetaminophen) are always used. As in any condition with an uncertain outcome, the family needs emotional support.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC), also known as consumption coagulopathy, is characterized by diffuse fibrin deposition in the microvasculature, consumption of coagulation factors, and endogenous generation of thrombin and plasmin. DIC is a secondary disorder of coagulation that occurs as a complication of a number of pathologic processes, such as hypoxia, acidosis, shock, and endothelial damage. It can result from many severe systemic diseases, such as congenital heart disease, necrotizing enterocolitis, gram-negative bacterial sepsis, rickettsial infections, and some severe viral infections.

Pathophysiology

DIC occurs when the first stage of the coagulation process is abnormally stimulated. Although no well-defined sequence of events occurs, two distinct phases can be identified. First, when the clotting mechanism is triggered in the circulation, thrombin is generated in greater amounts than can be neutralized by the body. Consequently, there is rapid conversion of fibrinogen to fibrin, with aggregation and destruction of platelets. If local and widespread fibrin deposition in blood vessels takes place, obstruction and eventual necrosis of tissues occur. Second, the fibrinolytic mechanism is activated, causing extensive destruction of clotting factors. With a deficiency of clotting factors, the child is vulnerable to uncontrollable hemorrhage into vital organs. An additional complication is damage and hemolysis of RBCs.

Diagnostic Evaluation

DIC is suspected when the patient has an increased tendency to bleed (Box 43-8). Hematologic findings include prolonged prothrombin time, PTT, and thrombin time. There is a profoundly depressed platelet count, fragmented RBCs, and depleted fibrinogen.

Therapeutic Management

Treatment of DIC is directed toward control of the underlying or initiating cause, which in most instances stops the coagulation problem spontaneously. Platelets and fresh-frozen plasma may be needed to replace lost plasma components, especially in children whose underlying disease remains uncontrolled. Extremely ill newborn infants may require exchange transfusion with fresh blood. The IV administration of heparin to inhibit thrombin formation is most often restricted to patients who have not responded to treatment of the underlying disease or replacement of coagulation factors and platelets.

BOX 43-8 CLINICAL MANIFESTATIONS OF DISSEMINATED INTRAVASCULAR COAGULATION

- Petechiae
- Purpura
- Bleeding from openings in the skin
  - Venipuncture site
  - Surgical incision
- Bleeding from umbilicus, trachea (newborn)
- Evidence of gastrointestinal bleeding
- Hypotension
- Organ dysfunction from infarction and ischemia

CARE MANAGEMENT

The goals of nursing care are to be aware of the possibility of DIC in severely ill children and to recognize signs that might indicate its presence. The skills needed to monitor IV infusion and blood transfusions and to administer heparin are the same as for any child receiving these therapies (see p. 1388). (See Chapter 36 for care of children with life-threatening illnesses.)

Epistaxis (Nosebleeding)

Isolated and transient episodes of epistaxis, or nosebleeding, are common in childhood. The nose, especially the septum, is a highly vascular structure, and bleeding usually results from direct trauma, including blows to the nose, foreign bodies, and nose picking, or from mucosal inflammation associated with allergic rhinitis and upper respiratory tract infections. The bleeding ordinarily stops spontaneously or with minimal pressure and requires no medical evaluation or therapy.

Recurrent epistaxis and severe bleeding may indicate an underlying disease, particularly vascular abnormalities, leukemia, thrombocytopenia, and clotting factor deficiency diseases (e.g., hemophilia, vWD). Nosebleeds are sometimes associated with administration of aspirin, even in normal amounts. Persistent episodes of epistaxis require medical evaluation.

CARE MANAGEMENT

In the event of a nosebleed, an essential intervention is to remain calm. Otherwise, the child will become more agitated, the blood pressure will increase, and the child will not cooperate. Although in most instances a nosebleed is not serious, it can be upsetting to family members as well. They need reassurance that the loss of blood is not serious and that the bleeding usually stops in less than 10 minutes with nasal pressure.

To control the bleeding, the child is instructed to sit up and lean forward (not to lie down) to avoid aspiration of blood. Most of the nosebleeding originates in the anterior part of the nasal septum and can be controlled by applying pressure to the soft lower portion of the nose with the thumb and forefinger (see Emergency box). During this time, the child breathes through the mouth.

In the event that hemorrhage continues, the child should be evaluated by a health care practitioner, who may pack the nose with epinephrine-soaked gauze. After a nosebleed, petroleum or water-soluble jelly can be inserted into each nostril to prevent crusting of old blood and to lessen the likelihood of the child's picking at the nose and restarting the hemorrhage. If a child has numerous nosebleeds, factors believed to increase the likelihood of bleeds are eliminated, such as discouraging nose picking or altering the household humidity by placing a cool-mist humidifier in the child's room.

EMERGENCY

Epistaxis

- Have child sit up and lean forward (not lie down).
- Apply continuous pressure to nose with thumb and forefinger for at least 10 minutes.
- Insert cotton or wadded tissue into each nostril and apply ice or cold cloth to bridge of nose if bleeding persists.
- Keep child calm and quiet.

Repeated bleeding episodes lasting longer than 30 minutes may be an indication to refer the child for evaluation for the possibility of a bleeding disorder.

NEOPLASTIC DISORDERS

Neoplastic disorders are the leading cause of death from disease in children past infancy, and almost half of all childhood cancers involve the blood or blood-forming organs. Leukemias and lymphomas are discussed here. Malignant solid tumors of childhood are discussed elsewhere in relation to the tissues or organs involved.

Leukemias

Leukemia, cancer of the blood-forming tissues, is the most common form of childhood cancer. The annual incidence is 3 to 4 cases per 100,000 Caucasian children (Jemal, Siegel, Ward, et al., 2009). It is more common in boys and Caucasians, with the peak onset between 2 and 5 years of age (Hutter, 2010; Margolin, Rabin, Steuber, et al., 2011; Pui, Relling, and Downing, 2004). It is one of the forms of cancer that has demonstrated dramatic improvements in survival rates. Whereas current long-term disease-free survival for children with acute lymphoid leukemia approaches 80% (Margolin, Rabin, Steuber, et al., 2011; Pui, Relling, and Downing, 2004), acute nonlymphoid leukemia has a 50% to 65% survival rate (Kaspers and Creutzig, 2005; Pearce and Sills, 2005). (See also Prognosis, p. 1381.)

Classification

Leukemia is a broad term given to a group of malignant diseases of the bone marrow and lymphatic system. Research has revealed that it is a complex disease of varying heterogeneity. Consequently, classification has become increasingly complex, sophisticated, and essential because identification of the subtype of leukemia has therapeutic and prognostic implications. The following is a brief overview of the major classification systems currently being used.

Morphology. Two forms are generally recognized in children—acute lymphoid leukemia (ALL) and acute nonlymphoid (myelogenous) leukemia (ANLL or AML). Synonyms for ALL include *lymphatic, lymphocytic, lymphoblastic,* and *lymphoblastoid leukemia.* Usually the terms stem cell or blast cell leukemia also refer to the lymphoid type. Synonyms for the AML type include *granulocytic, myelocytic, monocytic, myelogenous, monoblastic,* and *monomyeloblastic.*

Cytochemical markers—Several chemical stains (e.g., terminal deoxynucleotidyl transferase [TdT]) aid in differentiation between ALL and ANLL.

Chromosome studies—Chromosome analysis has become an important tool in the diagnosis of ALL. For example, children with trisomy 21 have 20 times the risk of other children for developing ALL. Children with more than 50 chromosomes on the leukemic cells (hyperdiploid) have the best prognosis (Margolin, Rabin, Steuber, et al., 2011). Translocations of chromosomes also found on the leukemic cells can denote good prognosis, as in the trisomies 4 and 10, or a poor prognosis, as in the t(9:22) or Philadelphia chromosome.

Cell-surface immunologic markers—Cell-surface antigens have permitted differentiation of ALL into three broad classes: B-cell ALL; T-cell ALL; and common ALL antigen (CALLA or CD 10+) formally known as *non-T, non-B ALL,* which is actually of early B-cell lineage (Margolin, Rabin, Steuber, et al., 2011). Children with the common ALL antigen on their cell surfaces have the more favorable prognosis (Margolin, Rabin, Steuber, et al., 2011).

Pathophysiology

Leukemia is an unrestricted proliferation of immature WBCs in the blood-forming tissues of the body. Although not a "tumor" as such, the leukemic cells demonstrate the same neoplastic properties as solid cancers. Therefore the resulting pathologic condition and clinical manifestations are caused by infiltration and replacement of any tissue of the body with nonfunctional leukemic cells. Highly vascular organs, such as the spleen and liver, are the most severely affected.

To understand the pathophysiology of the leukemic process, it is important to clarify two common misconceptions. First, although leukemia is an overproduction of WBCs, most often in the acute form, the leukocyte count is low (thus the term *leukemia*). Second, these immature cells do not deliberately attack and destroy the normal blood cells or vascular tissues. Cellular destruction takes place by infiltration and subsequent competition for metabolic elements.

In all types of leukemia, the proliferating cells depress the production of formed elements of the blood in bone marrow by competing for and depriving the normal cells of the essential nutrients for metabolism. The most frequent presenting signs and symptoms of leukemia are a result of infiltration of the bone marrow. The three main consequences are (1) anemia from decreased RBCs, (2) infection from **neutropenia,** and (3) bleeding from decreased platelet production. The invasion of the bone marrow with leukemic cells gradually causes a weakening of the bone and a tendency toward fractures. As leukemic cells invade the periosteum, increasing pressure causes severe pain.

The spleen, liver, and lymph glands demonstrate marked infiltration, enlargement, and eventually fibrosis. Hepatosplenomegaly is typically more common than lymphadenopathy. The next most important site of involvement is the central nervous system (CNS) secondary to leukemic infiltration, which may cause increased intracranial pressure (see Box 45-1).

Leukemic cells may also invade the testes, kidneys, prostate, ovaries, GI tract, and lungs. With long-term survivors becoming more common, such sites of leukemia invasion, especially the testes, are becoming more important clinically.

Diagnostic Evaluation

Leukemia is usually suspected based on the history and physical presentation that often includes fever, signs and symptoms of low blood counts, lymph node enlargement, and an enlarged liver and spleen. Peripheral blood smear may reveal immature forms of leukocytes, frequently combined with low blood counts. Definitive diagnosis is based on bone marrow aspiration or biopsy. Flow cytometry identifies the specific type of blast cell. Typically, the bone marrow is hypercellular, with primarily **blast cells.** After the diagnosis is confirmed, a lumbar puncture is performed to determine whether there is any CNS involvement. A few children will have CNS involvement at diagnosis, although most are asymptomatic.

Therapeutic Management

Treatment of leukemia involves the use of chemotherapeutic agents, with or without cranial irradiation, in four phases: (1) induction therapy, which achieves a complete remission or less than 5% leukemic cells in the bone marrow; (2) CNS prophylactic therapy, which prevents leukemic cells from invading the CNS; (3) intensification therapy (consolidation), which eradicates residual leukemia cells, followed by delayed intensification, which prevents emergence of resistant leukemic clones; and (4) maintenance therapy, which serves to maintain the remission phase.

Hematopoietic Stem Cell Transplantation. Hematopoietic stem cell transplantation has been used successfully for treating children who have ALL and AML. HSCT is *not* recommended for children with ALL during the first remission because of the excellent results possible with chemotherapy. In the United States, patients with intermediate risk and high risk AML with a suitable donor available are recommended for transplant during the first clinical remission (Bollard, Krance, and Heslop, 2011).

Hematopoietic stem cell transplantation may be not only from antigen-matched related donors but also from matched unrelated donors or mismatched donors. Peripheral blood stem cell transplants are capable of differentiating into specialized cells of the hematologic system and can be obtained from related or unrelated donors or from umbilical cord blood. Regardless of the type of transplant, it is accompanied by significant morbidity and mortality, including graft-versus-host disease (GVHD), overwhelming infection, or severe organ damage.

Prognosis. The most important prognostic factors for determining long-term survival for children with ALL (in addition to treatment) are (1) the initial WBC count, (2) the child's age at the time of diagnosis, (3) the type of cell involved, (4) the sex of the child, and (5) karyotype analysis. Children with a normal or low WBC count who are CALLA positive have a much better prognosis than those with a high count or other cell types. Children diagnosed between 2 and 9 years of age have consistently demonstrated a better outlook than those diagnosed before 2 or after 10 years of age, and girls appear to have a more favorable prognosis than boys. Children with more than 50 chromosomes indicated by a DNA index greater than 1.16 (hyperdiploid) have a better prognosis. Similarly, patients with ALL and trisomies of chromosomes 4 and 10 have a good prognosis with a low risk for treatment failure (Margolin, Rabin, Steuber, et al., 2011).

Late Effects of Treatment

Although vigorous treatment of childhood cancers has resulted in dramatically improved survival rates, increasing concern surrounds late effects—adverse changes related to treatment modalities—and recurrence of the disease process. Almost no organ is exempt, and almost every antineoplastic agent, especially irradiation, is responsible for some adverse effect.

The most devastating late effect is development of a second malignancy. Children who received cranial irradiation at age 5 years or younger are most susceptible to developing brain tumors and increase risk for developing cognitive defects that can affect school performance (Bhatia, 2004; Hutter, 2010). Treatment with an anthracycline is associated with cardiomyopathy; cranial irradiation and intrathecal chemotherapy are associated with cognitive and neuropsychologic deficits, which are just a few of the long-term sequelae. Consequently, close monitoring for late effects is essential, especially with the advent of additional clinical trials.

CARE MANAGEMENT

Nursing care of the child with leukemia is directly related to the therapeutic regimen. General psychologic interventions during each phase of therapy are discussed in Chapter 36.

Prepare the Child and Family for Diagnostic and Therapeutic Procedures. From the time before diagnosis to cessation of therapy, children must undergo several tests; the most traumatic are bone marrow aspiration, bone marrow biopsy, and lumbar punctures. Multiple fingersticks and venipunctures for blood analysis and drug infusion are common occurrences. Therefore the child needs an explanation of each procedure and what can be expected. In addition, effective pharmacologic measures, including conscious and unconscious sedation, and nonpharmacologic strategies are used to reduce discomfort associated with these painful procedures.

Relieve Pain. The effective use of analgesia is especially important when the malignant process is uncontrolled and causes acute pain. Dosages of opioids (narcotics) are adjusted, or *titrated,* to the child's needs and administered *around the clock* for optimal pain control. Nonpharmacologic strategies should be implemented as needed but are not substitutes for pharmacologic management. Readers are encouraged to review the principles of pain assessment and management presented in Chapter 30 and Preparation for Diagnostic and Therapeutic Procedures, Chapter 39, when caring for a child with leukemia.

Prevent Complications of Myelosuppression. The leukemic process and most of the chemotherapeutic agents cause myelosuppression. The reduced numbers of blood cells result in secondary problems of infection, bleeding tendencies, and anemia. Supportive care involves both medical and nursing management. Because these are so closely linked, they are discussed together.

Infection. A frequent complication of treatment for childhood cancer is overwhelming infection secondary to neutropenia. The child is most susceptible to overwhelming infection during three phases of the disease: (1) at the time of diagnosis and relapse when the leukemic process has replaced normal leukocytes; (2) during immunosuppressive therapy; and (3) after prolonged antibiotic therapy, which predisposes the child to the growth of resistant organisms. However, the use of granulocyte colony-stimulating factor (GCSF) has reduced the incidence and duration of infection in children receiving treatment for cancer.

The first defense against infection is prevention. When the child is hospitalized, the nurse uses all measures to control transfer of infection. These typically include the use of a private room, restriction of all visitors and health care personnel with active infection, and strict hand washing technique with an antiseptic solution. In some research centers, special germ-free environments are available during complete myelosuppression from intensive chemotherapy or for bone marrow transplant. The nurse should be aware of these guidelines and educate patients and families.

! NURSING ALERT

The child is not immunized against live viral vaccines (measles, rubella, mumps) until the immune system is capable of responding appropriately to the vaccine (AAP Committee on Infectious Diseases, 2009; Koh and Pizzo, 2011). Most institutions have individual guidelines regarding vaccinations in children undergoing immunosuppressive therapy.

The child is evaluated for potential sites of infection (e.g., mucosal ulceration; skin abrasion; skin tear, such as a hangnail) and observed for any elevation in temperature. To identify the source of infection, chest radiographs and blood, stool, urine, and nasopharyngeal cultures are taken. IV antibiotics are administered, and if this therapy is prolonged, a venous access device, such as a peripherally inserted central catheter or intermittent infusion device (saline lock or PRN [as-needed] adaptor), is used to maintain IV access.

Prevention of infection continues to be a priority after discharge from the hospital. Ordinarily, the child is allowed to return to school when the WBC count is at a satisfactory level—usually an absolute neutrophil count greater than 500/mm^3 (see Guidelines box). At all times, family members are encouraged to practice good hand washing to prevent introducing pathogens into the home. The child

GUIDELINES

Calculating the Absolute Neutrophil Count

Determine the total percent of neutrophils ("polys," or "segs," and bands). Multiply WBC count by percent of neutrophils.

Example:

WBC = 1000; neutrophils = 7%; nonsegmented neutrophils (bands) = 7%

Step 1: 7% + 7% = 14%

Step 2: 0.14 × 1000 = 140 ANC

ANC, Absolute neutrophil count; *WBC,* white blood cell.

may need to be isolated from school contacts in the event of an outbreak of a childhood disease, especially chickenpox.

Nutrition is another important component of infection prevention. An adequate protein-caloric intake provides the child with better host defenses against infection and increased tolerance to chemotherapy and irradiation. However, providing optimal nutrition during periods of anorexia and vomiting from chemotherapy is a tremendous challenge (see Feeding the Sick Child, Chapter 39).

Hemorrhage. Before the use of transfused platelets, hemorrhage was a leading cause of death in patients with leukemia. Now most bleeding episodes can be prevented or controlled with the administration of platelet concentrates or platelet-rich plasma.

Skin punctures are avoided whenever possible because bleeding sites can become easily infected. When fingersticks, venipunctures, IM injections, and bone marrow aspirations are performed, aseptic technique must be used along with continued observation for bleeding. Meticulous mouth care is essential because gingival bleeding with resultant mucositis is a frequent problem. Because the rectal area is prone to ulceration from various drugs, feces and urine are removed immediately and the perianal area is washed. Using rectal temperatures is avoided to prevent trauma. Children are advised to avoid activities that might cause injury or bleeding, such as riding bicycles and skateboards, climbing trees and playground equipment, and playing contact sports.

Platelet transfusions are generally reserved for active bleeding episodes that do not respond to local treatment and that may occur during induction or relapse therapy. Epistaxis and gingival bleeding are the most common. The nurse teaches parents and older children measures to control nosebleeding (see p. 1379). Pressure at the site without disturbing clot formation is the general rule.

During bleeding episodes, the parents and child need much emotional support. Often parents request a platelet transfusion, unaware of the need for trying local measures first. The nurse can be instrumental in allaying anxiety by acknowledging the feelings of the child and family and explaining the reason for delaying a platelet transfusion until absolutely necessary.

Anemia. Initially, anemia may be profound from complete replacement of the bone marrow by leukemic cells. During induction therapy, blood transfusions may be necessary. The usual precautions in caring for the child with anemia are instituted (see p. 1365).

Use Precautions in Administering and Handling Chemotherapeutic Agents. In addition to the nurse's many responsibilities in regard to the child and family, nurses must also use safeguards to protect themselves. Handling chemotherapeutic agents may present risks to handlers and to their offspring, although the exact degree of risk is not known. Many chemotherapeutic agents are vesicants (sclerosing agents) that can cause severe cellular damage if even minute amounts of the drug infiltrate surrounding tissue. Only nurses experienced with chemotherapeutic agents should administer vesicants. Guidelines are available* and must be followed exactly to prevent tissue damage to patients. Interventions for extravasation vary, but each nurse should be aware of the institution's policies and implement them at once.

In addition to extravasation, a potentially fatal complication is anaphylaxis, especially from L-asparaginase, teniposide (VM-26), etoposide (VP-16), bleomycin, and cisplatin. Nursing responsibilities include prevention of, recognition of, and preparation for serious reactions. Prevention begins with a careful history for known allergies.

Most children with cancer have a venous access device, which facilitates administration of IV drugs. During treatment and remission, many drugs are taken orally at home. Compliance with the medication schedule is essential, and nurses play an important role in educating the family about the drugs and encouraging adherence to the plan.

! NURSING ALERT

Chemotherapeutic drugs must be given through a free-flowing IV line. The infusion is stopped immediately if any sign of infiltration (pain, stinging, swelling, or redness at the cannulation site) occurs. When chemotherapeutic and immunologic agents are given, the child must be observed for 20 minutes after the infusion for signs of anaphylaxis (cyanosis, hypotension, wheezing, severe urticaria). Emergency equipment (especially blood pressure monitor and bag-valve-mask) and emergency drugs (especially oxygen, epinephrine, antihistamine, aminophylline, corticosteroids, and vasopressors) must be available. If a reaction is suspected, the drug is discontinued, the IV line is flushed with saline, and the child's vital signs and subsequent responses are monitored.

Manage Problems of Drug Toxicity. Chemotherapy presents several nursing challenges. The complexity of the treatment protocols is often overwhelming to families. In addition, each therapy is associated with a number of predictable side effects. Nurses must be aware of these side effects and use judgment in recognizing reactions, as well as toxicities.†

Nausea and Vomiting. The nausea and vomiting that occur shortly after administration of several of the drugs and from cranial or abdominal radiation can be profound. The serotonin-receptor antagonists (e.g., ondansetron, granisetron, palonosetron) are effective in the control of nausea and vomiting occurring after emetogenic chemotherapy and radiotherapy. When combined with dexamethasone, these agents are the treatment of choice in the prevention of delayed emesis (Lindley, Goodin, McCune, et al., 2005; Saito, Aogi, Sekine, et al., 2009).

The most beneficial regimen for antiemetic control has been the administration of the antiemetic *before* chemotherapy begins. The goal is to prevent the child from ever experiencing nausea or vomiting, thus preventing development of anticipatory symptoms (the conditioned response of developing nausea and vomiting before receiving the drug).

**Cancer Chemotherapy Guidelines* can be obtained from the Oncology Nursing Society, 125 Enterprise Drive, Pittsburgh, PA 15275; 866-257-4ONS, 412-859-6100; fax: 877-369-5497; e-mail: customer.service@ons.org; www.ons.org.

†Detailed chemotherapeutic agents are outlined in Wilson D, Hockenberry MJ: *Wong's clinical manual of pediatric nursing,* ed 8, St Louis, 2012, Mosby.

Anorexia. Loss of appetite is a direct consequence of the chemotherapy or irradiation. It is a major problem for parents because it is the one area they feel responsible for, particularly when so many other facets of care are outside their control. There are no universally successful techniques for encouraging a sick child to eat. However, the guidelines in Chapter 39 can be helpful during the anorexic period and can prevent additional problems during the remission.

Some children still do not eat despite these approaches. When loss of appetite and weight persist, the nurse should investigate the family situation to determine whether any factors (e.g., conditioned aversion to food, environmental stress related to eating, controlling behavior, anger) might be contributing to the problem. Nasogastric tube feedings or total parenteral nutrition may be implemented for children with significant nutritional problems.

Mucosal Ulceration. One of the most distressing side effects of several drugs is GI mucosal cell damage, which can produce ulcers anywhere along the alimentary tract. Oral ulcers greatly compound anorexia because eating is extremely uncomfortable, but the following interventions may be helpful:

- Provide a bland, moist, soft diet appropriate for the child's age and preferences.
- Use a soft sponge toothbrush (Toothette) or cotton-tipped applicator.
- Provide frequent mouthwashes with normal saline (using a solution of 1 tsp of table salt in 1 pt of water) or sodium bicarbonate mouth rinses (using a solution of 1 tsp of baking soda in 1 qt of water).
- Use local anesthetics (e.g., Chloraseptic lozenges) or nonprescription preparations without alcohol (e.g., hydrocortisone dental paste [Orabase], antiseptic mouth rinse [UlcerEase], diphenhydramine [Benadryl], and aluminum and magnesium hydroxide [Maalox] solution). Although local anesthetics are effective in temporarily relieving the pain, many children dislike the taste and numb feeling they produce.

Other preparations that may be used to prevent or treat mucositis include chlorhexidine gluconate (Peridex) because of its dual effectiveness against candidal and bacterial infections, antifungal troches (lozenges) or mouthwash, and lip balm (e.g., Aquaphor) to keep the lips moist. Agents that should not be used include lemon glycerin swabs (irritate eroded tissue and can decay teeth), hydrogen peroxide (delays healing by breaking down protein), and milk of magnesia (dries mucosa).

Stomatitis may cause such difficulty with eating that the child may require hospitalization for hydration, parenteral nutrition, and pain control (often with IV morphine). The child will usually choose the foods that are best tolerated, and the nurse should encourage parents to relax any eating pressures. Because the stomatitis is a temporary condition, the child can resume good food habits after the ulcers heal. Dental hygiene can become a serious problem for children with orthodontic appliances. Sometimes it may be necessary to remove the braces to allow chemotherapy to continue.

Rectal ulcers are managed by meticulous toilet hygiene, warm sitz baths after each bowel movement, and use of an occlusive ointment or dressing applied to the ulcerated area to promote epithelialization. Stool softeners are necessary to prevent further discomfort. Parents are advised to record bowel movements because the child may voluntarily avoid defecation to prevent discomfort. Rectal thermometers and suppositories are contraindicated because insertion may further traumatize the area.

Neuropathy. Vincristine and, to a lesser extent, vinblastine can cause various neurotoxic effects. Nursing interventions for management of these effects include:

- Administering stool softeners or laxatives for severe constipation caused by decreased bowel innervation
- Maintaining good body alignment and, if patient is on bed rest, using a footboard or high-top shoes to minimize or prevent footdrop
- Carrying out safety measures during ambulation because of weakness and numbing of the extremities, which may cause difficulty in walking or fine hand movement
- Providing a soft or liquid diet for severe jaw pain

Hemorrhagic Cystitis. Sterile hemorrhagic cystitis, a side effect of chemical irritation to the bladder from cyclophosphamide, can be decreased and often prevented by (1) promoting a liberal fluid intake (at least 1½ times the recommended daily fluid requirement); (2) frequent voiding immediately after feeling the urge, before bed, and after arising; (3) administering the drug early in the day to allow for sufficient oral intake and voiding; and (4) administering mesna (an agent that provides protection to the bladder) as ordered. If oral home administration is prescribed, the family needs *specific* instructions regarding exactly how much fluid the child must have.

Alopecia. Hair loss is a common side effect of several chemotherapeutic drugs and cranial irradiation, although not all children lose their hair during drug therapy. It is better to warn children and parents of this side effect than to allow them to think that it is only a remote possibility. A soft cotton cap is the most comfortable headwear for children. Polyester increases perspiration and causes itching. Other options include scarves, hats, or a wig.

The nurse should also inform the family that hair regrows in 3 to 6 months and may be of a different color and texture. Frequently, the hair is darker, thicker, and curlier than before. If the child chooses not to wear a wig, attention to some type of head covering, especially in cold climates and during exposure to sun, and scalp hygiene are important. The scalp should be washed like any other body part.

Moon Face. Short-term steroid therapy produces no acute toxicities and produces two beneficial reactions: increased appetite and a sense of well-being. However, it does produce alterations in appearance, which, although not clinically significant, can be extremely distressing to older children. One of these is *moon face,* in which the child's face becomes rounded and puffy. It is helpful to reassure the child that after cessation of the drug, the facial shape will return to normal. Unlike hair loss, little can be done to camouflage this obvious change. If the child resumes activity early in the course of treatment, the change may be less noticeable to peers than after a long absence.

Mood Changes. Shortly after beginning steroid therapy, children experience a number of mood changes that range from feelings of well-being and euphoria to depression and irritability. If parents are unaware of these drug-induced changes, they may become unduly concerned. The nurse should warn them of the reactions and encourage them to discuss the behavioral changes with each other and the child.

Provide Emotional Support. An important aspect of continued emotional support involves the prognosis. Although leukemia is no longer invariably fatal, it must be remembered that survival statistics are only average estimates and apply to those children treated with the latest protocols since diagnosis. For low risk children, the chances may be better, but for high risk children, they may be significantly poorer. Of those who do survive after discontinuing therapy, some will relapse. Therefore, at present, only the passage of time is positive confirmation of the child's being ultimately "cured" of the disease. Remission, even in excess of 5 years, cannot be equated with a cure.

With increasing concern regarding late effects of treatment, continued surveillance of the child's health status is needed. The nurse who is working with family members must individualize information regarding the "numbers" and the potential risks. An understanding of each member's emotional needs, as well as competent care of physical ones, is essential to the positive, growth-promoting support of the family. Comprehensive emotional support for the family of the child with a potentially fatal illness is discussed in Chapter 36.

Lymphomas

Pediatric lymphomas are the third most common group of malignancies in children and adolescents. The lymphomas, a group of neoplastic diseases that arise from the lymphoid and hematopoietic systems, are divided into Hodgkin lymphoma (HL) and non-Hodgkin lymphoma (NHL). These diseases are further subdivided according to tissue type and extent of disease. Whereas NHL is more prevalent in children younger than 14 years, HL is prevalent in adolescence and the young adult period, with a striking increase between ages 15 and 19 years.

Hodgkin Lymphoma

Hodgkin lymphoma is a neoplastic disease that originates in the lymphoid system and primarily involves the lymph nodes. It predictably metastasizes to nonnodal or extralymphatic sites, especially the spleen, liver, bone marrow, and lungs, although no tissue is exempt from involvement (Fig. 43-5). It is classified according to four histologic types: (1) lymphocytic predominance, (2) nodular sclerosis, (3) mixed cellularity, and (4) lymphocytic depletion. Accurate staging of the extent of disease is the basis for treatment protocols and expected prognoses.

The Ann Arbor staging system assigns a stage based on the number of sites of lymph node involvement, presence of extranodal disease, and history of any symptoms. Patients are classified as *A* if asymptomatic and as *B* if they have the following symptoms: temperature of 38° C (100.4° F) or higher for 3 consecutive days, drenching night sweats, or unexplained loss of body weight (≥10%) over the preceding 6 months. Nonspecific systemic symptoms include fatigue, anorexia, mild to severe pruritus, and slight weight loss (Metzger, Krasin, Hudson, et al., 2011).

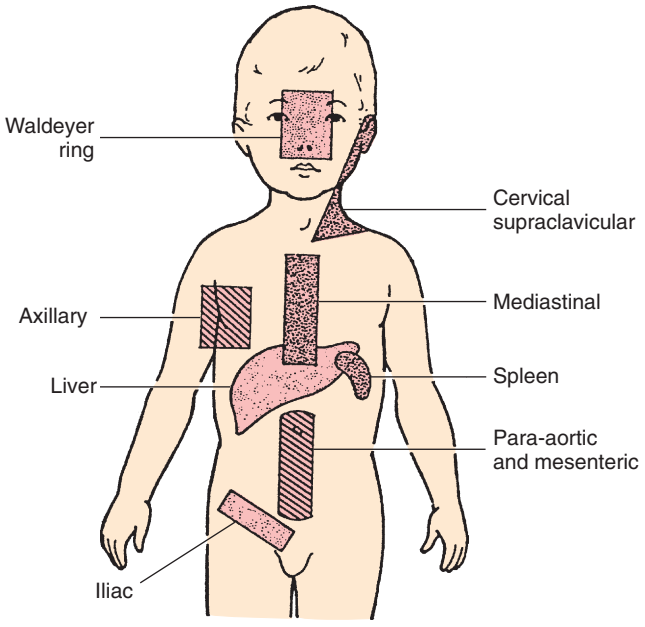

FIG 43-5 Main areas of lymphadenopathy and organ involvement in Hodgkin lymphoma.

Asymptomatic enlarged cervical or supraclavicular lymphadenopathy is the most common presentation of HL. Other systemic symptoms may be manifested, including cough, abdominal discomfort, and anorexia. Because multiple organs may be involved, diagnosis is based on several tests and the extent of metastatic disease. Tests include a CBC, erythrocyte sedimentation rate, serum copper, ferritin level, fibrinogen, immunoglobulins, uric acid level, liver function tests, T-cell function studies, and urinalysis. Radiographic tests include chest radiography and computed tomography (CT) of the neck and chest; CT and magnetic resonance imaging of the abdomen and pelvis; and positron emission tomography (PET), which is replacing the gallium scan and bone scan to identify metastatic disease.

A lymph node biopsy is essential to establish histologic diagnosis and staging. The presence of Reed-Sternberg cells is characteristic of HL. These large cells, which are multilobed and nucleated with abundant cytoplasm and a typically halolike clear zone around the nucleolus, are often described as having an "owl's eyes" appearance (Metzger, Krasin, Hudson, et al., 2011). A bone marrow aspiration and biopsy is usually performed in patient with advanced disease, B symptoms, or disease recurrence (Metzger, Krasin, Hudson, et al., 2011). With the advent of CT and PET scans to identify metastatic disease and multiagent therapy to eradicate metastatic disease, surgical staging involving a laparotomy with splenectomy is no longer performed.

Therapeutic Management. The primary modalities of therapy are radiation and chemotherapy. Each may be used alone or in combination based on the clinical staging. Radiation may involve only the involved field (IF), an extended field (EF) (involved areas plus adjacent nodes), or total nodal irradiation (TNI), depending on the extent of involvement.

An effective combination of chemotherapy widely used is MOPP (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone) or ABVD (Adriamycin, bleomycin, vinblastine, dacarbazine). However, this therapy combination has caused severe late effects, especially secondary malignancies. Other drug combinations such as COPP (cyclophosphamide, vincristine, prednisone, procarbazine) as a substitute for MOPP have minimized late effects.

Follow-up care of children no longer receiving therapy is essential to identify relapse and secondary cancers. In children with splenic irradiation, prophylactic antibiotics are administered for an indefinite period. Also, immunizations against pneumococci and meningococci are recommended.

Prognosis. Long-term survival for all stages of HL is excellent. The goal for pediatric HL's curative treatment is to provide minimal morbidity with the highest quality of life (Metzger, Krasin, Hudson, et al., 2011).

CARE MANAGEMENT

Nursing care involves the same objectives as for patients with other types of cancer, specifically: (1) preparation for diagnostic and operative procedures, (2) explanation of treatment side effects, and (3) child and family support (see Chapter 36). Because this is most often a disease of adolescents and young adults, the nurse must have an appreciation of their psychologic needs and reactions during the diagnostic and treatment phases.

The most common side effect of irradiation is fatigue. This is particularly difficult for active, outgoing school-age children and adolescents because it prevents them from keeping up with their

peers. Sometimes adolescents will push themselves to the point of physical exhaustion rather than admit and succumb to the decreased activity tolerance. The nurse cautions parents to observe for behavior such as extreme fatigue at the end of the day, falling asleep at the dinner table, inability to concentrate on homework, or an increased susceptibility to infection. A regular bedtime and scheduled rest periods are important for these children, especially during chemotherapy, when myelosuppression increases the risk for infection and debilitation. Before discharge, the nurse should discuss a feasible school schedule with the parents and child.

An area of concern for adolescents is the high risk for sterility from irradiation and chemotherapy. Both drugs, particularly procarbazine and alkylating agents, and irradiation to the gonads can lead to infertility. Adolescents should be informed of these side effects early in the course of the diagnosis and treatment. Sperm banking is now offered at many cancer centers before the initiation of treatment in adolescent boys. Sexual function is not altered, although the appearance of secondary sexual characteristics and menstruation may be delayed in pubescent children. Delayed sexual maturation may be an extremely sensitive and stressful issue for children (see Chapter 35).

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma occurs more frequently in children than HL. Histologic classification of childhood NHL is strikingly different from that of HL, as demonstrated in the following statements:

- The disease is usually diffuse rather than nodular.
- The cell type is either undifferentiated or poorly differentiated.
- Dissemination occurs early, more often, and rapidly.
- Mediastinal involvement and invasion of meninges are common.

NHL exhibits a variety of morphologic, cytochemical, and immunologic features, similar to the diversity seen in leukemia. Classification is based on the histologic pattern: (1) lymphoblastic, (2) Burkitt or non-Burkitt, or (3) large cell. Immunologically, these cells are also classified as T cells; B cells; or non-T, non-B cells (lacking immunologic properties). The clinical staging system used in HL is of little value in NHL, although it has been modified, and other systems have been developed.

Diagnostic Evaluation. Because the clinical presentation of most children with NHL is widespread disseminated disease, thorough pathologic staging is unnecessary. Clinical manifestations depend on the anatomic site and extent of involvement. These manifestations include many of those seen in Hodgkin disease and leukemia, as well as organ symptoms related to pressure from enlargement of adjacent lymph nodes, such as intestinal or airway obstruction, cranial nerve palsies, and spinal paralysis.

Recommendations for staging include a surgical biopsy of an enlarged node, histopathologic confirmation of disease with cytochemical and immunologic evaluation, bone marrow examination, radiographic studies (especially tomograms of the lungs and GI organs), and lumbar puncture.

Therapeutic Management. The treatment protocols for NHL include aggressive use of irradiation and chemotherapy. Similar to leukemic therapy, the protocols include induction, consolidation, and maintenance phases, some with intrathecal chemotherapy. Several antineoplastic agents used in the treatment of NHL include vincristine, prednisone, L-asparaginase, methotrexate, 6-mercaptopurine, cytarabine, cyclophosphamide, anthracyclines, and teniposide or etoposide. Chemotherapy is the main component of treatment for NHL in children (Gross and Perkins, 2011).

Prognosis. The prognosis is excellent for children with NHL. In developed countries, more than 80% of children with NHL are now cured with modern therapy, even patients with widely disseminated disease (Gross and Perkins, 2011).

CARE MANAGEMENT

Nursing care of children with NHL is similar to that required for children with leukemia. Many of the same drugs are used, although the schedules differ. Because of the intense chemotherapy, nursing care is directed primarily toward managing the side effects of these agents and providing supportive care to the child and family.

IMMUNOLOGIC DEFICIENCY DISORDERS

A number of disorders can cause profound, often life-threatening alterations within the body's immune system. The most serious are those conditions that completely depress immunity, such as severe combined immunodeficiency disease (SCID). However, the one disorder that generates the most anxiety, within both the family and the community at large, is human immunodeficiency virus (HIV) infection/AIDS.

Several classifications of immune dysfunction exist. AIDS, SCID, and Wiskott-Aldrich syndrome (WAS) are syndromes wherein the body is unable to mount an immune response. The immune response can also be misdirected. In autoimmune disorders, antibodies, macrophages, and lymphocytes attack healthy cells.

Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Since the first cases of AIDS were identified in the early 1980s, HIV infection has generated intense medical investigation. Research has led to early diagnosis of and improved medical treatments for HIV infection, changing this disease from a rapidly fatal one to a chronic disease.

Epidemiology

The first AIDS cases in the pediatric population in the United States were identified in children born to HIV-infected mothers and in children who received blood products. More than 90% of these children acquired the disease perinatally from their mothers. Smaller numbers of children were infected through the transfusion of contaminated blood or blood products before 1985 or were infected through sexual abuse. Currently, the principal modes of HIV transmission to the pediatric population are mother-to-child transmission and adolescent risky behaviors such as sexual activity and IV drug use (Simpkins, Siberry, and Hutton, 2009).

The estimated number of children with perinatally acquired AIDS peaked in 1992; subsequent years have seen significant declines. This trend is a result of implementation of recommended HIV counseling and voluntary testing practices and the use of highly active antiretroviral therapy (HAART) to prevent perinatal transmission. HAART, typically a combination of two nucleoside analog reverse transcriptase inhibitors and a protease inhibitor, is the current standard in the United States for the treatment of HIV-infected pregnant women, and it has significantly reduced the transmission of HIV (Perinatal HIV Guidelines Working Group, 2007; Simpkins, Siberry, and Hutton, 2009). Routine HIV counseling and voluntary testing using the opt-out approach (right of refusal) is the recommended standard of care for pregnant women in the United States (AAP Committee on Pediatric AIDS, 2008; Centers for Disease Control and Prevention [CDC], 2007; Simpkins, Siberry, and Hutton, 2009).

Etiology

Human immunodeficiency virus is a retrovirus that is transmitted by lymphocytes and monocytes. It is found in the blood, semen, vaginal secretions, and breast milk. It has an incubation or latency period of months to years (Yogev and Chadwick, 2007). There are different strains of HIV. Whereas HIV-2 is prevalent in Africa, HIV-1 is the dominant strain in the United States and elsewhere. Horizontal transmission of HIV occurs through intimate sexual contact or parenteral exposure to blood or body fluids containing visible blood. Perinatal (vertical) transmission occurs when an HIV-infected pregnant woman passes the infection to her infant. There is no evidence that *casual* contact between infected and uninfected individuals can spread the virus.

Pathophysiology

The HIV virus primarily infects a specific subset of T lymphocytes, the CD_4^+ T cells. The virus takes over the machinery of the CD_4^+ lymphocyte, using it to replicate itself, rendering the CD_4^+ cell dysfunctional. The CD_4^+ lymphocyte count gradually decreases over time, leading to progressive immunodeficiency. The count eventually reaches a critical level below which there is substantial risk for opportunistic illnesses, followed by death.

Clinical Manifestations

Common clinical manifestations of HIV infection in children are varied (Box 43-9). The diagnosis of AIDS is associated with certain illnesses or conditions. The most common AIDS-defining conditions observed among American children are listed in Box 43-10. Other problems in these children may include short stature, malnutrition, and cardiomyopathy. CNS abnormalities resulting from HIV infection may include neuropsychologic deficits, developmental disabilities, and deficits in motor skills, communication, and behavioral functioning.

BOX 43-9 COMMON CLINICAL MANIFESTATIONS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN CHILDREN

- Lymphadenopathy
- Hepatosplenomegaly
- Oral candidiasis
- Chronic or recurrent diarrhea
- Failure to thrive
- Developmental delay
- Parotitis

BOX 43-10 COMMON DEFINING CONDITIONS FOR ACQUIRED IMMUNODEFICIENCY SYNDROME IN CHILDREN

- *Pneumocystis carinii* pneumonia
- Lymphoid interstitial pneumonitis
- Recurrent bacterial infections
- Wasting syndrome
- Candidal esophagitis
- Human immunodeficiency virus encephalopathy
- Cytomegalovirus disease
- *Mycobacterium avium-intracellulare* complex infection
- Pulmonary candidiasis
- Herpes simplex disease
- Cryptosporidiosis

Diagnostic Evaluation

For children 18 months of age and older, the HIV enzyme-linked immunosorbent assay (ELISA) and Western blot immunoassay are performed to determine HIV infection. In infants born to HIV-infected mothers, these assays will be positive because of the presence of maternal antibodies derived transplacentally. Maternal antibodies may persist in the infant up to 18 months of age. Therefore other diagnostic tests are used, most commonly the HIV polymerase chain reaction for detection of proviral DNA. With this technique, almost all infected infants can be diagnosed between 1 and 6 months of age (Goldschmidt and Fogler, 2006; Yogev and Chadwick, 2007).

The Centers for Disease Control and Prevention (CDC) (CDC, 1994) has developed a classification system to describe the spectrum of HIV disease in children (Table 43-2). The system indicates the severity of clinical signs and symptoms and the degree of immunosuppression. Mild signs and symptoms include lymphadenopathy, parotitis, hepatosplenomegaly, and recurrent or persistent sinusitis or otitis media. Moderate signs and symptoms include lymphoid interstitial pneumonitis (LIP) and a variety of organ-specific dysfunctions or infections. Severe signs and symptoms include AIDS-defining illnesses with the exception of LIP. Children with LIP have a better prognosis than those with other AIDS-defining illnesses. In children whose HIV infection is not yet confirmed, the letter *E* (vertically exposed) is placed in front of the classification. The immune categories are based on CD_4^+ lymphocyte counts and percentages. Age adjustment of these numbers is necessary because normal counts, which are relatively high in infants, decline steadily until 6 years of age, when they reach adult norms.

Therapeutic Management

The goals of therapy for HIV infection include slowing the growth of the virus, preventing and treating opportunistic infections, and providing nutritional support and symptomatic treatment. Antiretroviral drugs work at various stages of the HIV life cycle to prevent reproduction of functional new virus particles. Although not a cure, these drugs can suppress viral replication, preventing further deterioration of the immune system, and thus delay disease progression. Classes of antiretroviral agents include nucleoside reverse transcriptase inhibitors (e.g., zidovudine, didanosine, stavudine, lamivudine, abacavir), nonnucleoside reverse transcriptase inhibitors (e.g., nevirapine, delavirdine, efavirenz), nucleotide reverse transcriptase inhibitors (e.g., adefovir), protease inhibitors (e.g., indinavir, saquinavir, ritonavir, nelfinavir, amprenavir), and adjunctive antiretrovirals (e.g., hydroxyurea). Combinations of antiretroviral drugs are used to stall the emergence of drug resistance. Antiretroviral therapy regimens and guidelines are continually evolving. Therapy is lifelong, making adherence difficult. Laboratory markers (CD_4^+ lymphocyte count, viral load) assist in monitoring both disease progression and response to therapy.

Pneumocystis carinii pneumonia (PCP) is the most common opportunistic infection of children infected with HIV. It occurs most frequently between 3 and 6 months of age. All infants born to HIV-infected women should receive prophylaxis until HIV infection is reasonably excluded (AAP Committee on Pediatric AIDS, 2000a; Havens, Mofenson, and AAP Committee on Pediatric AIDS, 2009; Simpkins, Siberry, and Hutton, 2009). Trimethoprim-sulfamethoxazole (TMP-SMZ) is the agent of choice. If adverse effects are experienced with TMP-SMZ, dapsone or pentamidine can be used.

Prophylaxis is often employed for other opportunistic infections, such as disseminated *Mycobacterium avium-intracellulare* complex,

candidiasis, or herpes simplex. IVIG has been helpful in preventing recurrent or serious bacterial infections in some HIV-infected children.

Immunization against common childhood illnesses, including the pneumococcal and influenza vaccines, is recommended for all children exposed to and infected with HIV (AAP Committee on Pediatric AIDS, 2000b; Simpkins, Siberry, and Hutton, 2009). Varicella (chickenpox) vaccine and measles, mumps, and rubella (MMR) vaccine can be administered if there is no evidence of severe immunocompromise. Because antibody production to vaccines may be poor or decrease over time, immediate prophylaxis after exposure to several vaccine-preventable diseases (e.g., measles, varicella) is warranted. It should be recognized that children receiving IV gamma globulin (IVGG) prophylaxis may not respond to the MMR vaccine if given in close proximity to the IVGG dose (Allen, 2007; CDC, 2003).

HIV infection often leads to marked failure to thrive and multiple nutritional deficiencies. Nutritional management may be difficult because of recurrent illness, diarrhea, and other physical problems. Intensive nutritional interventions should be instituted when the child's growth begins to slow or weight begins to decrease.

Prognosis. Early recognition and improved medical care have changed HIV disease from a rapidly fatal illness to a chronic disease. After the introduction of combination antiretroviral therapy, the numbers of new AIDS cases and deaths declined substantially. In the United States, the annual number of AIDS cases affecting children younger than 13 years had a sharp, steady decline since the early 1990s (Klause and Johnson, 2007; Simpkins, Siberry, and Hutton, 2009). In contrast, adolescents and young adults (13 to 24 years of age) with AIDS that represent a minority of U.S. cases (≈5%) constitute one of the fastest growing groups of newly infected persons in the country (Simpkins, Siberry, and Hutton, 2009; Yogev and Chadwick, 2007).

CARE MANAGEMENT

Education concerning transmission and control of infectious diseases, including HIV infection, is essential for individuals with HIV infection and anyone involved in their care. The basic tenets of Standard Precautions should be presented in an age-appropriate manner, with careful consideration of the educational levels of the individuals (see Infection Control, Chapter 39). Safety issues, including appropriate storage of special medications and equipment (e.g., needles and syringes), are emphasized.

Unfortunately, relatives, friends, and others in the general public may be fearful of contracting HIV infection, and criticism and ostracism of the child and family may occur. In an effort to protect the child, the family may limit the child's activities outside the home. Although certain precautions are justified in limiting exposure to sources of infections, they must be tempered with concern for the child's normal developmental needs. Both the family and the community need ongoing education about HIV to dispel many of the myths that have been perpetuated by uninformed persons.*

Prevention is a key component of HIV education. Educating adolescents about HIV is essential in preventing HIV infection in this age-group. Education should include the routes of transmission, the hazards of IV and other recreational drug use, and the value of sexual abstinence and safe sex practices. Such education should be a part of anticipatory guidance provided to all adolescent patients. Nurses can also encourage adolescents at risk to undergo HIV counseling and testing. In addition to identifying infected teenagers and getting them into care, such counseling affords adolescents an opportunity to learn about and possibly change their risky behaviors.

The multiple complications associated with HIV disease are potentially painful (Ezekowitz, 2009). Aggressive pain management is essential for these children to have an acceptable quality of life. Their pain may be caused by infections (e.g., otitis media, dental abscess), encephalopathy (e.g., spasticity), adverse effects of medications (e.g., peripheral neuropathy), or an unknown source (e.g., deep musculoskeletal pain). Pain is related not only to the disease processes but also to various treatments these children often undergo, including venipunctures, lumbar punctures, biopsies, and endoscopies. Ongoing assessment of pain is crucial and is most easily accomplished in older children who are able to communicate. Nonverbal and developmentally delayed children are more difficult to assess. The nurse should be alert for signs of pain such as emotional detachment, lack of interactive play, irritability, and depression. Effective pain management depends on the appropriate use of pharmacologic agents, including EMLA or LMX cream, acetaminophen, NSAIDs, muscle relaxants, and opioids. Tolerance to opioids may indicate increased dosing; monitored use ensures safety. Nonpharmacologic interventions (e.g., guided imagery, hypnosis, relaxation, and distraction techniques) are useful adjuncts.

Common psychosocial concerns include disclosing the diagnosis to the child, making custody plans when the parent is infected, and anticipating the loss of a family member. Other stressors may include financial difficulties, HIV-associated stigma, efforts to keep the diagnosis secret, other infected family members, and the

From Centers for Disease Control and Prevention (CDC): 1994 Revised classification system for human immunodeficiency virus infection in children less than 13 years of age, *MMWR Recomm Rep* 43(RR-12):1–10, 1994.

*Children whose human immunodeficiency virus infection status is not confirmed are classified by using this table with the letter *E* (for perinatally exposed) placed before the appropriate classification code (e.g., EN2).

†Both category C and lymphoid interstitial pneumonitis in category B are reportable to state and local health departments as acquired immunodeficiency syndrome.

multiple losses associated with HIV. Many mothers of these children are single mothers who are also HIV infected. As primary caregivers, they often attend to the needs of their child first, neglecting their own health in the process. The nurse is an integral part of the multidisciplinary team necessary for the successful management of the complex medical and social problems of these families.

Children with HIV infection attend day care centers and schools. It is well established that the risk for HIV transmission in these settings is minimal. These institutions are required to follow CDC and Occupational Safety and Health Administration (OSHA) guidelines for infection control measures. Standard Precautions describing proper management of blood and body fluids should also be followed. It is recommended that school personnel receive current HIV information and include it in the health education curriculum for kindergarten through twelfth grade (AAP Committee on Pediatric AIDS and Committee on Infectious Diseases, 1999; AAP Committee on Pediatric AIDS, 2000a). School nurses play a vital role in educating the school staff, students, and parents. They are also invaluable in monitoring the needs of known affected children.

Confidentiality is another major issue in day care or school attendance. Parents and legal guardians have the right to decide whether they inform the day care or school of their child's HIV diagnosis. Unfortunately, myths about HIV infection continue to exist, and the family often wishes to avoid any potential criticism or ostracism of the child.

Severe Combined Immunodeficiency Disease

Severe combined immunodeficiency disease is a defect characterized by absence of both humoral and cell-mediated immunity. The terms Swiss-type lymphopenic agammaglobulinemia (an autosomal recessive form of the disease) and X-linked lymphopenic agammaglobulinemia have been used to describe this disorder, which, as the names imply, can follow either mode of inheritance.

Susceptibility to infection occurs early in life, most often in the first month of life. The child has chronic infections, fails to completely recover from infections, is frequently reinfected, and is infected with unusual agents. Failure to thrive is a consequence of the persistent illnesses.

Diagnosis is usually based on a history of recurrent, severe infections from early infancy; a familial history of the disorder; and specific laboratory findings, which include lymphopenia, lack of lymphocyte response to antigens, and absence of plasma cells in the bone marrow. Documentation of immunoglobulin deficiency is difficult during infancy because of the normally delayed response of infants in producing their own immunoglobulins and material transfer of immunoglobulin G (IgG).

Therapeutic Management

The definitive treatment for SCID is HSCT from a histocompatible donor, a haplo-identical donor (usually a parent), or a matched unrelated donor. IVIG infusions and PCP prophylaxis are used to augment the humoral immunity until the transplant is performed. Several investigators are attempting gene therapy with some success, offering hope that gene therapy may eventually be the treatment of choice for cases of SCID (Bonilla and Geha, 2009; Buckley, 2007).

CARE MANAGEMENT

Nursing care focuses on preventing infection and supporting the child and family. The care is consistent with that needed for HSCT for any condition (see p. 1389). Because the prognosis for SCID is very poor if a compatible bone marrow donor is not available, nursing care is directed at supporting the family in caring for a child with a life-threatening illness (see Chapter 36). Genetic counseling is essential because of the modes of transmission in either form of the disorder.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked recessive disorder characterized by a triad of abnormalities: (1) thrombocytopenia, (2) eczema, and (3) immunodeficiency of selective functions of B lymphocytes and T lymphocytes. An abnormal gene has been identified on the proximal arm of the X chromosome and designated the *WAS protein* (Bonilla and Geha, 2009; Buckley, 2007). At birth, the presenting feature may be bleeding such as bloody diarrhea as a result of thrombocytopenia. As the child grows older, recurrent infection and eczema become more severe and the bleeding becomes less frequent.

Eczema is typical of the allergic type and readily becomes superinfected. Chronic infection with herpes simplex is a frequent problem and may lead to chronic keratitis of the eye with loss of vision. Chronic pulmonary disease, sinusitis, and otitis media result from repeated infections. In children who survive the bleeding episodes and overwhelming infections, malignancy presents an additional risk to survival. Medical treatment involves:

- Counteracting the bleeding tendencies with platelet transfusions
- Administering IVIG to provide passive immunity
- Administering prophylactic antibiotics to prevent and control infection.
- Providing aggressive local therapy for the eczema

WAS can be cured with HSCT (Albert, Notarangelo, and Ochs, 2011; Buckley, 2007). Several clinical trials focused on replacing the normal WAS gene are being conducted to determine the most effective vector (Albert, Notarangelo, and Ochs, 2011).

CARE MANAGEMENT

Because of the poor prognosis for these children, the main nursing consideration is supporting the family in the care of a fatally ill child (see Chapter 36). Physical care is directed at controlling the problems imposed by the disorder. The measures used to control bleeding are similar to those for hemophilia and vWD (see previous discussions). Another major goal is prevention or control of infection. Because eczema is a troublesome problem, nursing measures specific to this condition are especially important (see Chapter 47). The genetic implications of this X-linked recessive disorder differ little from those of any other X-linked disorder.

TECHNOLOGIC MANAGEMENT OF HEMATOLOGIC AND IMMUNOLOGIC DISORDERS

Blood Transfusion Therapy

Technologic advances in blood banking and transfusion medicine enable the administration of only the blood component needed by the child, such as packed RBCs for anemia or platelets for bleeding disorders. However, regardless of the blood component infused, all transfusions have some risks. Nurses need to be aware of the possible complications and the appropriate interventions. General guidelines that apply to all transfusions include:

- Take vital signs, including blood pressure, *before* administering blood to establish baseline data for intratransfusion and posttransfusion comparison; 15 minutes after initiation;

hourly while blood is infusing; and on completion of transfusion.
- Check the identification of the recipient with the donor's blood group and type regardless of the blood product being used.
- Administer the first 50 mL of blood or 20% of the volume (whichever is smaller) *slowly,* and stay with the child.
- Administer with normal saline on a piggyback setup, or have normal saline available.
- Administer blood through an appropriate filter to eliminate particles in the blood and prevent the precipitation of formed elements; gently shake the container frequently.
- Use blood within 30 minutes of its arrival from the blood bank; if it is not used, return it to the blood bank—do not store it in the regular unit refrigerator.
- Infuse a unit of blood (or the specified amount) within 4 hours. If the infusion will exceed this time, the blood should be divided into appropriate-size quantities by the blood bank and the unused portion refrigerated under controlled conditions.
- If a reaction of any type is suspected, stop the transfusion, take vital signs, maintain a patent IV line with normal saline and new tubing, notify the health care practitioner, and do not restart the transfusion until the child's condition has been medically evaluated.

Although hemolytic reactions are rare, ABO incompatibility remains the most common cause of death from blood transfusion, and human error (administration of the wrong type to the patient or mislabeling of the blood product) is usually responsible (Bell, 2007; Tondon, Pandey, Mickey, et al., 2010). **Hemolysis** can also cause the release of large quantities of phospholipids, which are capable of stimulating DIC (see p. 1379). Acute kidney shutdown and eventual renal failure are a result of renal vasoconstriction from antigen-antibody complexes derived from the RBC surface.

Blood is usually administered to children by infusion pump; therefore the usual precautions and management related to pumps apply. When the blood is started with a standard transfusion set, the filter chamber is filled to allow the total filter to be used. The drip chamber is partially filled with blood to permit counting of the drops. In adjusting the flow rate, it is important to remember that blood administration sets do not use microdrops (60 drops/mL) but, instead, regular drops (usually 10-15 drops/mL). The nurse must consider this when calculating the flow rate.

Hematopoietic Stem Cell Transplantation

Hematopoietic stem cell transplantation is used to establish healthy hematopoiesis in both malignant and nonmalignant disease. Candidates for transplantation are children who have disorders that are unlikely to be cured by other means. The most common conditioning allogenic regimens use intensive ablative therapy consisting of high-dose combination chemotherapy with or without total-body irradiation (Bollard, Krance, and Heslop, 2011). After the immune system is suppressed to prevent rejection of the transplanted marrow, the stem cells are harvested from the bone marrow, peripheral blood, or the umbilical vein of the placenta and given to the patient by IV transfusion. The newly transfused stem cells will begin to repopulate the ablative bone marrow. In essence, the recipient will accept a new blood-forming organ.

The selection process for a suitable donor and the potential complications in transplantation are related to the HLA system complex. Some of the major HLA antigens are A, B, C, D, and DR. There is a wide diversity for each of these HLA loci. There are more than 20 different HLA-A antigens that can be inherited and more than 40 different HLA-B antigens.

The genes are inherited as a single unit or haplotype. A child inherits one unit from each parent; thus a child and each parent have one identical and one nonidentical haplotype. Because the possible haplotype combinations among siblings follow the laws of mendelian genetics, there is a one-in-four chance that two siblings have two identical haplotypes and are perfectly matched at the HLA loci.

The importance of HLA matching is to prevent the serious complication known as GVHD. Because the child's immune system is essentially rendered nonfunctional, there is little difficulty with bone marrow rejection by the recipient. However, the donor's marrow may contain antigens not matched to the recipient's antigens, which begin attacking body cells. The more closely the HLA systems match, the less likely GVHD is to develop. However, for patients with low risk disease, the increase risk for chronic GVHD needs to be balanced against the risk for relapse (Bollard, Krance, and Heslop, 2011).

Different types of HSCT are now performed. Allogeneic HSCT involves matching a histocompatible donor with the recipient. However, allogeneic HSCT is limited by the presence of a suitable marrow donor.

Because of the limited numbers of patients having HLA-identical siblings, other types of allogeneic transplants have evolved. Umbilical cord blood stem cell transplantation is an established rich source of hematopoietic stem cells. Because stem cells can be found with high frequency in the circulation of newborns, cord blood transplantation has become an alternative for some children. The benefit of using umbilical cord blood is the blood's relative immunodeficiency at birth because of naivety of cord T cells, which have a lower risk for GVHD-related problems (Bollard, Krance, and Heslop, 2011).

Autologous HSCTs use the patient's own marrow that was collected from disease-free tissue, frozen, and sometimes treated to remove malignant cells. Children with solid tumors such as neuroblastoma, lymphomas, rhabdomyosarcoma, Ewing sarcoma, and Wilms tumor have been treated with autologous HSCTs.

Peripheral stem cell transplants (PSCTs) are also used in children with cancer. PSCT, a type of autologous transplant, differs in the way stem cells are collected from the patient. CSF is first given to stimulate the production of peripheral blood stem cells (PBSCs) as an alternative to marrow as source of stem cells (Bollard, Krance, and Heslop, 2011). After the WBC count is high enough, the stem cells are collected by an apheresis machine. This machine filters out peripheral stem cells from whole blood, returning the remainder of the blood cells and plasma to the child. The peripheral stem cells are then frozen until the patient is ready for the PSCT.

CARE MANAGEMENT

The care of children undergoing HSCT is similar to that of any child receiving chemotherapy and radiotherapy. These children are usually hospitalized for several weeks after HSCT. Because of the risk for infection, the unit may use such measures as strict hand washing, screening visitors, laminar airflow rooms, and institutional isolation policies. Throughout this long ordeal, the family is concerned with successful engraftment and fear of fatal complications (see Family-Centered Care box). Consequently, nurses need to provide sensitive care and maintain a supportive attitude during the many crises that may arise. If the procedure is not successful, the families need care consistent with that required by the family of any child with a life-threatening disorder (see Chapter 36).

FAMILY-CENTERED CARE

The Decision for a Hematopoietic Stem Cell Transplant

A family's decision for a child to undergo HSCT may be fraught with challenges. Often the child is facing certain death from the malignancy. The preparation of the child for the transplant also places the patient at great medical risk.

When the preparatory regimen is begun and the child's immune system is destroyed, there is no turning back. Unlike kidney transplantation, HSCT does not have a "rescue" procedure, such as dialysis, for supportive therapy. If the donor is a sibling, the issue of his or her marrow "saving" the brother or sister can be a concern, especially if the transplant fails. Parents often must leave the home to stay at the transplant center and encounter additional stressors such as arranging child care, taking a leave from work, and managing finances. The patient faces the greatest stress—fear of HSCT failure or life-threatening complications.

HSCT, Hematopoietic stem cell transplantation.

Apheresis

Apheresis is the removal of blood from an individual, separation of the blood into its components, retention of one or more of these components, and reinfusion of the remainder of the blood into the individual. Apheresis is most often used to remove large quantities of platelets from healthy adult donors. These transfusion products have greatly prolonged the survival of patients with hematologic and oncologic diseases.

This technique is used to remove PBSCs from children before they receive HSCT or high-dose chemotherapy or radiotherapy, which is severely toxic to the bone marrow. These PBSCs can then be used to restore the child's bone marrow. Apheresis is also used as a therapeutic modality. The blood component that is diseased or toxic is separated from the blood, and the remainder is returned to the individual. Therapeutic apheresis is considered part of standard therapy for many diseases. Plasma is selectively removed from individuals with hyperviscosity, life-threatening complications of myasthenia gravis, Guillain-Barré syndrome, thrombotic thrombocytopenic purpura, and certain drug overdoses. WBCs are removed from individuals with high-WBC-count leukemia.

CARE MANAGEMENT

Difficult venous access and small blood volume can limit the ability to use this therapy in infants and young children. Education of the family and child includes the purposes of the therapy and the technology.

Specially trained individuals perform the apheresis procedure. Attention focuses on the rate of removal, blood component separation, and reinfusion of blood into the child. Vital signs are monitored, and the child is continuously observed for any adverse reactions secondary to the circulatory volume changes and the anticoagulant used.

When apheresis components are infused, nursing measures differ depending on whether the product is autologous (blood component from the child) or allogeneic (blood component from another individual). Autologous components are the child's own blood; therefore a major precaution is proper identification to ensure the correct component. The rate of infusion should be adjusted to the child's tolerance. If the product is allogeneic, all precautions for blood transfusions apply.

KEY POINTS

- Anemia is defined as reduction of RBCs or Hgb concentration to levels below normal for age; disorders are classified by etiology and physiology or morphology.
- The nurse's role in treatment of anemia is to assist in establishing a diagnosis, prepare the child for laboratory tests, administer prescribed medications, decrease tissue oxygen needs, implement safety precautions, and observe for complications.
- The main nursing goal in prevention of nutritional anemia is parent education regarding correct feeding practices.
- SCA is a hereditary hemoglobinopathy caused by normal adult HbA being partly or completely replaced by sickle HbS.
- Nursing care of the child with SCA focuses on teaching the family how to prevent and recognize sickle cell problems; managing pain during crises; and helping the child and parents adjust to a lifelong, chronic disease.
- Nursing care of the child with β-thalassemia includes observing for complications of multiple blood transfusions, assisting the child in coping with the effects of illness, and fostering parent-child adjustment to long-term illness.
- Causes of acquired AA include irradiation, drugs, industrial and household chemicals, infections, and infiltration and replacement of myeloid elements; however, the majority of cases are idiopathic.
- Clotting depends on three processes: vascular spasm, platelet aggregation, and coagulation and clot formation.
- Nursing care of the child with hemophilia involves preventing bleeding by decreasing the risk for injury, recognizing and managing bleeding with factor replacement, preventing the crippling effects of joint degeneration, and preparing and supporting the child and family for home care.
- Goals in the care of the child with leukemia are to prepare the family for diagnostic and therapeutic procedures, prevent complications of myelosuppression, manage problems of irradiation and drug toxicity, and provide continued emotional support.
- The lymphomas include HL and NHL and are disorders involving the lymphoid system.
- Immunodeficiency disorders render the affected individual unable to fight infectious organisms.
- HIV infection is primarily acquired in infancy from a HIV-infected parent and in adolescence from engaging in high risk behaviors.
- Blood transfusions supply needed blood components.
- HSCT replaces the diseased or malfunctioning bone marrow with viable blood stem cells.
- Apheresis is the selective removal of a blood component. It can be used to supply cellular elements needed for therapy (i.e., platelets or stem cells) or to remove diseased components.

CHAPTER

44

Genitourinary Dysfunction

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe the various aspects of enuresis.
- Describe the various factors that contribute to urinary tract infections in infants and children.
- Discuss the preoperative preparation of the child and parents when the child has a structural defect of the genitourinary tract.
- Demonstrate an understanding of the causes and mechanisms of edema formation in nephrotic syndrome.
- Outline a nursing care plan for a child with nephrotic syndrome.
- Compare the child with minimal-change nephrotic syndrome and the child with acute glomerulonephritis in terms of clinical manifestations and nursing care.
- Contrast the causes, complications, and management of acute and chronic renal failure.
- List the types of renal dialysis.
- Recognize signs of kidney transplant rejection.

PROBLEMS RELATED TO ELIMINATION

Enuresis

Enuresis (bedwetting), or nocturnal enuresis, is a common and troublesome disorder that is defined as the intentional or involuntary passage of urine into the bed (usually at night) in children who are beyond the age when voluntary bladder control should normally have been acquired. The inappropriate voiding of urine must occur at least twice a week for at least 3 months, and the chronologic or developmental age of the child must be at least 5 years. The predominant symptom is urgency that is immediate and is accompanied by acute discomfort, restlessness, and urinary frequency. In addition, the urinary incontinence must not be related to the direct physiologic effects of a substance (e.g., diuretics) or a general medical condition (e.g., diabetes mellitus or diabetes insipidus, spina bifida, seizure disorder, or sickle cell disease).

Enuresis is more common in boys; nocturnal bedwetting usually ceases between 6 and 8 years of age. Enuresis can also be defined as primary (bedwetting in children who have never been dry for extended periods) or secondary (the onset of wetting after a period of established urinary continence). The passage of urine may be monosymptomatic and occur only during nighttime sleep, with the child remaining dry during the day; or it may be polysymptomatic, in which the child has daytime urinary urgency and an occasional daytime accident in conjunction with other conditions such as sleep apnea, urinary tract infection, neurologic impairment, constipation, or emotional stressors (Berry, 2006; Katz and DeMaso, 2011). The nocturnal, monosymptomatic type is most common. The condition may be particularly distressing to adolescents, who may refuse therapy. Although enuresis may occur during the daytime, the following discussion primarily focuses on nocturnal enuresis.

Before psychogenic factors are considered, organic causes that may be related to enuresis should be ruled out. These include structural disorders of the urinary tract; urinary tract infection; neurologic deficits; disorders that increase the normal output of urine, such as diabetes; and disorders that impair the concentrating ability of the kidneys, such as chronic renal failure or sickle cell disease. A bladder volume of 300 to 350 mL (10 to 12 oz) is sufficient to hold a night's urine. Normal bladder capacity (in ounces) is the child's age plus 2 (up to age 14 years). In other cases, enuresis is influenced by emotional factors, although it is doubtful that they are causative factors. Parents report that these children sleep more soundly than other children, but the depth of sleep has not been identified as the cause of nocturnal enuresis (Berry, 2006; Elder, 2011). Nocturnal enuresis has a strong familial tendency.

Therapeutic techniques used to manage nocturnal enuresis include medications, complementary and alternative medicine techniques (such as hypnotherapy), restriction or elimination of fluids after the evening meal, avoidance of caffeinated and sugar-containing beverages after 4 PM, purposeful interruption of sleep to void,

motivational therapy, and various devices designed to establish a conditioned reflex response to waken the child at the initiation of voiding (alarms).

Drug therapy is increasingly being prescribed to treat enuresis. Three types of drugs are used: tricyclic antidepressants (TCAs), antidiuretics, and antispasmodics. The drug used depends on the interpretation of the cause. The most commonly used drug is the TCA imipramine (Tofranil), which exerts an anticholinergic action in the bladder to inhibit urination. The dosage and time of administration are individualized, and the drug is given in amounts sufficient to lighten sleep but not to cause wakefulness. Some practitioners prescribe low doses, which reduces bedwetting in two thirds of children. However, it is important to note that almost all children relapse when the medication is stopped. The suggested length of treatment is 6 to 8 weeks followed by gradual withdrawal over 4 weeks. Because overdosage of this drug is especially dangerous, caution parents about the safe use of this drug and the need to keep supplies of the drug out of the reach of children.

Anticholinergic drugs, especially oxybutynin, reduce uninhibited bladder contractions and may be helpful for children with daytime urinary frequency. Success has also been achieved with desmopressin acetate (DDAVP) nasal spray, an analog of vasopressin, which reduces nighttime urinary output to a volume less than functional bladder capacity. Typically, the child receives two sprays before bedtime. The medication is generally well tolerated but may cause nasal irritation or, rarely, headache or nausea. A preparation of desmopressin acetate is also available in tablet form. This preparation is as effective and safe as the nasal spray but avoids the problem of nasal irritation.

These drugs are considered second-line management, and parents should be cautioned not to think these agents will cure the condition; parents are also advised of the side effects of these drugs (Katz and DeMaso, 2011; Sethi, Bhargava, and Shipra, 2005).

CARE MANAGEMENT

No matter which techniques are used, the nurse can help both children and parents understand the problem of enuresis, the treatment plan, and the difficulties they may encounter in the process. Essential to the success of any method is the supportive management of parents and their children. Both need encouragement and patience. The problem is discussed with both the parent and the child because all treatments involve and require the child's active participation. In some treatment interventions, the child is in charge of the intervention; therefore parents must learn to support the child rather than intervene themselves. For example, children can strip their wet covers, limit fluids, and use the toilet before bedtime. Parents should encourage the child to maintain a regular bowel evacuation regimen; constipation can contribute to nocturnal enuresis (Katz and DeMaso, 2011). A calendar with wet and dry nights may be helpful to motivate the child to stay dry and maintain a positive perspective on the problem; positive rewards are also helpful.

Parents need to understand that punishment such as scolding, shaming, and threatening is contraindicated because of its negative emotional impact and limited success in reducing the behavior. Positive reinforcement of the desired behavior may be beneficial. Children need to believe they are helping themselves, and they need to sustain feelings of confidence and hope. Many parents believe enuresis is caused by an emotional disturbance and fear that they have somehow produced the situation by improper childrearing practices. They need reassurance that bedwetting is not a manifestation of an emotional disturbance and does not represent willful misbehavior. Encourage parents to be patient and understanding and to communicate love and support to the child.

Communication with children is directed toward eliminating the emotional impact of the problem, relieving feelings of shame and guilt and the burden of parental disapproval, building self-confidence, and motivating children toward independent control. More important, the nurse can provide consistent support and encouragement to help children through the inconsistent and unpredictable treatment process. Children need to believe they are helping themselves and need to maintain feelings of confidence and hope.

Parents should also be taught to observe for side effects of any medications used. All children with primary enuresis should be encouraged to void before bedtime, and diapering should be avoided.

GENITOURINARY DYSFUNCTION

Assessment of kidney and urinary tract integrity and diagnosis of renal or urinary tract disease are based on several evaluative tools. Physical examination, history taking, and observation of symptoms are the initial procedures. In suspected urinary tract diseases or disorders, further assessment by laboratory, radiologic, and other evaluative methods is carried out. Fig. 44-1 provides a review of the kidney and nephron structures.

Clinical Manifestations

As in most disorders of childhood, the incidence and type of kidney or urinary tract dysfunction change with the age and maturation of the child. In addition, the presenting complaints and the their significance vary with maturation. For example, a complaint of enuresis has greater significance at age 8 years than at age 4 years. In newborns urinary tract disorders are associated with a number of obvious malformations of other body systems, including the curious and unexplained but frequent association between malformed or low-set ears and urinary tract anomalies.

Many of the clinical manifestations of renal disease are common to a variety of childhood disorders, but their presence is an indication to obtain further information from the child's history, family history, and laboratory studies as part of a complete physical examination. Suspected renal disease can be evaluated further by means of radiographic studies and renal biopsy (Table 44-1).

Laboratory Tests

Both urine and blood studies contribute vital information for detection of renal problems. The single most important test is probably routine urinalysis. Specific urine and blood tests provide additional information. Because nurses are usually the people who collect the specimens for examination and who often perform many of the screening tests, they should be familiar with the test, its function, and factors that can alter or distort the results of the test. The major urine and blood tests are outlined in Tables 44-2 and 44-3.

CARE MANAGEMENT

Nursing responsibilities in the assessment of genitourinary disorders or diseases begin with observation of the child for any manifestations that might indicate dysfunction. Many conditions have specific characteristics that distinguish them from other disorders. These are discussed as appropriate throughout the chapter.

The nurse is generally the one who is responsible for preparing infants, children, and parents for tests and collection of urine and (sometimes) blood specimens for observation and laboratory

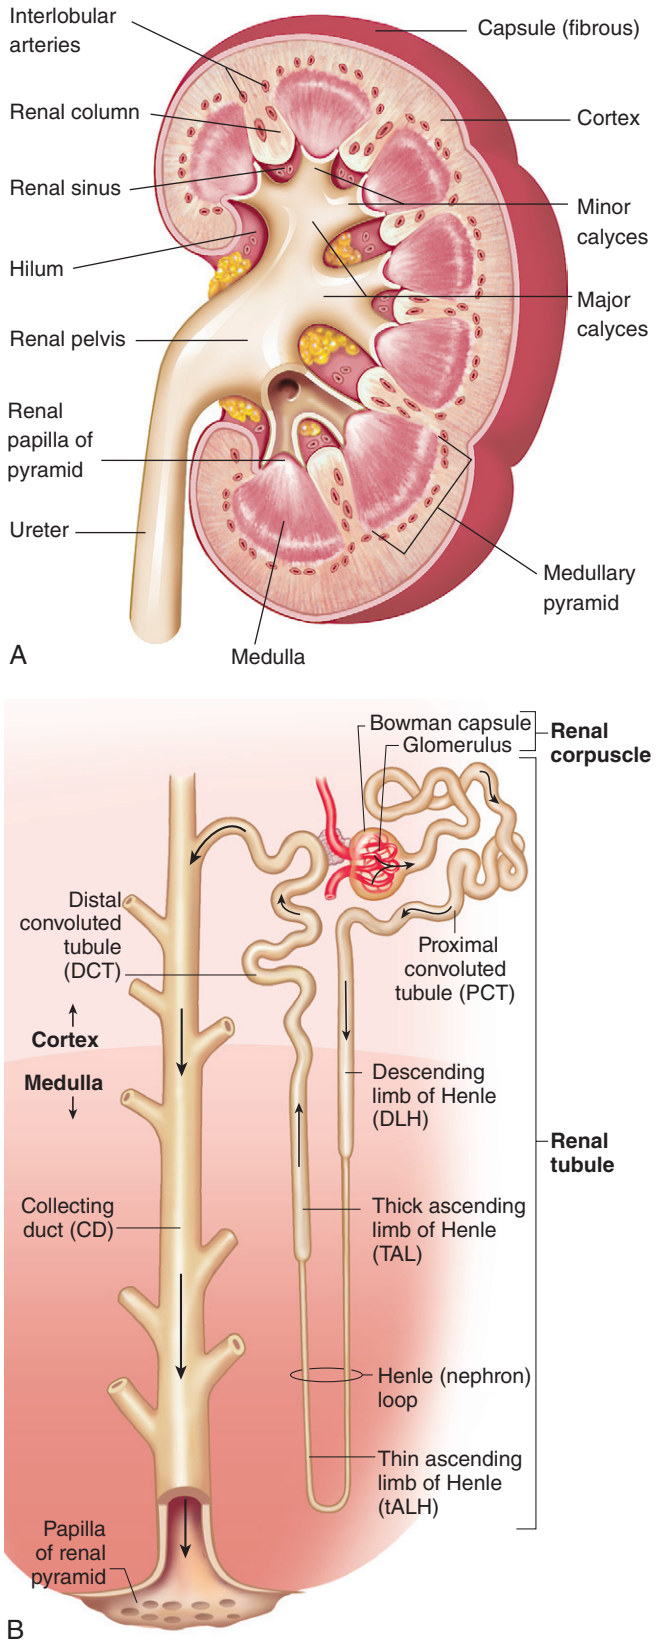

FIG 44-1 A, Kidney structure. **B,** Components of the nephron. (From Patton KT, Thibodeau GA: *Anatomy and physiology*, ed 7, St Louis, 2010, Mosby.)

analysis (see Preparation for Diagnostic and Therapeutic Procedures and Collection of Specimens, Chapter 39). An important nursing responsibility is to maintain careful intake and output measurements and blood pressure for most children with genitourinary dysfunction and those who might be at risk for developing renal complications (e.g., children in shock, postoperative patients). For example, any significant degree of renal disease can diminish the glomerular filtration rate (GFR), a measure of the amount of plasma from which a given substance is totally cleared in 1 minute. A number of substances can be used, but the most useful clinical estimation of glomerular filtration is the clearance of creatinine, an end product of protein metabolism in muscle and a substance that is filtered freely by the glomerulus and secreted by renal tubular cells. The nurse's responsibility in this test is collection of urine, usually a 12- or 24-hour specimen.

GENITOURINARY TRACT DISORDERS AND DEFECTS

Urinary Tract Infection

Infection of the genitourinary tract is one of the most common conditions of childhood. As many as 10% of children will have a febrile urinary tract infection (UTI) during the first 2 years of life (Kanellopoulos, Salakos, Spiliopoulou, et al., 2006). Among febrile boys circumcision status is important in determining the risk for UTI. Uncircumcised male infants younger than 3 months of age had the highest prevalence of UTI (20.1%) of any group, male or female (Shaikh, Morone, Bost, et al., 2008). Circumcision status should be assessed in male infants with unexplained fever. UTI may involve the urethra and bladder (lower urinary tract) or the ureters, renal pelvis, calyces, and renal parenchyma (upper urinary tract). Because it is often impossible to localize the infection, the broad designation UTI is applied to the presence of significant numbers of microorganisms anywhere within the urinary tract except the distal third of the urethra, which is usually colonized with bacteria.

Classification

Infection of the urinary tract may be present with or without clinical symptoms. As a result, the site of infection is often difficult to pinpoint with any degree of accuracy. Various terms used to describe urinary tract disorders include:

- **Bacteriuria**—Presence of bacteria in the urine
- **Asymptomatic bacteriuria**—Significant bacteriuria (usually defined as >100,000 colony-forming units [CFUs]) with no evidence of clinical infection
- **Symptomatic bacteriuria**—Bacteriuria accompanied by physical signs of UTI (dysuria, suprapubic discomfort, hematuria, fever)
- **Recurrent UTI**—Repeated episode of bacteriuria or symptomatic UTI
- **Persistent UTI**—Persistence of bacteriuria despite antibiotic treatment
- **Febrile UTI**—Bacteriuria accompanied by fever and other physical signs of UTI; presence of a fever typically implies pyelonephritis
- **Cystitis**—Inflammation of the bladder
- **Urethritis**—Inflammation of the urethra
- **Pyelonephritis**—Inflammation of the upper urinary tract and kidneys
- **Urosepsis**—Febrile UTI coexisting with systemic signs of bacterial illness; blood culture reveals presence of urinary pathogen

TABLE 44-1 RADIOLOGIC AND OTHER TESTS OF URINARY SYSTEM FUNCTION

TEST	PROCEDURE	PURPOSE	COMMENTS AND NURSING RESPONSIBILITIES
Urine culture and sensitivity	Collection of sterile specimen	Determines presence of pathogens and drugs to which they are sensitive	Does not require specific parental permission Send specimen to laboratory immediately after collection Catheterization, clean-catch, or suprapubic specimen
Renal and bladder ultrasonography	Transmission of ultrasonic waves through renal parenchyma, along ureteral course, and over bladder	Allows visualization of renal parenchyma and renal pelvis without exposure to external-beam radiation or radioactive isotopes Visualization of dilated ureters and bladder wall also possible	Noninvasive procedure
Testicular (scrotal) ultrasonography	Transmission of ultrasonic waves through scrotal contents and testis	Allows visualization of scrotal contents, including testis Testicular ultrasonography is used to identify masses, and Doppler-enhanced ultrasonography is used to differentiate hyperemia of epididymo-orchitis from ischemia or torsion	Noninvasive procedure
Scout film	Flat plate radiograph of abdomen and pelvis for KUB	Detects and establishes renal outlines, presence of calculi, or opaque foreign bodies in bladder	Prepare as for routine x-ray film
Voiding cystourethrography	Contrast medium injected into bladder through urethral catheter until bladder is full; films taken before, during, and after voiding	Visualizes bladder outline and urethra, reveals reflux of urine into ureters, and shows complications of bladder emptying	Prepare child for catheterization
Radionuclide (nuclear) cystogram	Radionuclide-containing fluid injected through urethral catheter until bladder is full; images generated before, during, and after voiding	Alternative to voiding cystourethrography in children with allergy to intravesical contrast material Allows evaluation of reflux, although visualization of anatomic details is relatively poor	Prepare child for catheterization Reassure patient and parents that allergic response to contrast materials is avoided by use of radionuclide
Radioisotope imaging studies	Contrast medium injected intravenously; computer analysis to measure uptake or washout (excretion) for analysis of organ function	DTPA radioisotope used to measure GFR; estimate of differential renal function and renal washout to determine presence and location of upper urinary tract obstruction DMSA radioisotope used to visualize renal scars and differential renal function; does not visualize ureters and bladder MAG3 radioisotope combines features of DTPA (evaluation of upper urinary tract obstruction) with features of DMSA radioisotope (differential renal function)	Insert or assist with insertion of IV infusion Monitor IV infusion Urethral catheterization may accompany DTPA radioisotope scan; prepare child for catheterization when indicated
IVP (IV urography; excretory urography)	IV injection of a contrast medium Medium secreted and concentrated by tubules X-ray films made 5, 10, and 15 minutes after injection; delayed films (30, 60 minutes, and so on) are obtained if obstruction suspected	Defines urinary tract Provides information about integrity of KUB Retroperitoneal masses visualized when they shift position of ureters	Preparation for test: **Infants up to 2 years of age**—no solid food; omit one bottle on morning of examination; perform studies early to avoid withholding of fluids **Children ages 2-14 years of age**—give cathartic evening before examination, nothing orally after midnight, enema (soapsuds) morning of examination

TABLE 44-1 RADIOLOGIC AND OTHER TESTS OF URINARY SYSTEM FUNCTION—cont'd

TEST	PROCEDURE	PURPOSE	COMMENTS AND NURSING RESPONSIBILITIES
CT	Narrow-beam x-ray films and computer analysis provide precise reconstruction of area	Visualizes vertical or horizontal cross section of kidney Especially valuable to distinguish tumors and cysts	Noncontrast scan is noninvasive Contrast-enhanced CT scan preparation similar to that for IVP
Cystoscopy	Direct visualization of bladder and lower urinary tract through small scope inserted via urethra	Investigation of bladder and lower tract lesions; visualizes ureteral openings, bladder wall, trigone, and urethra	Give nothing orally after midnight Carry out preoperative preparations Prepare child for cystoscopy
Retrograde pyelography	Contrast medium injected through ureteral catheter	Visualizes pelvic calyces, ureters, and bladder	Give cathartic if ordered Give preoperative medication if ordered Observe for reaction to contrast medium Monitor vital signs after procedure
Renal angiography	Contrast medium injected directly into renal artery via catheter placed in femoral artery (or umbilical artery in newborn) and advanced to renal artery	Visualizes renal vascular system, especially for renal arterial stenosis	Prepare child for insertion of spinal needle or perfusion catheter in renal pelvis (anesthetic often required)
Whitaker perfusion test	Injection of contrast material through renal pelvis and ureters Measures pressures in renal pelvis and urinary bladder	Determine presence of obstruction causing upper urinary tract dilation	
Renal biopsy	Removal of kidney tissue by open or percutaneous technique for study by light, electron, or immunofluorescent microscopy	Yields histologic and microscopic information about glomeruli and tubules; helps distinguish among types of nephritic syndromes Distinguishes other renal disorders	Nothing orally 4-6 hours before test Premedicate as ordered Prepare setup for procedure Assist with procedure Take vital signs Apply pressure to area with pressure dressing and, if feasible, a sandbag Bed rest for 24 hours Observe for abdominal pain, tenderness Monitor input and output Surgical incision may be required in infants
Urodynamics	Set of tests designed to measure bladder filling, storage, and evacuation functions **Uroflowmetry**—Test to determine efficiency of urination **Cystometrography**—Graphic comparison of bladder pressure as a function of volume **Voiding pressure study**—Comparison of detrusor contraction pressure, sphincter electromyelogram, and urinary flow	Determine characteristic of voiding dysfunction Used to identify type (cause) of incontinence or urinary retention Especially valuable for voiding dysfunction complicated by urinary infection, urinary retention, or neurogenic bladder dysfunction	Prepare child for urinary catheterization Bladder will be filled with saline solution, and filling pressures will be recorded; child may experience fullness, coolness from saline fluid, and urine leakage during study Insertion of needles may be required for sphincter EMG

CT, Computed tomography; *DMSA,* dimercaptosuccinic acid; *DTPA,* diethylenetriamine pentaacetic acid; *EMG,* electromyography; *GFR,* glomerular filtration rate; *IV,* intravenous; *IVP,* intravenous pyelography; *KUB,* kidney, ureters, and bladder; *MAG3,* mercaptoacetyltriglycine.

TABLE 44-2 URINE TESTS OF RENAL FUNCTION

TEST	NORMAL RANGE	DEVIATIONS	SIGNIFICANCE OF DEVIATIONS
Physical Tests			
Volume	Age related Newborn—30-60 mL Children—Bladder capacity (oz) = Age (years) + 2	Polyuria Oliguria Anuria	Osmotic factors (urinary glucose level in diabetes mellitus) Retention caused by obstructive disease Inadequate bladder emptying caused by neurogenic bladder or obstructive disorder Obstruction of urinary tract; ARF
Specific gravity	With normal fluid intake—1.016-1.022 Newborn—1.001-1.020 Others—1.001-1.030	High Low	Dehydration Presence of protein or glucose Presence of radiopaque contrast medium after radiologic examinations Excessive fluid intake Distal tubular dysfunction Insufficient ADH Diuresis
Osmolality	Newborn—50-600 mOsm/L Thereafter—50-1400 mOsm/L	Fixed at 1.010 High or low	Chronic glomerular disease Same as for specific gravity More sensitive index than specific gravity
Appearance	Clear pale yellow to deep gold	Cloudy Cloudy reddish-pink to reddish-brown Light Dark Red	Contains sediment Blood from trauma or disease Myoglobin after severe muscle destruction Dilute Concentrated Trauma
Chemical Tests			
pH	Newborn—5-7 Thereafter—4.8-7.8 Average—6	Weak acid or neutral Alkaline	If associated with metabolic acidosis, suggests tubular acidosis If associated with metabolic alkalosis, suggests potassium deficiency Urinary infection Metabolic alkalosis
Protein level	Absent	Present	Abnormal glomerular permeability (e.g., glomerular disease, changes in blood pressure) Most kidney disease Orthostatic in some individuals
Glucose level	Absent	Present	Diabetes mellitus Infusion of concentrated glucose-containing fluids Glomerulonephritis Impaired tubular reabsorption
Ketone levels	Absent	Present	Conditions of acute metabolic demand (stress) Diabetic ketoacidosis
Leukocyte esterase	Absent	Present	Can identify both lysed and intact WBCs via enzyme detection
Nitrites	Absent	Present	Most species of bacteria convert nitrates to nitrites in urine
Microscopic Tests			
WBC count	<1 or 2	>5 polymorphonuclear leukocytes/field Lymphocytes	Urinary tract inflammatory process Allograft rejection Malignancy
RBC count	<1 or 2	4-6/field in centrifuged specimen	Trauma Stones Glomerular injury Infection Neoplasms

TABLE 44-2 URINE TESTS OF RENAL FUNCTION—cont'd

TEST	NORMAL RANGE	DEVIATIONS	SIGNIFICANCE OF DEVIATIONS
Presence of bacteria	Absent to a few	>100,000 organisms/mL in centrifuged specimen	UTI
Presence of casts	Occasional	Granular casts	Tubular or glomerular disorders Degenerative process in advanced renal disease
		Cellular casts WBC RBC	Pyelonephritis Glomerulonephritis
		Hyaline casts	Proteinuria; usually transient

ADH, Antidiuretic hormone; *ARF,* acute renal failure; *RBC,* red blood cell; *UTI,* urinary tract infection; *WBC,* white blood cell.

TABLE 44-3 BLOOD TESTS OF RENAL FUNCTION

TEST	NORMAL RANGE (MG/DL)	DEVIATIONS	SIGNIFICANCE OF DEVIATIONS
BUN	Newborn—4-18 Infant, child—5-18	Elevated	Renal disease—acute or chronic (the higher the BUN, the more severe the disease) Increased protein catabolism Dehydration Hemorrhage High protein intake Corticosteroid therapy
Uric acid	Child—2.0-5.5	Increased	Severe renal disease
Creatinine	Infant—0.2-0.4 Child—0.3-0.7 Adolescent—0.5-1	Increased	Renal impairment

BUN, Blood urea nitrogen.

Etiology

A variety of organisms can be responsible for UTI. *Escherichia coli* (80% of cases) and other gram-negative enteric organisms are most frequently implicated; these organisms are usually found in the anal and perineal region. Other organisms associated with UTI include *Proteus*, *Pseudomonas*, *Klebsiella*, and *Haemophilus* spp.; *Staphylococcus aureus;* and coagulase-negative *Staphylococcus* organisms. Several factors contribute to the development of UTI in childhood.

Anatomic and Physical Factors. The structure of the lower urinary tract is believed to account for the increased incidence of bacteriuria in females (Rosenthal, 2004). The short urethra, which measures about 2 cm (0.75 inch) in young girls and 4 cm (1.6 inches) in mature women, provides a ready pathway for invasion of organisms. In addition, the closure of the urethra at the end of micturition may return contaminated bacteria to the bladder. The longer male urethra (as long as 20 cm [8 inches] in an adult) and the antibacterial properties of prostatic secretions inhibit the entry and growth of pathogens.

! NURSING ALERT

Considerable evidence suggests that there are fewer UTIs among circumcised male infants than among uncircumcised male infants, but the difference is not significant enough to recommend routine circumcision in newborns (American Academy of Pediatrics Task Force on Circumcision, 1999).

The single most important host factor influencing the occurrence of UTI is urinary stasis. Ordinarily urine is sterile, but at 37°C (98.6°F) it provides an excellent culture medium. Under normal conditions the act of completely and repeatedly emptying the bladder flushes away any organisms before they have an opportunity to multiply and invade surrounding tissue. However, urine that remains in the bladder allows bacteria from the urethra to rapidly become established in the rich medium. Incomplete bladder emptying (stasis) may result from reflux (see Vesicoureteral Reflux, p. 1400), anatomic abnormalities (especially those involving the ureters), dysfunction of the voiding mechanism, or extrinsic ureteral or bladder compression that may be caused by constipation. The key to preventing UTI is to maintain adequate blood supply to the bladder wall by avoiding overdistention and high bladder pressure.

Altered Urine and Bladder Chemistry. Several mechanical and chemical characteristics of the urine and bladder mucosa help maintain urinary sterility. Increased fluid intake promotes flushing of the normal bladder and lowers the concentration of organisms in the infected bladder. Diuresis also seems to enhance the antibacterial properties of the renal medulla.

Most pathogens favor an alkaline medium. Normally urine is slightly acidic with a median pH of 6.0. A urine pH of about 5.0 hampers but does not eliminate bacterial multiplication. Much has been reported about the use of cranberry products to increase urine acidity in an effort to prevent UTI. Recent review of the literature in adult subjects supports the use of cranberry products in reducing the incidence of UTI in women (Jepson, Mihaljevic, and Craig, 2008). Results of one study in children suggests that daily consumption of concentrated cranberry juice can prevent recurrence of symptomatic UTIs (Ferrara, Romaniello, Vitelli, et al., 2009). Further research that controls for type of cranberry product used, dosing regimens, and patient selection based on age and underlying medical condition is required to clarify unanswered questions before recommendations can be made regarding the use of this supplement, especially in the pediatric population.

BOX 44-1 CLINICAL MANIFESTATIONS OF URINARY TRACT DISORDERS OR DISEASE

Neonatal Period (Birth-1 Month)
- Poor feeding
- Vomiting
- Failure to gain weight
- Rapid respiration (acidosis)
- Respiratory distress
- Spontaneous pneumothorax or pneumomediastinum
- Frequent urination
- Screaming on urination
- Poor urine stream
- Jaundice
- Seizures
- Dehydration
- Other anomalies or stigmata
- Enlarged kidneys or bladder

Infancy (1-24 Months)
- Poor feeding
- Vomiting
- Failure to gain weight
- Excessive thirst
- Frequent urination
- Straining or screaming on urination
- Foul-smelling urine
- Pallor
- Fever
- Persistent diaper rash
- Seizures (with or without fever)
- Dehydration
- Enlarged kidneys or bladder

Childhood (2-14 Years)
- Poor appetite
- Vomiting
- Growth failure
- Excessive thirst
- Enuresis, incontinence, frequent urination
- Painful urination
- Swelling of face
- Seizures
- Pallor
- Fatigue
- Blood in urine
- Abdominal or back pain
- Edema
- Hypertension
- Tetany

Diagnostic Evaluation

The clinical manifestations of UTI depend on the child's age (Box 44-1). Diagnosis is confirmed by detection of bacteriuria in urine culture; but urine collection is often difficult, especially in infants and very small children. Several factors may alter a urine specimen, and contamination of a specimen by organisms from sources other than the urine such as perineal and perianal flora in bag specimens is the most frequent cause of false-positive results. Unless the specimen is a first morning sample, a recent high fluid intake may indicate a falsely low organism count. Therefore children should not be encouraged to drink large volumes of water in an attempt to obtain a specimen quickly.

! NURSING ALERT

A child who exhibits the following should be evaluated for UTI:
- Incontinence in a toilet-trained child
- Strong-smelling urine
- Frequency or urgency

More accurate estimates of bacterial content are obtained from suprapubic aspiration (in children younger than 2 years of age) and properly performed bladder catheterization (as long as the first few milliliters are excluded from collection). The specimen should be taken directly to the laboratory for immediate culture.

Tests to detect bacteriuria are being used with increased frequency in screening for UTI. The dipstick tests for leukocyte esterase or nitrite are quick and inexpensive methods for detecting infection before obtaining final culture results.

Localization of the infection site may involve more specific tests, including percutaneous kidney taps and bladder washout procedures. Other tests such as ultrasonography, voiding cystourethrogram (VCUG), intravenous pyelogram (IVP), and dimercaptosuccinic acid (DMSA) scan, may be performed after the infection subsides to identify anatomic abnormalities contributing to the development of infection and existing kidney changes from recurrent infection.

Therapeutic Management

The objectives of treatment of children with UTI are to (1) eliminate current infection, (2) identify contributing factors to reduce the risk of recurrence, (3) prevent systemic spread of the infection, and (4) preserve renal function. Antibiotic therapy should be initiated on the basis of identification of the pathogen, the child's history of antibiotic use, and the location of the infection. Several antimicrobial drugs are available for treating UTI, but all of them can be ineffective occasionally because of resistance of organisms. Common antiinfective agents used for UTI include the penicillins, sulfonamide (including trimethoprim and sulfisoxazole in combination), the cephalosporins, and nitrofurantoin.

If anatomic defects such as primary reflux or bladder neck obstruction are present, surgical correction of these abnormalities may be necessary to prevent recurrent infection. Follow-up study is an important component of medical management because the relapse rate is high and infection tends to recur 1 to 2 months after termination of treatment. The aim of therapy and careful follow-up is to reduce the chance of renal scarring. However, recurrent infection of the urinary bladder predisposes the individual to transient episodes of vesicoureteral reflux (VUR).

Vesicoureteral Reflux. VUR refers to the abnormal retrograde flow of bladder urine into the ureters. During voiding urine is swept up the ureters and then flows back into the empty bladder, where it acts as a reservoir for bacterial growth until the next void. Primary reflux results from congenitally abnormal insertion of ureters into the bladder; secondary reflux occurs as a result of an acquired condition.

It is not clear that reflux necessarily causes infections. What is clear is that it is more likely to be associated with recurring kidney infections rather than simple bladder infections (cystitis). In the presence of reflux, infected urine (bacteria) from the bladder has access to the kidney, resulting in kidney infections (pyelonephritis). These children are usually very symptomatic with high fevers, vomiting, and chills. When reflux is associated with UTI, it is the most common cause of renal scarring in children. Renal scarring may occur with the first episode of febrile UTI. Reflux in the presence of sterile urine does not cause renal damage. Therefore the most important concept in managing VUR is preventing bacteria from reaching the kidneys. VUR is managed conservatively with daily low-dose antibiotic therapy. A urine culture should be done every 2 to 3 months and any time the child has a fever. This method of management requires a motivated, reliable, and cooperative family. Many children outgrow the reflux over a period of years. An annual VCUG is done to assess the status of the reflux.

For children with mild-to-moderate reflux, a minimally invasive endoscopic option (subtrigonal injection or STING) is an

alternative to daily antibiotics or open surgical intervention. A bulking agent—dextranomer–hyaluronic acid polymer (Deflux)—is injected into the mucous membrane of the ureter, making retrograde flow of urine more difficult. Overall cure rates relate to degree of reflux and range from 67.4% to 88.3%, although more than one injection may be needed to achieve resolution (Chen, Yeh, and Chou, 2010).

Indications for open surgical intervention include significant anatomic abnormality at the ureterovesical junction, recurrent UTIs, severe forms of VUR, noncompliance with medical therapy, intolerance to antibiotics, and VUR after puberty in women.

Prognosis. With prompt and adequate treatment at the time of diagnosis, the long-term prognosis for UTI is usually excellent. However, the hazard of progressive renal injury is greatest when infection occurs in young children (especially those younger than 2 years of age) and is associated with congenital renal malformations and reflux. Therefore early diagnosis of children at risk is particularly important.

CARE MANAGEMENT

Nurses should instruct parents to observe regularly for clues suggesting UTI. Unfortunately the signs of UTI are not as evident as those of upper respiratory tract infection. Therefore many cases go undetected because no one thought to investigate this very common problem.

Because infants and young children often are unable to express their feelings and sensations verbally, it is difficult to detect discomfort that they may be experiencing from dysuria. A careful history regarding voiding habits, stooling pattern, and episodes of unexplained irritability may help to detect less obvious cases of UTI. Consequently parents should be cautioned to observe for specific clues of UTI in suspected cases.

! NURSING ALERT

Check the diaper every half hour. This increases the opportunity for observing the stream for such findings as straining or fretting before voiding begins, signs of discomfort before and during urinating, starting and stopping the stream intermittently, and frequent dripping of small amounts of urine.

When infection is suspected, collecting an appropriate specimen is essential. It is the nurse's responsibility to take every precaution to obtain acceptable clean-voided specimens to avoid the use of other more invasive collecting procedures except when absolutely indicated. Because of the unreliability of a specimen obtained via a urine collection bag, suprapubic aspiration of urine or sterile catheterization should be done in infants and young children who are seen with fever.

Frequently additional tests are performed to detect anatomic defects. Children are prepared for these tests as appropriate for their age. This includes an explanation of the procedure, its purpose, and what the children will experience (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 39). Sometimes a simple description of the urinary system is helpful. Especially for preschool children, the nurse must clarify that the urinary tract is separate from any sexual function and that the test is for a problem that they did not cause. Children may associate blame for perceived wrongdoing (e.g., masturbation) or unacceptable thoughts with the reason for the illness or the tests. For children younger than 3 to 4 years of age, the procedure can be explained on a doll. For those who are older, a simple drawing of the bladder, urethra, ureters, and kidneys makes the procedure more understandable.

Handling actual equipment when feasible can help to allay anxiety in children of all ages. Anticipatory instruction on distraction techniques such as deep breathing, storytelling, and imagery may help the child relax and be more cooperative during the actual procedures. If surgery is indicated, facts and understanding of the procedure help decrease the child's fear and anxiety concerning more extensive medical-surgical intervention.

Because antibacterial drugs are indicated in UTI, the nurse advises parents of proper dosage and administration. When antiseptics such as nitrofurantoin are used for prolonged therapy to maintain urine sterility, parents need an explanation of the continued need for the drug when no signs of infection are present. For all children an adequate or increased fluid intake is encouraged.

Prevention. Prevention is the most important goal in both primary and recurrent infection, and most preventive measures are simple hygienic habits that should be a routine part of daily care (see Guidelines box). For example, parents are taught to cleanse their infant's genital areas from front to back to avoid contaminating the urethral area with fecal organisms. Girls are taught to wipe from front to back after voiding and defecating. Children should void as soon as they feel the urge (see Critical Thinking Case Study).

Sexually active female adolescents are advised to urinate as soon as possible after they have intercourse to flush out bacteria introduced during the activity. Children who have recurrent UTIs or neurogenic bladder are frequently maintained on daily low-dose antibiotics. Giving the dose at bedtime allows the drug to remain in the bladder overnight. The nurse should reinforce the importance of compliance to parents and older children.

GUIDELINES

Prevention of Urinary Tract Infection

Factors Predisposing to Development

- Short female urethra close to vagina and anus
- Incomplete emptying (reflux) and overdistention of bladder
- Concentrated urine
- Constipation

Measures of Prevention

- Practice perineal hygiene: wipe from front to back.
- Avoid tight clothing or diapers; wear cotton panties rather than nylon.
- Check for vaginitis or pinworms, especially if child scratches between legs.
- Avoid "holding" urine; encourage child to void frequently, especially before long trips or other circumstances in which toilet facilities are not available.
- Empty bladder completely with each void. Have child "double void" (void, wait a few minutes, and void again). Severe cases may require clean, intermittent catheterization or biofeedback instruction.
- Avoid straining during defecation and avoid constipation.
- Encourage generous fluid intake.

Obstructive Uropathy

Structural or functional abnormalities of the urinary system that obstruct the normal flow of urine can produce renal disorders. When there is interference with urine flow, the backup of urine

CRITICAL THINKING CASE STUDY

Urinary Tract Infection and Constipation

During your assessment of Lisa, a 5-year-old girl admitted to the hospital for a severe UTI, her mother tells you that Lisa has bowel movements every third or fourth day. They are usually large, hard-formed stools, and Lisa sometimes has trouble evacuating the stool.

1. Evidence—Is there sufficient evidence to draw a conclusion about Lisa's UTI and constipation?
2. Assumptions—Describe an underlying assumption about each of the following:
   a. UTIs and girls
   b. Normal bowel patterns for 4-year-old children
   c. Association between UTIs and constipation
3. Which priorities for nursing care should be established for Lisa?
4. Does the evidence support your nursing intervention?

UTI, Urinary tract infection.

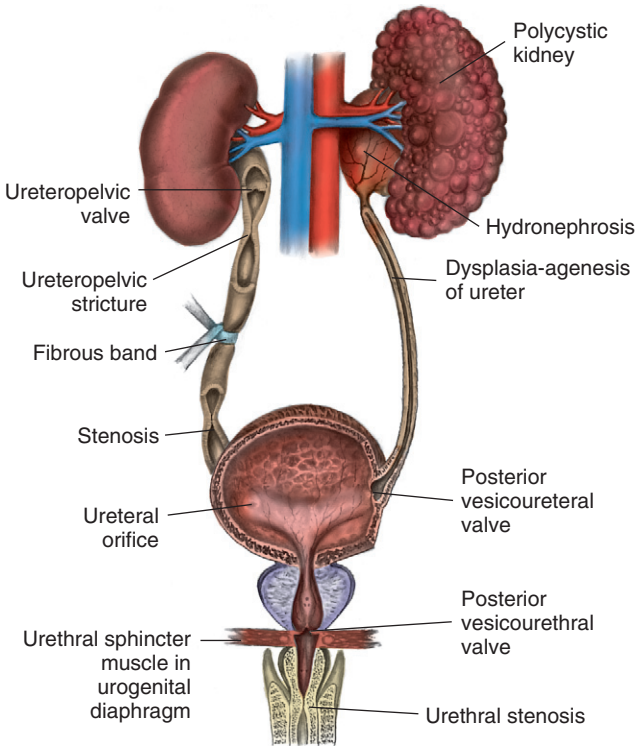

FIG 44-2 Major sites of urinary tract obstruction.

above the obstruction causes hydronephrosis (dilation of the renal pelvis from distention) with eventual pressure destruction of renal parenchyma, although the dilating ureters form a reservoir that reduces the effect on the kidneys for a long time.

Obstruction may be congenital or acquired, unilateral or bilateral, and complete or incomplete with acute or chronic manifestations. The obstruction can occur at any level of the upper or lower urinary tract (Fig. 44-2). Partial obstruction may not be symptomatic unless there is a water or solute diuresis. Boys are affected more frequently than girls, and malformations should be suspected when patients have some other congenital defects (e.g., prune belly syndrome, chromosome anomalies, anorectal malformations, defects of the pinna of the ear).

Damage to distal nephrons in chronic uropathy alters the ability to concentrate urine, contributing to increased urine flow and metabolic acidosis occurring from decreased excretion of acid secondary to impaired ability of the distal nephron to secrete hydrogen ions. Partial obstruction results in progressive loss of renal function as a result of irreversible damage to the nephrons. Pooled urine serves as a medium for bacterial growth; therefore UTIs further increase the extent of renal damage.

Early diagnosis and surgical correction or procedures that divert the flow of urine to bypass the obstruction such as placement of a temporary percutaneous nephrostomy tube or cutaneous ureterostomy are essential to prevent progressive renal damage. Medical complications of acute or chronic renal failure (CRF) or infection are managed as described for those disorders.

CARE MANAGEMENT

Nursing goals in urinary tract obstruction include helping to identify cases, assisting with diagnostic procedures, and caring for children with complications (described elsewhere). Preparing parents and children for procedures is a major nursing responsibility. Preparation for urinary diversion procedures is of special importance (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 39).

Parents and children need emotional support and counseling during the lengthy management of these disorders. Many children are discharged with ureteral drainage systems in place that must be protected from damage, and the danger of infection is a constant concern. Parents are taught to care for the equipment and recognize the signs of possible obstruction or infection within the system. Maintaining adequate urine flow is imperative. Fluids should be encouraged. The tube should be observed frequently for indications of obstruction resulting from sediment, small blood clots, or kinking. The health care provider should inspect any drainage from around the tube.

Children with external diversional systems need psychologic support and guidance, especially as they reach adolescence and body image concerns assume more prominence. Those with progressive renal deterioration may face the prospect of dialysis or transplantation and the emotions that accompany these procedures.

External Defects

Defects of the external genitourinary tract are serious conditions primarily because of the psychologic impact on the child. Satisfactory surgical repair is successful for the more common disorders and is carried out or initiated as early as possible. The major anomalies of the lower genitourinary tract, their description, and their management are outlined in Table 44-4.

Psychologic Problems Related to Genital Surgery

Surgery involving sexual organs can be particularly disruptive to children, especially preschoolers fearing punishment, retaliation, body mutilation, or castration. Some of the problems of hospitalization, separation, and anxiety can be eased by hospital practices that are sensitive to the child's needs (see Chapter 38).

A child's body image is largely derived as a result of feedback from the primary caregivers, and parental anxiety regarding an acceptable physical appearance and adequate future sexual competency is readily communicated to an affected child. Therefore children with birth defects are at risk for developing a distorted body image that reflects the caregiver's subtly communicated evaluation of their bodies. The trend toward repair of visible genital defects is

TABLE 44-4 DEFECTS OF THE GENITOURINARY TRACT

DEFECT	THERAPEUTIC MANAGEMENT
Inguinal hernia—Protrusion of abdominal contents through inguinal canal into scrotum	Detected as painless inguinal swelling of variable size Surgical closure of inguinal defect
Hydrocele—Fluid in scrotum	Surgical repair indicated if spontaneous resolution not accomplished in 1 year
Phimosis—Narrowing or stenosis of preputial opening of foreskin	**Mild cases**—Manual retraction of foreskin and proper cleansing of area **Severe cases**—Circumcision or vertical division and transverse suturing of foreskin
Hypospadias—Urethral opening located behind glans penis or anywhere along ventral surface of penile shaft	Objectives of surgical correction: Enable child to void in standing position and direct stream voluntarily in usual manner Improve physical appearance of genitalia Produce a sexually adequate organ
Chordee—Ventral curvature of penis, often associated with hypospadias	Surgical release of fibrous band causing deformity
Epispadias—Meatal opening located on dorsal surface of penis	Surgical correction, usually including penile and urethral lengthening and bladder neck reconstruction (if necessary)
Cryptorchidism—Failure of one or both testes to descend normally through inguinal canal	Detected by inability to palpate testes within scrotum **Medical**—Administration of human chorionic gonadotropin (older child) **Surgical**—Orchiopexy Objectives of therapy: Prevent damage to undescended testicle Decrease incidence of malignant tumor formation Avoid trauma and torsion Close inguinal canal Prevent cosmetic and psychologic disability from empty scrotum
Exstrophy of bladder—Eversion of posterior bladder through anterior bladder wall and lower abdominal wall; associated with open pubic arch (severe defect)	Potential objectives of surgical correction: Preserve renal function Attain urinary control Provide adequate reconstructive repair Improve sexual function (especially in males)
Disorders of Sexual Differentiation	
Masculinized female (female pseudohermaphrodite)	Assign gender as female; assign gender while avoiding irreversible surgery, realizing that some children may change gender later in life; family participation essential
Incompletely masculinized male (male pseudohermaphrodite)	Assign gender while avoiding irreversible surgery, realizing that some children may change gender later in life; family participation essential
True hermaphrodite (both ovaries and testes)	Assign gender while avoiding irreversible surgery, realizing that some children may change gender later in life; gender assignment depends on predominant characteristics; family participation essential
Mixed gonadal dysgenesis	Assign gender while avoiding irreversible surgery, realizing that some children may change gender later in life; gender assignment depends on predominant characteristics; family participation essential

based in large part on these psychologic variables. The earlier a repair can be achieved, the more likely it is that the child will develop a normal body image.

During the years from ages 3 to 6 (i.e., the phallic-oedipal period), children show a strong interest and concern about the genital area, sex differences, and genital normality or its lack. It is also a time when children are frightened of what they perceive to be threats to their body and bodily function. They also view any untoward happening as a punishment for real or imagined wrongdoing or unacceptable sexual feelings such as masturbation, sex play, or erotic feelings. Surgical repair is recommended before these fears and anxieties develop.

After extensive review of the emotional, cognitive, and body image problems that may occur in children undergoing surgical reconstruction of a genital deformity, Kass (1996) recommended that surgery be accomplished between the ages of 6 and 15 months to minimize the psychologic effects of surgery and anesthesia.

CARE MANAGEMENT

Preparing children and their families for diagnostic and surgical procedures (see Preparation for Diagnostic and Therapeutic Procedures, Chapter 39) and for home care is a major nursing function. Most postoperative care involves care of the surgical site. Tub baths are discouraged for 1 week after simple surgeries. The surgical site is kept clean and otherwise protected from infection and inspected for signs of infection. Dressings, if any, are inspected regularly. More complex surgeries require additional care and observation (e.g.,

catheter care for urethral reconstruction and care of urinary diversion stomas and collection devices).

Some older children's activities such as pushing, lifting, playing with straddle toys or in sandboxes, swimming, and rough activities may be restricted after some types of surgical repairs. Precise restrictions depend on the specific type of surgery. Activities of infants and toddlers are not limited.

In most cases the results of surgery are satisfactory. However, in some of the more severe defects such as exstrophy and those that require stomas, additional emotional interventions may be needed. A major concern of parents and children is related to surgery affecting the genitalia directly. Concerns about penis size, appearance of the genitalia, potential ability to procreate, and rejection by peers (especially the opposite sex) are potential fears that require psychologic adjustment, particularly during adolescence.

GLOMERULAR DISEASE

Nephrotic Syndrome

Nephrotic syndrome is a clinical state that includes massive proteinuria, hypoalbuminemia, hyperlipidemia, and edema. The disorder can occur as (1) a primary disease known as idiopathic nephrosis, childhood nephrosis, or minimal-change nephrotic syndrome (MCNS); (2) a secondary disorder that occurs as a clinical manifestation after or in association with glomerular damage that has a known or presumed cause; or (3) a congenital form inherited as an autosomal recessive disorder. The disorder is characterized by increased glomerular permeability to plasma protein, which results in massive urinary protein loss. The glomerulus is responsible for the initial step in the formation of urine, and the filtration rate depends on an intact glomerular membrane. This discussion is devoted to MCNS because it constitutes 80% of nephrotic syndrome cases.

Pathophysiology

The onset of MCNS can occur at any age but predominantly occurs in children between 2 and 7 years of age. It is rare in children younger than 6 months of age, uncommon in infants younger than 1 year of age, and unusual after the age of 8 years. Patients with MCNS are twice as likely to be male.

The pathogenesis of MCNS is not fully understood. There may be a metabolic, biochemical, physiochemical, or immune-mediated disturbance that causes the basement membrane of the glomeruli to become increasingly permeable to protein; but the cause and mechanisms are only speculative.

The glomerular membrane, normally impermeable to albumin and other proteins, becomes permeable to proteins, especially albumin, that leak through the membrane and are lost in urine (hyperalbuminuria). This reduces the serum albumin level **(hypoalbuminemia),** decreasing the colloidal osmotic pressure in the capillaries. As a result the vascular hydrostatic pressure exceeds the pull of the colloidal osmotic pressure, causing fluid to accumulate in the interstitial spaces (edema) and body cavities, particularly in the abdominal cavity (ascites). The shift of fluid from the plasma to the interstitial spaces reduces the vascular fluid volume (hypovolemia), which in turn stimulates the renin-angiotensin system and the secretion of antidiuretic hormone and aldosterone. Tubular reabsorption of sodium and water is increased in an attempt to increase intravascular volume. The elevation of serum lipids is not fully understood. The sequence of events in nephrotic syndrome is diagrammed in Fig. 44-3.

Diagnostic Evaluation

The disease is suspected on the basis of clinical manifestations (Box 44-2), especially when weight gain in a previously well child increases slowly over days or weeks. The generalized edema may develop rapidly or gradually but eventually prompts the family to seek medical attention. Parents usually give a history of the child being well but steadily gaining weight; appearing edematous; and then becoming anorexic, irritable, and less active.

The diagnosis of MCNS is suspected on the basis of the history and clinical manifestations (edema, proteinuria, hypoalbuminemia, and hypercholesterolemia in the absence of hematuria and hypertension) in children between the ages of 2 and 8 years. The hallmark of MCNS is massive proteinuria (higher than 2+ on urine dipstick). Hyaline casts, oval fat bodies, and a few red blood cells (RBCs) can be found in the urine of some affected children, although there is seldom gross hematuria. The GFR is usually normal or high.

Total serum protein concentration is low, with the serum albumin significantly reduced and plasma lipids elevated. Hemoglobin and hematocrit are usually normal or elevated as a result of hemoconcentration. The platelet count may be elevated. Serum sodium concentration may be low. If the patient does not respond to a 4- to 8-week course of steroids, a renal biopsy may be needed to distinguish among other types of nephrotic syndrome. The biopsy results of children with MCNS are remarkable for effacement of the foot processes of the epithelial cells lining the basement membrane, but otherwise the kidney tissue is normal.

Therapeutic Management

Objectives of therapeutic management include (1) reducing excretion of urinary protein, (2) reducing fluid retention in the tissues, (3) preventing infection, and (4) minimizing complications related to therapies. Dietary restrictions include a low-salt diet and in more severe cases fluid restriction. If complications of edema develop, diuretic therapy may be initiated to provide temporary relief. Sometimes infusions of 25% albumin are used. Acute infections are treated with appropriate antibiotics.

Corticosteroids are the first line of therapy for MCNS. The starting dosage for prednisone is usually 2 mg/kg of body weight per day for 6 weeks followed by 1.5 mg/kg every other day for 6 weeks (Gipson, Massengill, Yao, et al., 2009). Approximately two thirds of children with MCNS have a relapse, heralded first by increased urine protein. Relapses can be diagnosed early if parents are taught routine home monitoring of urine protein by dipstick. They are treated with a repeated, but usually shorter, course of high-dose steroid therapy. Side effects of the steroids include weight gain, rounding of the face, behavior changes, and increased appetite. Long-term therapy may result in hirsutism, growth retardation, cataracts, hypertension, gastrointestinal bleeding, bone demineralization, infection, and hyperglycemia. Children who do not respond to steroid therapy, those who have frequent relapses, and those in whom the side effects threaten their growth and general health may be considered for a course of therapy using other immunosuppressant medications (cyclophosphamide, chlorambucil, or cyclosporine).

Episodes of MCNS, both the first episode and relapse, often happen in conjunction with a viral or bacterial infection. Relapses can also be triggered by allergies and immunizations. Relapses in children with MCNS may continue over many years.

Complications of nephrotic syndrome include infection, circulatory insufficiency secondary to hypovolemia, and thromboembolism. Infections that may be seen in children with nephrotic syndrome include peritonitis, cellulitis, and pneumonia and require

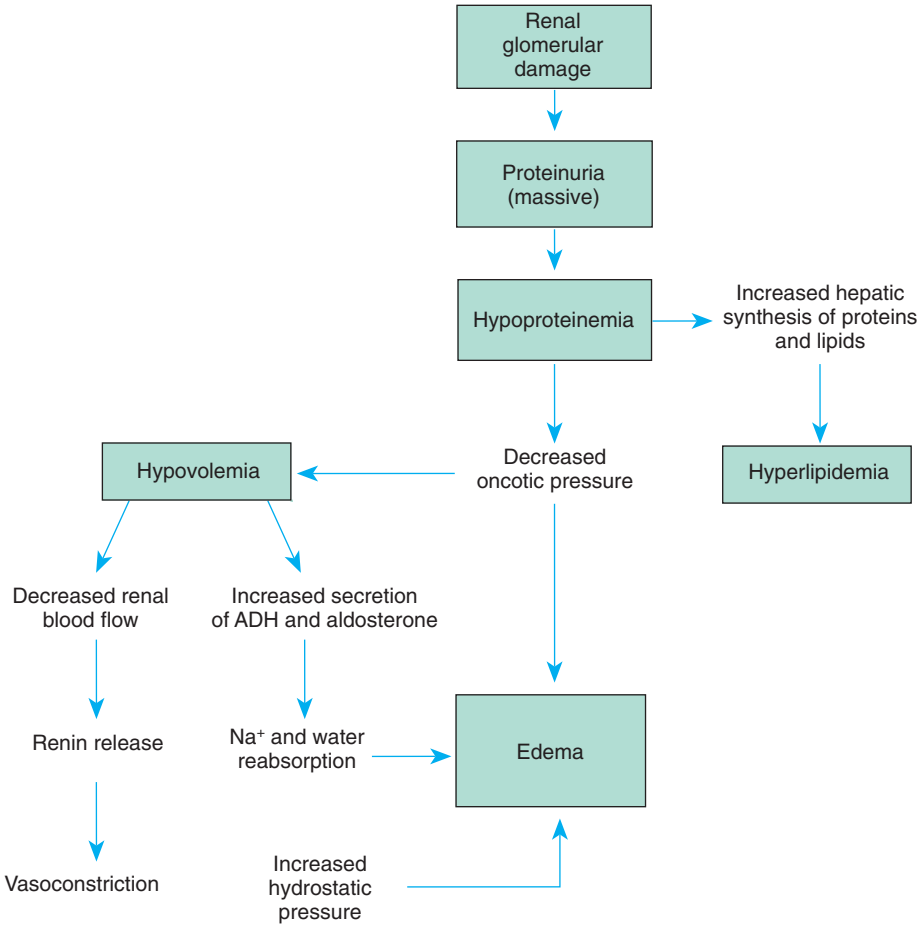

FIG 44-3 Sequence of events in nephrotic syndrome. *ADH,* Antidiuretic hormone.

BOX 44-2 CLINICAL MANIFESTATIONS OF NEPHROTIC SYNDROME

- Weight gain
- Puffiness of face (facial edema):
  - Especially around the eyes
  - Apparent on arising in the morning
  - Subsides during the day
- Abdominal swelling (ascites)
- Pleural effusion
- Labial or scrotal swelling
- Edema of intestinal mucosal, possibly causing:
  - Diarrhea
  - Anorexia
  - Poor intestinal absorption
- Ankle or leg swelling
- Irritability
- Easily fatigued
- Lethargic
- Blood pressure normal or slightly decreased
- Susceptibility to infection
- Urine alterations:
  - Decreased volume
  - Frothy

prompt recognition and vigorous treatment with appropriate antibiotic therapy.

Prognosis. The prognosis for ultimate recovery in most cases is good. It is a self-limiting disease, and in children who respond to steroid therapy the tendency to relapse decreases with time. With early detection and prompt implementation of therapy to eradicate proteinuria, progressive basement membrane damage is minimized so that, when the tendency to relapse is past, renal function is usually normal or near normal. It is estimated that approximately 80% of affected children have this favorable prognosis.

CARE MANAGEMENT

Continuous monitoring of fluid retention or excretion is an important nursing function. Strict intake and output records are essential but may be difficult to obtain from very young children. Application of collection bags is irritating to edematous skin that is readily subject to breakdown. Applying diapers or weighing wet pads may be necessary.

Other methods of monitoring progress include urine examination for albumin, daily weight, and measurement of abdominal girth. Assessment of edema (e.g., increased or decreased swelling around the eyes and dependent areas), the degree of pitting, and the color and texture of skin are part of nursing care. Vital signs are monitored to detect any early signs of complications such as shock or an infective process.

Infection is a constant source of danger to edematous children and those receiving corticosteroid therapy. These children are particularly vulnerable to upper respiratory tract infection; therefore they must be kept warm and dry, active, and protected from contact with infected individuals (e.g., roommates, visitors, and personnel). Vital signs are monitored to detect any early signs of an infective process.

Loss of appetite accompanying active nephrosis creates a perplexing problem for nurses. During this time the combined efforts

of nurse, dietitian, parents, and child are needed to formulate a nutritionally adequate and attractive diet. Salt is usually restricted (but not eliminated) during the edema phase and while the child is on steroid therapy. Fluid restriction (if prescribed) is limited to short-term use during massive edema. Every effort should be made to serve attractive meals with preferred foods and a minimum of fuss, but it usually requires considerable ingenuity to entice the child to eat (see Feeding the Sick Child, Chapter 39).

Children usually adjust activities according to their tolerance level. However, they may require guidance in selecting play activities. Suitable recreational and diversional activities are an important part of their care. Irritability and mood swings that accompany steroid therapy are not unusual in these children and may create an additional challenge for the nurse and family.

Family Support and Home Care. Continuous support of the child and family is one of the major nursing considerations. Most children are treated at home during relapses. Parents are taught to detect signs of relapse and call for changes in treatment at the earliest indications. Unless the edema and proteinuria are severe or the parents, for some reason, are unable to care for the ill child, *home care is preferred.* Parents are instructed in testing urine for albumin, administering medications, and providing general care. They are also instructed regarding avoiding contact with infected playmates, but the child should attend school.

The prolonged course of the relapsing form of nephrotic syndrome is taxing to both the child and the family. The up-and-down course of remissions and exacerbations with periodic disruption of family life by hospitalization places a severe strain on the child and the family, both psychologically and financially. Reassurance regarding this characteristic of the course of the disease, with emphasis on the importance of long-term care, needs to be provided to parents and children to gain their cooperation. A satisfactory response is more likely when relapses are detected and therapy is instituted early, and remissions are prolonged when instructions are carried out faithfully. Continuous support of the child and family is one of the major nursing considerations (see Chapter 36).

Acute Glomerulonephritis

Acute glomerulonephritis (AGN) may be a primary event or a manifestation of a systemic disorder that can range from minimal to severe. Common features include oliguria, edema, hypertension and circulatory congestion, hematuria, and proteinuria. Most cases are postinfectious and have been associated with pneumococcal, streptococcal, and viral infections. Acute poststreptococcal glomerulonephritis (APSGN) is the most common of the postinfectious renal diseases in childhood and the one for which a cause can be established in the majority of cases. It can occur at any age but affects primarily early school-age children, with a peak age of onset of 6 to 7 years. It is uncommon in children younger than 2 years of age, and boys outnumber girls two to one.

Etiology

APSGN is an immune-complex disease that occurs after an antecedent streptococcal infection with certain strains of the group A β-hemolytic streptococcus. Most streptococcal infections *do not* cause APSGN. A latent period of 10 to 21 days occurs between the streptococcal infection and the onset of clinical manifestations. Disease secondary to streptococcal pharyngitis is more common in the winter or spring; however, when APSGN is associated with pyoderma (principally impetigo), it may be more prevalent in later summer or early fall, especially in warmer climates. Second episodes of AGN are rare.

Pathophysiology

The pathophysiology of APSGN is still uncertain. Immune complexes are deposited in the glomerular basement membrane. The glomeruli become edematous and infiltrated with polymorphonuclear leukocytes, which occlude the capillary lumen. The resulting decrease in plasma filtration results in an excessive accumulation of water and retention of sodium that expands plasma and interstitial fluid volumes, leading to circulatory congestion and edema. The cause of the hypertension associated with AGN cannot be explained completely by fluid retention. Excess renin may also be produced.

Diagnostic Evaluation

Typically affected children are in good health until they experience streptococcal infection. In some instances they have a history of only a mild cold or no previous infection at all. The onset of nephritis appears after an average latency period of about 10 days (Box 44-3). Because the child appears to be well during the latency period, parents do not recognize the association. The edema is relatively moderate and may not be appreciated by someone unfamiliar with the child's normal appearance.

Urinalysis during the acute phase characteristically shows hematuria and proteinuria. Proteinuria generally parallels the hematuria and may be 3+ or 4+ in the presence of gross hematuria. Gross discoloration of the urine reflects RBC and hemoglobin content. Microscopic examination of the sediment shows many RBCs, leukocytes, epithelial cells, and granular and RBC casts. Bacteria are not seen.

Azotemia that results from impaired glomerular filtration is reflected in elevated blood urea nitrogen (BUN) and creatinine levels in at least 50% of cases. Occasionally proteinuria is excessive, and the patient may have nephrotic syndrome (i.e., hypoproteinemia and hyperlipidemia).

Cultures of the pharynx are rarely positive for streptococci because the renal disease occurs weeks after the infection.

BOX 44-3 CLINICAL MANIFESTATIONS OF ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

- Edema:
  - Especially periorbital
  - Facial edema more prominent in the morning
  - Spreads during the day to involve extremities and abdomen
- Anorexia
- Urine:
  - Cloudy, smoky brown (resembles tea or cola)
  - Severely reduced volume
- Pallor
- Irritability
- Lethargy
- Child appearing ill
- Child seldom expresses specific complaints
- Older children complaining of the following:
  - Headaches
  - Abdominal discomfort
  - Dysuria
- Vomiting possible
- Mildly to severely elevated blood pressure

Some serologic tests are necessary to make the diagnosis of AGN. Circulating serum antibodies to streptococci indicate the presence of a previous infection. The antistreptolysin O (ASO) titer is the most familiar and readily available test for streptococcal infection. Other antibodies that may aid in diagnosis are elevated antihyaluronidase (AHase), antideoxyribonuclease B (ADNase-B), and streptozyme.

All patients with APSGN have reduced serum complement (C3) activity in the early stages of the disease. Rising C3 levels are used as a guide to indicate improvement of the disease and should be normal in almost all patients 8 weeks after the disease onset.

Studies that may be useful include chest x-ray film examination, which generally shows cardiac enlargement, pulmonary congestion, or pleural effusion during the edematous phase of acute disease. Renal biopsy for diagnostic purposes is seldom required but may be useful in the diagnosis of atypical cases.

Therapeutic Management

Management consists of general supportive measures and early recognition and treatment of complications. Children who have normal blood pressure and a satisfactory urinary output can generally be treated at home. Those with substantial edema, hypertension, gross hematuria, or significant oliguria should be hospitalized because of the unpredictability of complications.

Dietary restrictions depend on the stage and severity of the disease, especially the extent of edema. Moderate sodium restriction and even fluid restriction may be instituted for children with hypertension and edema. Foods with substantial amounts of potassium are generally restricted during the period of oliguria.

Regular measurement of vital signs, body weight, and intake and output is essential to monitor the progress of the disease and detect complications that may appear at any time during its course. *A record of daily weight is the most useful means for assessing fluid balance.* Rarely children with AGN develop acute renal failure (ARF) with oliguria that significantly alters the fluid and electrolyte balance (resulting in hyperkalemia, acidosis, hypocalcemia, or hyperphosphatemia). These children require careful management. Peritoneal dialysis or hemodialysis is seldom needed.

Acute hypertension must be anticipated and identified early. Blood pressure measurements are taken every 4 to 6 hours. A variety of antihypertensive medications and diuretics are used to control hypertension. Antibiotic therapy is indicated only for children with evidence of persistent streptococcal infections. It is used to prevent transmission of nephritogenic streptococci to other family members.

Prognosis. Almost all children correctly diagnosed as having APSGN recover completely, and specific immunity is conferred; thus subsequent recurrences are uncommon. Some of these children have been reported to develop chronic disease, but most of these cases are now believed to be different glomerular diseases misdiagnosed as poststreptococcal disease.

CARE MANAGEMENT

Nursing care of the child with glomerulonephritis involves careful assessment of the disease status, with regular monitoring of vital signs (including frequent measurement of blood pressure), fluid balance, and behavior.

Vital signs provide clues to the severity of the disease and early signs of complications. They are carefully measured, and any deviations are reported and recorded. The volume and character of urine are noted, and the child is weighed daily. Children with restricted fluid intake, especially those who are not severely edematous or those who have lost weight, are observed for signs of dehydration.

Assessment of the child's appearance for signs of cerebral complications is an important nursing function because the severity of the acute phase is variable and unpredictable. The child with edema, hypertension, and gross hematuria may be subject to complications; anticipatory preparations such as seizure precautions and intravenous (IV) equipment are included in the nursing care plan.

For most children a regular diet is allowed, but it should contain no added salt. Foods high in sodium and salted treats are eliminated, and parents and friends are advised not to bring snacks such as potato chips or pretzels. However, the total amount of salt ingested is usually less than prescribed because of the child's poor appetite. Fluid restriction, if prescribed, is more difficult, and the amount permitted should be divided evenly throughout the waking hours. Meal preparation and service require special attention because the child is indifferent to meals during the acute phase. Again collaboration with parents and the dietitian and special consideration for food preferences facilitate meal planning.

During the acute phase children are generally content to lie in bed. As they begin to feel better and their symptoms subside, they want to be up and about. Activities should be planned to allow for frequent rest periods and avoidance of fatigue. Children who have mild edema and no hypertension and convalescent children who are being treated at home need follow-up care. Parents are instructed regarding general measures, including diet and prevention of infection.

Health supervision is continued with weekly followed by monthly visits for evaluation and urinalysis. Parent education and support in preparation for discharge and home care include education in home management and the need for follow-up care and health supervision.

MISCELLANEOUS RENAL DISORDERS

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome (HUS) is an uncommon, acute renal disease that occurs primarily in infants and small children between the ages of 6 months and 5 years. It is one of the most frequent causes of acquired ARF in children (Duzova, Bakkaloglu, Kalyoncu, et al., 2010). The clinical features of the disease include acquired hemolytic anemia, thrombocytopenia, renal injury, and central nervous system (CNS) symptoms. The etiology of HUS is thought to be associated with bacterial toxins, chemicals, and viruses. The appearance of the disease has been associated with *Rickettsia* organisms, viruses (especially coxsackievirus, echovirus, and adenovirus), *E. coli,* pneumococci, shigellae, and salmonellae and may represent an unusual response to these infections. Multiple cases of HUS caused by enteric infection of the *E. coli* O157:H7 serotype have been traced to undercooked meat, especially ground beef. Other sources are unpasteurized milk or fruit juice, especially apple; alfalfa sprouts; lettuce; and salami. Drinking or swimming in sewage-contaminated water can also cause infection. The clinical presentation is usually a history of a prodromal illness (most often gastroenteritis or an upper respiratory tract infection) followed by the sudden onset of hemolysis and renal failure.

Pathophysiology

The primary site of injury appears to be the endothelial lining of the small glomerular arterioles, which become swollen and occluded with deposits of platelets and fibrin clots (intravascular coagulation). RBCs are damaged as they attempt to move through the

  - Bruising
  - Petechiae
  - Jaundice
  - Bloody diarrhea
- Oliguria or anuria
- CNS involvement:
  - Seizures
  - Stupor or coma
- Signs of acute heart failure (sometimes)

CNS, Central nervous system.

partially occluded blood vessels. These damaged cells are removed by the spleen, causing acute hemolytic anemia. The platelet aggregation within the damaged blood vessels or the damage and removal of platelets produce the characteristic thrombocytopenia.

Diagnostic Evaluation

The triad of anemia, thrombocytopenia, and renal failure is sufficient for diagnosis (Box 44-4). Renal involvement is evidenced by proteinuria, hematuria, and urinary casts; BUN and serum creatinine levels are elevated. A low hemoglobin and hematocrit and a high reticulocyte count confirm the hemolytic nature of the anemia.

Therapeutic Management

The goals of therapy are early diagnosis and aggressive, supportive care of the ARF and hemolytic anemia. The most consistently effective treatment of HUS is hemodialysis or peritoneal dialysis, which is instituted in any child who has been anuric for 24 hours or who demonstrates oliguria with uremia or hypertension and seizures. Other treatments include use of pharmacologic agents, fresh-frozen plasma, and plasmapheresis. Blood transfusions with fresh, washed packed cells are administered for severe anemia but are used with caution to prevent circulatory overload from added volume.

Prognosis. With prompt treatment, the recovery rate is about 95%, but residual renal impairment ranges from 10% to 50%. Long-term complications include CRF, hypertension, and CNS disorders. Death is usually caused by residual renal impairment or CNS injury.

CARE MANAGEMENT

Nursing care is the same as that provided in ARF and, for children with continued impairment, includes management of chronic disease. Because of the sudden and life-threatening nature of the disorder in a previously well child, parents are often ill prepared for the impact of hospitalization and treatment. Therefore support and understanding are especially important aspects of care.

Wilms' Tumor

Wilms' tumor, or nephroblastoma, is the most common malignant renal and intraabdominal tumor of childhood. The incidence is estimated to be eight cases per million children. Approximately 500 new cases are diagnosed each year in the United States, with 6% involving both kidneys (Cendron and Gomez, 2010).Wilms' tumor occurs about 3 times more often in African-Americans than in East Asians in the United States. The peak age at diagnosis is approximately 3 years, and occurrence is slightly more frequent in boys than in girls. The majority of patients with Wilms' tumor are diagnosed at younger than 5 years of age, with 1% to 2.5% having a familial origin. Unfortunately there is no method of identifying gene carriers at this time.

BOX 44-5 CLINICAL MANIFESTATIONS OF WILMS' TUMOR

- Abdominal swelling or mass:
  - Firm
  - Nontender
  - Confined to one side
- Hematuria (less than one fourth of cases)
- Fatigue and malaise
- Hypertension (occasionally)
- Weight loss
- Fever
- Manifestations resulting from compression of tumor mass
- Secondary metabolic alterations from tumor or metastasis
- If metastasis, symptoms of lung involvement:
  - Dyspnea
  - Cough
  - Shortness of breath
  - Chest pain (sometimes)

Etiology

Wilms' tumor probably arises from a malignant, undifferentiated cluster of primordial cells capable of initiating the regeneration of an abnormal structure. Its occurrence slightly favors the left kidney, which is advantageous because surgically this kidney is easier to manipulate and remove. In about 10% of cases both kidneys are involved. Studies have shown that development of Wilms' tumor is frequently associated with aniridia, hemihypertrophy, Beckwith-Wiedemann syndrome, or genitourinary anomalies (Cendron and Gomez, 2010; Dome, Perlman, Ritchey, et al., 2006).

Diagnostic Evaluation

In a child suspected of having Wilms' tumor, special emphasis is placed on the history and physical examination for the presence of congenital anomalies, a family history of cancer, and signs of malignancy (e.g., weight loss, size of liver and spleen, indications of anemia, lymphadenopathy). Most children with Wilms' tumor are brought to the practitioner because of abdominal swelling or an abdominal mass (Box 44-5). Specific tests include radiographic studies, including abdominal ultrasonography and abdominal and chest computed tomography scan; hematologic studies; biochemical studies; and urinalysis. Studies to demonstrate the relationship of the tumor to the ipsilateral kidney and the presence of a normal, functioning kidney on the contralateral side are essential. If a large tumor is present, an inferior venacavogram is necessary to demonstrate possible tumor involvement adjacent to the vena cava. A bone marrow aspiration may be performed to rule out metastasis, which is rare in children with Wilms' tumor.

! NURSING ALERT

To reinforce the need for caution, it may be necessary to post a sign on the bed that reads, "DO NOT PALPATE ABDOMEN." Careful bathing and handling are also important in preventing trauma to the tumor site.

Therapeutic Management

Combined treatment with surgery and chemotherapy with or without radiation is based on the histologic pattern and clinical stage.

Surgery is scheduled as soon as possible after confirmation of a renal mass, usually within 24 to 48 hours of admission. A large transabdominal incision is performed for optimal visualization of the abdominal cavity. The tumor, affected kidney, and adjacent adrenal gland are removed. Great care is taken to keep the encapsulated tumor intact because rupture can seed cancer cells throughout the abdomen, lymph channel, and bloodstream. The contralateral kidney is inspected carefully for evidence of disease or dysfunction. Regional lymph nodes are inspected, and a biopsy is performed when indicated. Any involved structures such as part of the colon, diaphragm, or vena cava are removed. Metal clips are placed around the tumor site for exact marking during radiotherapy.

If both kidneys are involved, the child may be treated with radiotherapy or chemotherapy before surgery to decrease the size of the tumor, allowing more conservative surgery. It may be possible to perform a partial nephrectomy on the less affected kidney, with a total nephrectomy on the opposite side. When a transplant is feasible such as from a twin, sibling, or parent, bilateral nephrectomy is considered as a last resort.

Postoperative radiotherapy is indicated for children with large tumors, metastasis, residual postoperative disease, unfavorable histologic characteristics, or recurrence. Chemotherapy is indicated for all stages. The most effective agents for treating Wilms' tumor are actinomycin D (dactinomycin), vincristine, and Adriamycin, with the addition of cyclophosphamide for unfavorable histology or advanced disease (Cendron and Gomez, 2010; Dome, Perlman, Ritchey, et al., 2006). The duration of therapy ranges from 6 to 15 months.

Prognosis. Survival rates for Wilms' tumor are the highest among all childhood cancers. Children with localized tumor (stages I and II) have a 90% chance of cure with multimodal therapy. Factors that favorably affect the success of further therapy include initial treatment with only vincristine and dactinomycin, relapse to the lungs only, relapse in the abdomen of a patient who received no prior abdominal irradiation, and relapse more than 12 months after diagnosis. Wilms' tumor may recur, especially in the lungs. Both chemotherapy and radiotherapy can induce second malignancies, usually in areas that have been irradiated (Cendron and Gomez, 2010; Dome, Perlman, Ritchey, et al., 2006).

CARE MANAGEMENT

Nursing care of the child with Wilms' tumor is similar to that of children with other cancers treated with surgery, irradiation, and chemotherapy. However, there are some significant differences; these are discussed for each phase of nursing intervention.

Preoperative Care. The preoperative period is one of swift diagnosis. The nurse faces the challenge of preparing the child and parents for all laboratory and operative procedures within 24 to 48 hours of admission. Because of the minimal preparatory time, explanations should be simple, repetitive, and focused on the child's actual experiences. In addition to the usual preoperative observations, blood pressure is monitored because hypertension from excess renin production is a possibility.

There are several special preoperative concerns, the most important of which is that the *tumor is not palpated unless absolutely necessary* because manipulation of the mass may cause dissemination of cancer cells to adjacent and distant sites.

Because radiotherapy and chemotherapy are usually begun immediately after surgery, parents need an explanation of what to expect such as major benefits and side effects. The timing of the information should be considered to avoid overwhelming the family. Ideally the nurse should be present during physician-parent conferences to answer questions as they arise. It is usually better to postpone telling the child about these side effects until after surgery. Alopecia, usually of most concern to older children, does not occur until approximately 2 weeks after the initial treatment regimen. Therefore the child can be prepared for the hair loss after surgery.

Postoperative Care. Despite the extensive surgical intervention necessary in many children with Wilms' tumor, the recovery is usually rapid. The major nursing responsibilities are the same as those after any abdominal surgery (see Surgical Procedures, Chapter 39). Because these children are at risk for intestinal obstruction from vincristine-induced ileus, radiation-induced edema, and postsurgical adhesion formation, the nurse carefully monitors gastrointestinal activity such as bowel movements, bowel sounds, distention, vomiting, and pain. She or he also monitors blood pressure, urinary output, and signs of infection and institutes pulmonary hygiene to prevent postoperative pulmonary complications.

Family Support. The postoperative period is frequently difficult for parents. The shock of seeing their child immediately after surgery may be the first realization of the seriousness of the diagnosis. It also marks the confirmation of the stage of the tumor. During this period the nurse should be with the parents to assure them of the child's recovery after surgery and assess their understanding of the total experience. They need an opportunity to express their feelings and need to be provided the same emotional care discussed in Chapter 36 for families who have a child with a life-threatening disorder.

! NURSING ALERT

Prompt detection and treatment of any genitourinary signs or symptoms are mandatory. Children with a solitary kidney should be assessed and advised about the need for protective equipment before engaging in contact, collision, or limited contact activities (Rice and Council on Sports Medicine and Fitness, 2008).

Older children need an opportunity to deal with their feelings concerning the many procedures to which they have been subjected in rapid succession. Play therapy with dolls or puppets or through drawing can be extremely beneficial in helping them adjust. It is not unusual for children to feel angry because of the extent of surgery, the need for additional therapy, or the seriousness of the disorder.

RENAL FAILURE

Renal failure is the inability of the kidneys to excrete waste material, concentrate urine, and conserve electrolytes. It can occur suddenly (acute renal failure [ARF]) in response to inadequate perfusion, kidney disease, or urinary tract obstruction; or it can develop slowly (chronic renal failure [CRF]) as a result of longstanding kidney disease or an anomaly.

Azotemia and *uremia* are terms often used in relation to renal failure. Azotemia is the accumulation of nitrogenous waste within the blood. Uremia is a more advanced condition in which retention of nitrogenous products produces toxic symptoms. Azotemia is not life threatening, but uremia is a serious condition that often involves other body systems.

Acute Renal Failure

ARF is said to exist when the kidneys suddenly are unable to regulate the volume and composition of urine appropriately in response to food and fluid intake and the needs of the organism. The principal feature of ARF is oliguria* associated with azotemia, metabolic acidosis, and diverse electrolyte disturbances. ARF is not common in childhood; but the outcome depends on the cause, associated findings, and prompt recognition and treatment.

The pathologic conditions that produce ARF caused by glomerulonephritis and HUS are discussed in relation to those disorders. ARF can also develop as a result of a large number of related or unrelated clinical conditions: poor renal perfusion; urinary tract obstruction; acute renal injury; or the final expression of chronic, irreversible renal disease. The most common cause in children is transient renal failure resulting from severe dehydration or other causes of poor perfusion that may respond to restoration of fluid volume.

Pathophysiology

ARF is usually reversible, but the deviations of physiologic function can be extreme, and mortality in the pediatric age-group remains high. There is severe reduction in the GFR, an elevated BUN level, and a significant reduction in renal blood flow.

The clinical course varies and depends on the cause. In reversible ARF there is a period of severe oliguria, or a low-output phase, followed by an abrupt onset of diuresis, or a high-output phase, and then a gradual return to (or toward) normal urine volumes.

Diagnostic Evaluation

In many instances of ARF, the infant or child is already critically ill with the precipitating disorder, and the explanation for development of oliguria may or may not be readily apparent (Box 44-6). When a previously well child develops ARF without an obvious cause, a careful history is taken to reveal symptoms that may be related to glomerulonephritis, obstructive uropathy, or exposure to nephrotoxic chemicals (e.g., ingestion of heavy metals, inhalation of carbon tetrachloride or other organic solvents, or medications such as nonsteroidal antiinflammatory drugs [Patzer, 2008] known to be toxic to the kidneys). Significant laboratory measurements during renal shutdown that serve as a guide for therapy are BUN, serum creatinine, pH, sodium, potassium, and calcium.

! NURSING ALERT

Diminished urinary output and lethargy in a child who is dehydrated, is in shock, or has recently undergone surgery should be evaluated for possible ARF.

! NURSING ALERT

Any of the following signs of hyperkalemia constitute an emergency and are reported immediately:

- Serum potassium concentrations in excess of 7 mEq/L
- Presence of electrocardiographic abnormalities, such as prolonged QRS complex, depressed ST segment, high peaked T waves, bradycardia, or heart block

*The definition of oliguria varies extensively in the literature, from 1.8 to 4 dL/m^2/24 hr.

BOX 44-6 CLINICAL MANIFESTATIONS OF ACUTE RENAL FAILURE

- Specific:
  - Oliguria
  - Anuria uncommon (except in obstructive disorders)
- Nonspecific (may develop):
  - Nausea
  - Vomiting
  - Drowsiness
  - Edema
  - Hypertension
- Manifestations of underlying disorder or pathologic condition

Therapeutic Management

Treatment of ARF is directed toward (1) treatment of the underlying cause, (2) management of the complications of renal failure, and (3) provision of supportive therapy within the constraints imposed by the renal failure.

Treatment of poor perfusion resulting from dehydration consists of volume restoration, as described in Chapter 41 in treatment of dehydration. If oliguria persists after restoration of fluid volume or if the renal failure is caused by intrinsic renal damage, the physiologic and biochemical abnormalities that have resulted from kidney dysfunction must be corrected or controlled. Initially a Foley catheter is inserted to rule out urine retention, collect available urine for analysis, and monitor results of diuretic administration. The catheter may or may not be removed during the oliguric phase.

The amount of exogenous water provided should not exceed the amount needed to maintain zero water balance. It is calculated on the basis of estimated endogenous water formation and losses from sensible (primarily gastrointestinal) and insensible sources. No allotment is calculated for urine as long as oliguria persists.

When the output begins to increase, either spontaneously or in response to diuretic therapy, the intake of fluid, potassium, and sodium must be monitored, and adequate replacement provided to prevent depletion and its consequences. Some patients pass enormous amounts of electrolyte-rich urine.

Complications. The child with ARF has a tendency to develop water intoxication and hyponatremia, which makes it difficult to provide calories in sufficient amounts to meet his or her needs and reduce tissue catabolism, metabolic acidosis, hyperkalemia, and uremia. If the child is able to tolerate oral foods, food sources high in concentrated carbohydrate and fat but low in protein, potassium, and sodium may be provided. However, many children have functional disturbances of the gastrointestinal tract such as nausea and vomiting; therefore the IV route generally is preferred and usually consists of essential amino acids or a combination of essential and nonessential amino acids administered by the central venous route.

Control of water balance in these patients requires careful monitoring of feedback information such as accurate intake and output, body weight, and electrolyte measurements. In general, during the oliguric phase no sodium, chloride, or potassium is given unless there are other large, ongoing losses. Regular measurement of plasma electrolyte, pH, BUN, and creatinine levels is required to assess the adequacy of fluid therapy and anticipate complications that require specific treatment.

Hyperkalemia is the most immediate threat to the life of the child with ARF. It can be minimized and sometimes avoided by

eliminating potassium from all food and fluid, reducing tissue catabolism, and correcting acidosis. Measures used for the reduction of serum potassium levels are oral or rectal administration of an ion-exchange resin such as sodium polystyrene sulfonate (Kayexalate) and peritoneal dialysis or hemodialysis (see p. 1414). The resin produces its effect by exchange of its sodium for the potassium, thus binding potassium for removal from the body. This increased sodium concentration may contribute to fluid overload, hypertension, and cardiac failure. Dialysis removes potassium and other waste products from the serum by diffusion through a semipermeable membrane.

Hypertension is a frequent and serious complication of ARF; to detect it early, blood pressure measurements are made every 4 to 6 hours. The most common cause of hypertension in ARF is overexpansion of extracellular fluid and plasma volume together with activation of the renin-angiotensin system. Hypertension is controlled with antihypertensive drugs. Other measures that may be used include limiting fluids and salt.

Anemia is frequently associated with ARF, but transfusion is not recommended unless the hemoglobin drops below 6 g/dL. Transfusions, if used, consist of fresh, packed RBCs given slowly to reduce the likelihood of increasing blood volume, hypertension, and hyperkalemia.

Seizures occur often when renal failure progresses to uremia and are also related to hypertension, hyponatremia, and hypocalcemia. Treatment is directed to the specific cause when known. More obscure causes are managed with antiepileptic drugs.

Cardiac failure with pulmonary edema is almost always associated with hypervolemia. Treatment is directed toward reduction of fluid volume, with water and sodium restriction and administration of diuretics.

Prognosis. The prognosis of ARF depends largely on the nature and severity of the causative factor or precipitating event and the promptness and competence of management. The outcome is least favorable in children with rapidly progressive nephritis and cortical necrosis. Children in whom ARF is a result of HUS or AGN may recover completely, but residual renal impairment or hypertension is more often the rule. Complete recovery is usually expected in children whose renal failure is a result of dehydration, nephrotoxins, or ischemia. ARF after cardiac surgery is less favorable. It is often impossible to assess the extent of recovery for several months.

CARE MANAGEMENT

Meticulous attention to fluid intake and output is mandatory and includes all of the physical measurements discussed previously in relation to problems of fluid balance. Monitoring fluid balance and vital signs is a continuous process, and observers are constantly on the alert for signs of complications so appropriate interventions can be implemented. Because these children require intensive observation and often specialized treatment such as dialysis, they are usually admitted to an intensive care unit in which needed equipment and trained personnel are available.

Limiting fluid intake requires ingenuity on the part of caregivers to cope with the child who is thirsty. Rationing the daily intake in small amounts of fluid served in containers that give the impression of larger volumes is one strategy. Older children who understand the rationale of fluid limits can help determine how their daily ration should be distributed.

Meeting nutritional needs is sometimes a problem. The child may be nauseated, and encouraging concentrated foods without fluids may be difficult. When nourishment is provided by the IV route, careful monitoring is essential to prevent fluid overload. In addition, nursing measures such as maintaining an optimal thermal environment, reducing any elevation of body temperature, and reducing restlessness and anxiety are used to decrease the rate of tissue catabolism.

The nurse must be continually alert for changes in behavior that indicate the onset of complications. Infection from reduced resistance, anemia, and general morbidity is a constant threat. Fluid overload and electrolyte disturbances can precipitate cardiovascular complications such as hypertension and cardiac failure. Fluid and electrolyte imbalances, acidosis, and accumulation of nitrogenous waste products can produce neurologic involvement manifested by coma, seizures, or alterations in sensorium.

Although children with ARF are usually quite ill and voluntarily diminish their activity, infants may become restless and irritable, and children are often anxious and frightened. Frequent, painful, and stress-producing treatments and tests must be performed. A supportive, empathetic nurse can provide comfort and stability in a threatening and unnatural environment.

Family Support. Providing support and reassurance to parents are among the major nursing responsibilities. The seriousness of ARF and its emergency nature are stressful to parents; and most feel some degree of guilt regarding the child's condition, especially when the illness is a result of ingestion of a toxic substance, dehydration, or a genetic disease. They need reassurance and a sympathetic listener. They also need to be kept informed of the child's progress and provided explanations regarding the therapeutic regimen. The equipment and the child's behavior are sometimes frightening and anxiety provoking. Nurses can do much to help parents comprehend and deal with the stresses of the situation.

Chronic Renal Failure

The kidneys are able to maintain the chemical composition of fluids within normal limits until more than 50% of functional renal capacity is destroyed by disease or injury. Chronic renal insufficiency or failure begins when the diseased kidneys can no longer maintain the normal chemical structure of body fluids under normal conditions. Progressive deterioration over months or years produces a variety of clinical and biochemical disturbances that eventually culminate in the clinical syndrome known as uremia.

A variety of diseases and disorders can result in CRF. The most frequent causes are congenital renal and urinary tract malformations, VUR associated with recurrent UTI, chronic pyelonephritis, hereditary disorders, chronic glomerulonephritis, and glomerulonephropathy associated with systemic diseases such as anaphylactoid purpura and lupus erythematosus.

Pathophysiology

Early in the course of progressive nephrotic destruction, the child remains asymptomatic with only minimal biochemical abnormalities. Unless the presence of CRF is detected in the process of routine assessment, signs and symptoms that indicate advanced renal damage frequently emerge only late in the course of the disease. Midway in the disease process, as increasing numbers of nephrons are totally destroyed and most others are damaged to varying degrees, the few that remain intact are hypertrophied but functional. These few normal nephrons are able to make sufficient adjustments to stresses to maintain reasonable degrees of fluid and electrolyte balance. Definitive biochemical examination at this time reveals restricted tolerance to excesses or restrictions. As the disease progresses to the end stage, because of a severe reduction in the number of functioning nephrons, the kidneys are no longer able to maintain

fluid and electrolyte balance, and the features of uremic syndrome appear.

The accumulation of various biochemical substances in the blood resulting from diminished renal function produces complications such as the following:

- Retention of waste products, especially BUN and creatinine
- Water and sodium retention, which contributes to edema and vascular congestion
- Hyperkalemia of dangerous levels
- Metabolic acidosis of a sustained nature because of continual hydrogen ion retention and bicarbonate loss
- Calcium and phosphorus disturbances, resulting in altered bone metabolism, which in turn causes growth arrest or retardation, bone pain, and deformities known as renal osteodystrophy
- Anemia caused by hematologic dysfunction, including a shortened life span of RBCs, impaired RBC production related to decreased production of erythropoietin, prolonged bleeding time, and nutritional anemia
- Growth disturbance, probably caused by such factors as renal osteodystrophy, poor nutrition associated with dietary restrictions and loss of appetite, and biochemical abnormalities

Children with CRF seem to be more susceptible to infection, especially pneumonia, UTI, and septicemia, although the reason for this is unclear. These children become extraordinarily sensitive to changes in vascular volume that may cause pulmonary overload, CNS symptoms, hypertension, and cardiac failure.

Diagnostic Evaluation

The diagnosis of CRF is usually suspected on the basis of any number of clinical manifestations, a history of prior renal disease, or biochemical findings. The onset is usually gradual, and the initial signs and symptoms are vague and nonspecific (Box 44-7).

Laboratory and other diagnostic tools and tests are of value in assessing the extent of renal damage, biochemical disturbances, and related physical dysfunction (see Tables 44-1 to 44-3). Often they can help establish the nature of the underlying disease and differentiate among other disease processes and the pathologic consequences of renal dysfunction.

BOX 44-7 CLINICAL MANIFESTATIONS OF CHRONIC RENAL FAILURE

- Early signs:
  - Loss of normal energy
  - Increased fatigue on exertion
  - Pallor, subtle (may not be noticed)
  - Elevated blood pressure (sometimes)
- As the disease progresses:
  - Decreased appetite (especially at breakfast)
  - Less interest in normal activities
  - Increased or decreased urinary output with compensatory intake of fluid
  - Pallor more evident
  - Sallow, muddy appearance of skin
- Child may complain of:
  - Headache
  - Muscle cramps
  - Nausea
- Other signs and symptoms:
  - Weight loss
  - Facial edema
  - Malaise
  - Bone or joint pain
  - Growth retardation
  - Dryness or itching of the skin
  - Bruised skin
  - Sensory or motor loss (sometimes)
  - Amenorrhea (common in adolescent girls)
- Uremic syndrome (untreated):
  - Gastrointestinal symptoms:
    - Anorexia
    - Nausea and vomiting
  - Bleeding tendencies:
    - Bruises
    - Bloody diarrheal stools
    - Stomatitis
    - Bleeding from lips and mouth
  - Intractable itching
  - Uremic frost (deposits of urea crystals on skin)
  - Unpleasant "uremic" breath odor
  - Deep respirations
  - Hypertension
  - Congestive heart failure
  - Pulmonary edema
  - Neurologic involvement:
    - Progressive confusion
    - Dulled sensorium
    - Coma (ultimately)
    - Tremors
    - Muscular twitching
    - Seizures

Therapeutic Management

In irreversible renal failure the goals of medical management are to (1) promote maximum renal function, (2) maintain body fluid and electrolyte balance within safe biochemical limits, (3) treat systemic complications, and (4) promote as active and normal a life as possible for the child for as long as possible. The child is allowed unrestricted activity and to set his or her own limits regarding rest and extent of exertion. School attendance is encouraged as long as the child is able. When the effort is too great, home tutoring is arranged.

Diet regulation is the most effective means, short of dialysis, of reducing the quantity of materials that require renal excretion. The goals of diet management in renal failure are to provide sufficient calories and protein for growth while limiting the excretory demands made on the kidneys, to minimize metabolic bone disease (osteodystrophy), and to minimize fluid and electrolyte disturbances. Dietary protein intake is limited only to the reference daily intake (RDI) for the child's age. Restriction of protein intake below the RDI is believed to negatively affect growth and neurodevelopment. Malnutrition may develop in patients with CRF even before they need dialysis (Sylvestre, Fonseca, Stinghen, et al., 2007).

Sodium and water are not usually limited unless there is evidence of edema or hypertension, and potassium is not usually restricted. However, restrictions of any or all three may be imposed in later stages or at any time that abnormal serum concentrations are evident.

Dietary phosphorus is controlled through reduction of protein and milk intake to prevent or correct the calcium-phosphorus imbalance. Phosphorus levels can be reduced further by oral administration of calcium carbonate preparations or other phosphate-binding agents that combine with the phosphorus to decrease gastrointestinal absorption and thus the serum levels of phosphate. Treatment with 25-OH vitamin D is begun to increase calcium absorption and suppress elevated parathyroid hormone levels.

Metabolic acidosis is alleviated through administration of alkalizing agents such as sodium bicarbonate or a combination of sodium and potassium citrate.

Growth failure is one major consequence of CRF, especially in preadolescents. These children grow poorly both before and after the initiation of hemodialysis. The use of recombinant human growth hormone to accelerate growth in children with growth retardation secondary to CRF has been successful (Vimalachandra,

Hodson, Willis, et al., 2006). Osseous deformities that result from renal osteodystrophy, especially those related to ambulation, are troublesome and require correction if they occur. Dental defects are common in children with CRF; the earlier the onset of the disease, the more severe are the dental manifestations (including hypoplasia, hypomineralization, tooth discoloration, alteration in size and shape of teeth, malocclusion, and ulcerative stomatitis). Therefore regular dental care is important in these children.

Anemia in children with CRF is related to decreased production of erythropoietin. Recombinant human erythropoietin (rHuEPO) is being offered to these children as thrice-weekly or weekly subcutaneous injections and is replacing the need for frequent blood transfusions. The drug corrects the anemia and in turn increases appetite, activity, and general well-being in the children who receive it.

Hypertension may be managed initially by cautious use of a low-sodium diet, fluid restriction, and perhaps diuretics such as hydrochlorothiazide or furosemide. Severe hypertension requires the use of antihypertensive agents singly or in combination.

Intercurrent infections are treated with appropriate antimicrobials at the first sign of infection; however, any drug eliminated through the kidneys is administered with caution. Other complications are treated symptomatically (e.g., central-acting antiemetics for nausea, antiepileptics for seizures, and diphenhydramine [Benadryl] for pruritus).

When evidence of end-stage renal disease (ESRD) appears in a child, the disease runs its relentless course and results in death in a few weeks unless waste products and toxins are removed from body fluids by dialysis or kidney transplantation. These techniques have been adapted for infants and small children and are implemented in most cases of renal failure after conservative management is no longer effective (see Technologic Management of Renal Failure, p. 1414).

Prognosis. Dialysis and transplantation are the only treatments currently available for children with ESRD. Although they may survive on dialysis, it is not an ideal long-term modality. Complications include infection of access sites, growth failure, and disruption of normal socialization. Many pediatric centers encourage families of children with ESRD to consider kidney transplantation. The North American Pediatric Renal Trials and Collaborative Studies' annual transplant report (2010) documents graft survival of 96% at 1 year and 84% at 5 years for living donor kidneys and 95% at 1 year and 78% at 5 years for deceased donor kidneys.

Posttransplant complications include infection, hypertension, steroid toxicity, hyperlipidemia, aseptic necrosis, malignancy, and growth retardation (Dharnidharka and Araya, 2009). Long-term graft survival is not guaranteed, and many children require a second or third transplant. Successful kidney transplantation does improve rehabilitation of children with CRF, both educationally and psychologically. Increasing use of primary or preemptive kidney transplants is becoming the optimal form of renal replacement therapy, leading to substantial improvement in quality of life (Goldstein, Graham, Burwinkle, et al., 2006).

CARE MANAGEMENT

The multiple complications of ESRD are managed according to medical protocols such as the evidence-based clinical practice guidelines of the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (www.kidney.org/professionals/kdoqi). However, progressive disease places a number of stresses on the child and family, including those of a potentially fatal illness (see Chapter 36). There is a continuing need for repeated examinations that often entail painful procedures, side effects, and frequent hospitalizations. Diet therapy becomes progressively more restricted and intense, and the child is required to take a variety of medications. Ever present in all aspects of the treatment regimen is the agonizing realization that without treatment death is inevitable.

Some specific stresses related to ESRD and its treatment are predictable. When it first becomes apparent that ESRD is inevitable, both parents and child experience depression and anxiety. Acceptance is particularly difficult if renal failure progresses rapidly after diagnosis. Denial and disbelief are usually pronounced, especially among the parents. After renal failure is established and symptoms become progressively more distressing, the initiation of dialysis is usually perceived as a positive experience; after experiencing initial concerns regarding the treatment, the child begins to feel better, and parental anxiety is relieved for a time.

Initiating a dialysis regimen is a traumatic and anxiety-provoking experience for most children because it involves surgery for implantation of a graft, fistula, or peritoneal catheter. The initial experience with the dialysis procedure is frightening to most children. They need reassurance about the nature of the preparations for dialysis and the conduct of the treatment.

Both the graft and the fistula require needle insertions at each dialysis. The goal is to perform pain-free venipuncture. Using buffered lidocaine with a small-gauge needle (30 gauge) to anesthetize the area before venipuncture of the graft or fistula is one method. Using an anesthetizing topical preparation such as EMLA (eutectic mixture of local anesthetics [lidocaine and prilocaine]) 1 hour before venipuncture is another approach (see Pain Management, Chapter 30). External dual-lumen venous access devices eliminate the need for needles but are more prone to infection and other central line complications.

Adolescents, with their increased need for independence and their urge for rebellion, usually adapt less well than younger children. They resent the control and enforced dependence imposed by the rigorous and unrelenting therapy program. They resent being dependent on hemodialysis technology, their parents, and the professional staff. Depression or hostility is common in adolescents undergoing hemodialysis.

The availability of home peritoneal dialysis has offered a greater degree of freedom for people undergoing long-term dialysis. The nurse is responsible for teaching the family about (1) the disease, its implications, and the therapeutic plan; (2) the possible psychologic effects of the disease and the treatment; and (3) the technical aspects of the procedure. The family learns to manage the various aspects of the dialysis procedure, how to maintain accurate records, and how to observe for signs of complications that need to be reported to the proper persons.

Body changes related to the disease process such as pale or ashen skin color, growth retardation, and lack of sexual maturation are stress provoking. Dietary restrictions are particularly burdensome for both children and parents. Children feel deprived when they are unable to eat foods previously enjoyed and that are unrestricted for other family members. Consequently they may fail to cooperate. Diet restrictions may be interpreted as punishment. Some children who are unable to understand fully the purpose of restrictions sneak forbidden food items at every opportunity. Allowing children, especially adolescents, maximum participation in and responsibility for their own treatment program is helpful.

After months or years of dialysis, the parents and child feel anxiety associated with the prognosis and continued pressures of the treatment. The relentless need for treatment interferes with family

FAMILY-CENTERED CARE

Family Priorities

Families who have children with long-term chronic illnesses such as end-stage renal disease spend much time in hospitals, outpatient clinics, and primary health care facilities. When they miss appointments or respond less quickly than anticipated, sometimes they are quickly labeled "noncompliant." It is important to remember that families have to develop priorities for the unit as a whole. Sometimes they may decide that it is more important for the parent to go to work or attend a sibling's school performance than to attend an appointment scheduled for them by health care personnel. The chronically ill child cannot and should not always be the number one priority for the family. The professional staff who work with the family can help the parents prioritize the needs of the ill child within the needs of the family constellation.

Teresa Hall, MS, RN
Hathaway Children's Services
Sylmar, CA

plans. The time spent in transportation to and from the dialysis unit and the time spent undergoing dialysis treatments cut into time for outside activities, including school. Graft and fistula problems and peritoneal catheter exit site infections may develop and present a common source of aggravation (see Family-Centered Care box).

The possibility of kidney transplantation often provides hope for relief from the rigors of hemodialysis and peritoneal dialysis. Most children and families respond well to a kidney transplant, and most children can be rehabilitated successfully.

The National Kidney Foundation* and other agencies provide a number of services and information for families of children with renal disease.

TECHNOLOGIC MANAGEMENT OF RENAL FAILURE

Dialysis

Dialysis is the process of separating colloids and crystalline substances in solution by the difference in their rate of diffusion through a semipermeable membrane. Methods of dialysis currently available for clinical management of renal failure are peritoneal dialysis, wherein the abdominal cavity acts as a semipermeable membrane through which water and solutes of small molecular size move by osmosis and diffusion according to their respective concentrations on either side of the membrane; and hemodialysis, in which blood is circulated outside the body through artificial membranes that permit a similar passage of water and solutes. A third type of dialysis is hemofiltration, in which blood filtrate is circulated outside the body by hydrostatic pressure exerted across a semipermeable membrane with simultaneous infusion of a replacement solution. Types of hemofiltration include continuous venovenous hemofiltration, continuous venovenous hemodialysis, and continuous venovenous hemodiafiltration. These continuous renal replacement therapies are used in ARF, severe fluid overload, and inborn errors of metabolism or after bone marrow transplant.

*30 E. 33rd St., New York, NY 10016, 212-889-2210, 800-622-9010, www.kidney.org. In Canada: Kidney Foundation of Canada, 300-5165 Sherbrooke St. West, Montreal, Canada QC H4A 1T6, 514-369-4806, 800-361-7494, www.kidney.ca.

Peritoneal dialysis is the preferred form of dialysis for infants, children, and parents who wish to remain independent; families who live a long distance from the medical center; and children who prefer fewer dietary restrictions and a gentler form of dialysis. Chronic peritoneal dialysis is most often performed at home. The two types of peritoneal dialysis are continuous ambulatory peritoneal dialysis and continuous cycling peritoneal dialysis. In both methods commercially available sterile dialysis solution is instilled into the peritoneal cavity through a surgically implanted indwelling catheter tunneled subcutaneously and sutured into place. The warmed solution is allowed to enter the peritoneal cavity by gravity and remains a variable length of time according to the rate of solute removal and glucose absorption in individual patients. The care and management of the procedure are the responsibility of the parents of young children. Some centers have initiated use of home health nurses to give parents respite from care. Older children and adolescents can carry out the procedure themselves, which provides them with some control and less dependency. This is especially important for adolescents.

NURSING ALERT

Observe for changes in the color of the dialysate draining from the child. The spent solution should be clear. If the color is cloudy, notify the practitioner immediately (Schaefer, 2003).

Hemodialysis requires the creation of a vascular access and the use of special dialysis equipment (i.e., the hemodialyzer, or so-called *artificial kidney*). Vascular access may be one of three types: fistulas, grafts, or external vascular access devices. An **arteriovenous fistula** is an access in which a vein and artery are connected surgically. The preferred site is the radial artery and a forearm vein that produces dilation and thickening of the superficial vessels of the forearm to provide easy access for repeated venipuncture. An alternative is the creation of a subcutaneous (internal) **arteriovenous graft** by anastomosing artery and vein, with a synthetic prosthetic graft for circulatory access. The most commonly used material is expanded polytetrafluoroethylene (ePTFE). Both the graft and the fistula require needle insertions with each dialysis treatment.

For external vascular access devices, percutaneous catheters are inserted in the femoral, subclavian, or internal jugular veins, even in very small children. A more permanent form of external access is available via a central catheter inserted surgically into the internal jugular vein. This catheter has a dual lumen, which allows a larger volume of blood flow with minimum recirculation. Catheters eliminate the need for skin punctures but may require some home care.

Hemodialysis is best suited to children who do not have someone in the family able to perform home peritoneal dialysis and to those who live close to a dialysis center. The procedure is usually performed 3 times per week for 4 to 6 hours, depending on the child's size. It achieves rapid correction of fluid and electrolyte abnormalities but can cause problems in association with this rapid change such as muscle cramping and hypotension. Disadvantages include school absence during dialysis and strict fluid and dietary restrictions between dialysis sessions. Boredom for the child and family is often a problem during dialysis, and planned activities should be introduced (Fig. 44-4).

Most children show rapid clinical improvement with the implementation of dialysis, although it is directly related to the duration of uremia before dialysis and good nutrition. Growth rate and skeletal maturation improve, but recovery of normal growth is

FIG 44-4 Diversional activities help lessen the boredom that children can experience during hemodialysis.

infrequent. In many cases sexual development, although delayed, progresses to completion.

Transplantation

Kidney transplantation is an acceptable and effective means of therapy in the pediatric age-group. Although peritoneal dialysis and hemodialysis are life preserving, both require major alterations in lifestyle. Transplantation offers the opportunity for a relatively normal life and is the preferred form of treatment for children with ESRD. Primary or preemptive transplants maintain the greatest amount of normalcy in the family's life.

Kidneys for transplant are available from two sources: a living related donor, usually a parent or a sibling, or a cadaver donor, wherein the family of a dead or brain-dead patient consents to donation of a healthy kidney. Retransplantation may be required.

The primary goal in transplantation is the long-term survival of grafted tissue by securing tissue that is antigenically similar to that of the recipient and suppressing the recipient's immune mechanism. The immunosuppressant therapy of choice has been corticosteroids (prednisone) in conjunction with cyclosporine or tacrolimus and mycophenolate mofetil. Other therapies include antilymphoblast globulin or monoclonal antibodies. New immunosuppressant medications and early withdrawal of steroids or steroid-free protocols are rapidly coming into clinical trials and use in large transplant centers (Grenda and Webb, 2010). It is important for the nurse to learn about the medications used in the antirejection protocol(s) and their side effects. Because the immunosuppressant medications are taken indefinitely, transplant patients experience many side effects of the drugs, including hypertension, growth retardation, cataracts, risk of infection, obesity, characteristics of Cushing syndrome, and hirsutism (McDonald, 2011).

! NURSING ALERT

The child with a kidney transplant who exhibits any of the following should be evaluated immediately for possible rejection:

- Fever
- Swelling and tenderness over graft area
- Diminished urinary output
- Elevated blood pressure
- Elevated serum creatinine

Rejection of the transplanted kidney is the most common cause of transplant failure. Rejection is treated aggressively with immunosuppressant medications and can often be reversed. Some patients do not respond to treatment of acute rejection or develop chronic rejection and must eventually return to dialysis or undergo another kidney transplant.

KEY POINTS

- Common inflammatory disorders of the genitourinary tract include UTI, nephrotic syndrome, and AGN.
- Management of UTIs is directed at eliminating infection, detecting and correcting functional or anatomic abnormalities, preventing recurrences, and preserving renal function.
- VUR is the retrograde flow of bladder urine into the ureters.
- Obstructive uropathy is a result of structural or functional abnormalities of the urinary system that obstruct the normal flow of urine.
- The more common defects of the genitourinary tract include phimosis, cryptorchidism, inguinal hernia, hydrocele, and hypospadias.
- Body image concerns and castration anxiety are particularly intense in children with defects in the genital area.
- Nephrotic syndrome is characterized by increased glomerular permeability to protein, with massive urinary loss of protein resulting in hypoproteinemia and edema.
- Management of nephrotic syndrome is aimed at reducing excretion of protein, reducing or preventing fluid retention by tissues, and preventing infection and other complications.
- Common features of AGN are oliguria, edema, hypertension, circulatory congestion, hematuria, and proteinuria.
- Therapeutic management of AGN involves maintenance of fluid balance, treatment of hypertension, and antibiotic therapy.
- Management of HUS is aimed at control of complications and hematologic manifestations of renal failure.
- Wilms' tumor is the most common malignant neoplasm of the kidney in infants and children.
- In ARF management is directed at determining treatment of the underlying cause, managing complications of renal failure, and providing supportive therapy.
- Abnormalities in CRF are waste product retention, water and sodium retention, hyperkalemia, acidosis, calcium and phosphorus disturbance, anemia, and growth disturbances.
- The types of dialysis used in ESRD are peritoneal dialysis and hemodialysis.
- When the child needs home dialysis, the nurse educates the family about the disease, its implications, the therapeutic plan, possible psychologic effects of the disease, and the treatment and technical aspects of the procedure.
- The major concerns in kidney transplantation are tissue matching and prevention of rejection; psychologic concerns involve self-image as related to possible body changes as a result of the effects of corticosteroid therapy.

CHAPTER

45

Cerebral Dysfunction

Marilyn J. Hockenberry

evolve WEBSITE

http://evolve.elsevier.com/Perry/maternal

LEARNING OBJECTIVES

On completion of this chapter, the reader will be able to:

- Describe the various modalities for assessment of cerebral function.
- Differentiate among the stages of consciousness.
- Formulate a care plan for the unconscious child.
- Distinguish among the types of head injuries and the serious complications.
- Describe the nursing care of a child with a tumor of the central nervous system.
- Outline a care plan for the child with bacterial meningitis.
- Differentiate between the various types of seizure disorders.
- Demonstrate an understanding of the manifestations of a seizure disorder and the management of a child with such a disorder.
- Describe the preoperative and postoperative care of a child with hydrocephalus.

CEREBRAL DYSFUNCTION

Most of the information about the status of the brain is obtained by indirect measurements. Some of these measurements are discussed elsewhere in relation to numerous aspects of child care (e.g., as part of assessments of health [Chapter 29], newborn status [Chapter 24], intellectual disability [Chapter 37], hypoxic injury [cerebral palsy, Chapter 49], and attainment of developmental milestones at each stage of development). Because increased intracranial pressure (ICP) and altered states of consciousness have such prominent places in neurologic dysfunction, they are described here, followed by techniques for neurologic assessment and diagnostic tests.

Increased Intracranial Pressure

The brain, tightly enclosed in the solid bony cranium, is well protected but highly vulnerable to pressure that may accumulate within the enclosure (Fig. 45-1). The total volume of the cranium—brain (80%), cerebrospinal fluid (CSF) (10%), and blood (10%)—must remain approximately the same at all times. A change in the proportional volume of one of these components (e.g., increase or decrease in intracranial blood) must be accompanied by a compensatory change in another. In this way the volume and pressure normally remain constant. Examples of compensatory changes are reduction in blood volume, decrease in CSF production, increase in CSF absorption, or shrinkage of brain mass by displacement of intracellular and extracellular fluid. Children with open fontanels compensate by skull expansion and widened sutures. However, at any age the capacity for spatial compensation is limited. An increase in ICP may be caused by tumors or other space-occupying lesions, accumulation of fluid within the ventricular system, bleeding, or edema of cerebral tissues. When compensation is exhausted, any further increase in the volume of the cranium results in a rapid rise in ICP.

Early signs and symptoms of increased ICP are often subtle and assume many patterns (Box 45-1). As pressure increases, signs and symptoms become more pronounced, and the level of consciousness (LOC) deteriorates.

Altered States of Consciousness

Consciousness implies awareness (i.e., the ability to respond to sensory stimuli and have subjective experiences). There are two components of consciousness: alertness, an arousal-waking state, including the ability to respond to stimuli; and cognitive power, including the ability to process stimuli and produce verbal and motor responses.

An altered state of consciousness usually refers to varying states of unconsciousness that may be momentary or extend for hours, for days, or indefinitely. Unconsciousness is depressed cerebral function (i.e., the inability to respond to sensory stimuli and have subjective

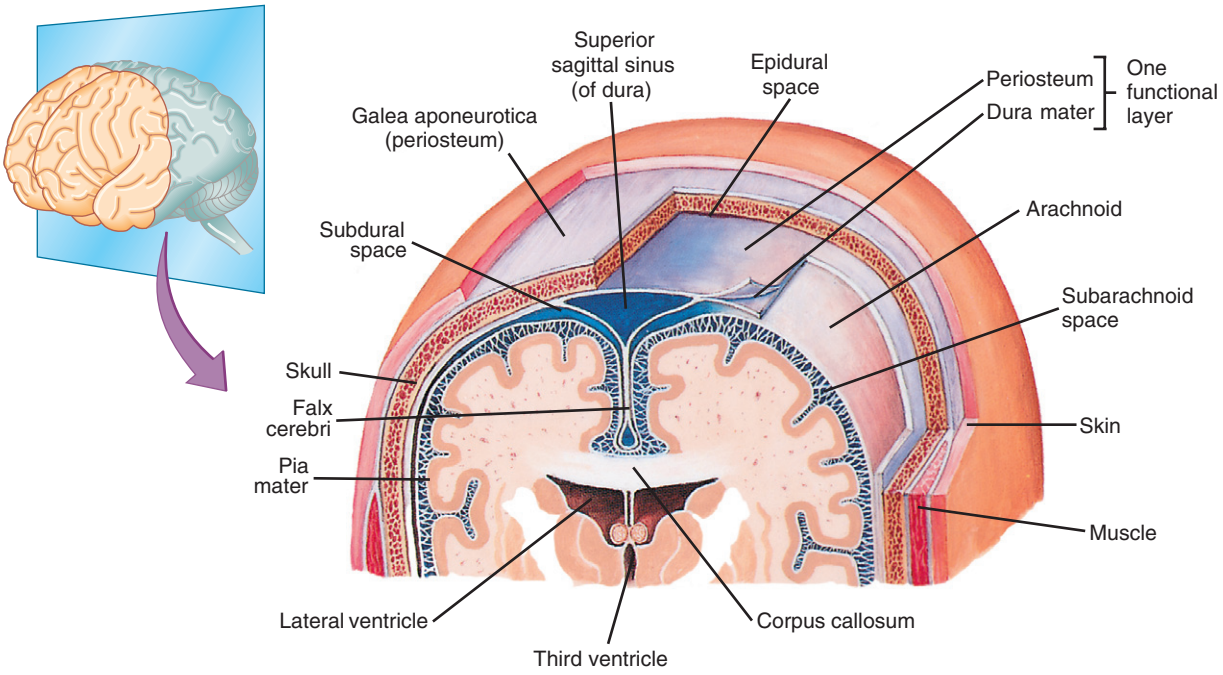

FIG 45-1 Coronal section of the top of the head showing meningeal layers. (From Patton KT, Thibodeau GA: *Anatomy and physiology,* ed 7, St Louis, 2010, Mosby.)

BOX 45-1 CLINICAL MANIFESTATIONS OF INCREASED INTRACRANIAL PRESSURE IN INFANTS AND CHILDREN

Infants

- Tense, bulging fontanel
- Separated cranial sutures
- Macewen (cracked-pot) sign
- Irritability and restlessness
- Drowsiness
- Increased sleeping
- High-pitched cry
- Increased fronto-occipital circumference
- Distended scalp veins
- Poor feeding
- Crying when disturbed
- Setting-sun sign

Children

- Headache
- Nausea
- Forceful vomiting
- Diplopia, blurred vision
- Seizures
- Indifference, drowsiness
- Decline in school performance
- Diminished physical activity and motor performance
- Increased sleeping
- Inability to follow simple commands
- Lethargy

Late Signs in Infants and Children

- Bradycardia
- Decreased motor response to command
- Decreased sensory response to painful stimuli
- Alterations in pupil size and reactivity
- Extension or flexion posturing
- Cheyne-Stokes respirations
- Papilledema
- Decreased consciousness
- Coma

experiences). Coma is defined as a state of unconsciousness from which the patient cannot be aroused even with powerful stimuli.

Levels of Consciousness

Assessment of LOC remains the earliest indicator of improvement or deterioration in neurologic status. LOC is determined by observations of the child's responses to the environment. When it is being assessed in young children, it is often useful to have a parent present to help elicit a desired response. An infant or child may not respond in an unfamiliar environment or to unfamiliar voices. Children older than 3 years of age should be able to give their name, although they may not be cognizant of place or time. Other diagnostic tests such as motor activity, reflexes, and vital signs vary more and do not necessarily directly parallel the depth of the comatose state. The most consistently used terms are described in Box 45-2.

Coma Assessment

Several scales have been devised in an attempt to standardize the description and interpretation of the degree of depressed consciousness. The most popular of these is the Glasgow Coma Scale (GCS),

BOX 45-2 LEVELS OF CONSCIOUSNESS

Full consciousness—Awake and alert, orientated to time, place, and person; behavior appropriate for age
Confusion—Impaired decision making
Disorientation—Confusion regarding time, place; decreased LOC
Lethargy—Limited spontaneous movement, sluggish speech, drowsy, falling asleep quickly
Obtundation—Arousable with stimulation
Stupor—Remaining in a deep sleep, slow response to vigorous and repeated stimulation or moaning responses to stimuli
Coma—No motor or verbal response or extension posturing to noxious (painful) stimuli
Persistent vegetative state—Permanently lost function of the cerebral cortex. Eyes follow objects only by reflex or when attracted to the direction of loud sounds; all four limbs are spastic but can withdraw from painful stimuli; hands show reflexive grasping and groping; the face can grimace, some food may be swallowed, and the child may groan or cry but utter no words.

LOC, Level of consciousness.

which consists of a three-part assessment: eye opening, verbal response, and motor response (Fig. 45-2). Numeric values of 1 through 5 are assigned to the levels of response in each category. The sum of these numeric values provides an objective measure of the patient's LOC. A person with an unaltered LOC would score the highest, 15; a score of 8 or below is generally accepted as a definition of coma; and the lowest score, 3, indicates deep coma. A decrease in the GCS score indicates a deterioration of the patient's condition. In 1987 major medical and legal societies developed specific guidelines for the determination of brain death among children of all ages (Mathur, Peterson, Stadtier, et al., 2008).

General Aspects

Children younger than 2 years of age require special evaluation because they are unable to respond to directions designed to elicit specific neurologic responses. Early neurologic responses in infants are primarily reflexive; these responses are gradually replaced by meaningful movement in the characteristic cephalocaudal direction of development. This evidence of progressive maturation reflects more extensive myelinization and changes in neurochemical and electrophysiologic properties.

Most information about infants and small children is gained by observing their spontaneous and elicited reflex responses as they develop increasingly complex motor skills and by eliciting progressively sophisticated communicative and adaptive behaviors. Delay or deviation from expected milestones helps identify high-risk children. Persistence or reappearance of reflexes that normally disappear indicates a pathologic condition. In evaluating an infant or young child, it is also important to obtain the pregnancy and delivery history to determine the possible impact of intrauterine environmental influences known to affect the orderly maturation of the central nervous system (CNS). These influences include maternal infections, cigarette or alcohol consumption, drug use, toxin exposure, trauma, and metabolic insults.

General aspects of assessment that provide clues to the etiology of dysfunction include the following:

Family history—Sometimes offers clues regarding possible genetic disorders with neurologic manifestations.

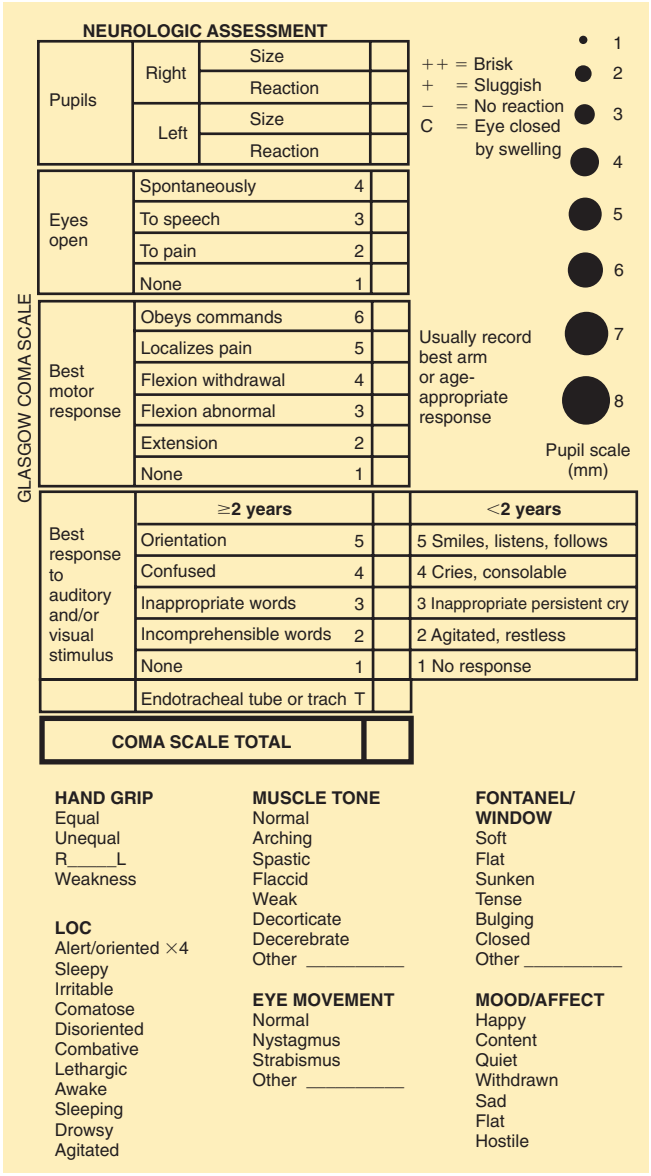

FIG 45-2 Pediatric coma scale.

Health history—May provide valuable clues regarding the cause of dysfunction. Information should include Apgar scores, age of developmental milestones, trauma or injuries, acute and chronic illnesses, encounters with animals or insects, and ingestion or inhalation of neurotoxic substances.

Physical evaluation of infants—Includes assessment of:

- Level of alertness.
- Size and shape of the head, including presence of fontanels.
- Sensory responses.
- Motor function, including posture, tone, and muscle strength.
- Motility, including symmetry of movements and involuntary movements.
- Respirations, including signs of prolonged apnea, ataxic breathing, paradoxical chest movement, or hyperventilation.
- Dysmorphic facial features.

- Behavioral cues, including consolability and habituation.
- Primitive and deep tendon reflexes.
- Cranial nerves.

Neurologic Examination

The purpose of the neurologic examination is to establish an accurate, objective baseline of neurologic information. It is essential that the neurologic examination be documented in a fashion that can be reproduced by others. This allows for a comparison of the findings so the observer can detect subtle changes in the neurologic status that might not otherwise be evident. Descriptions of behaviors should be simple, objective, and easily interpreted: "Drowsy but awake and conversationally rational/oriented"; "Sleepy but arousable with vigorous physical stimuli. Pressure to nail base of right hand results in upper-extremity flexion/lower-extremity extension."

Vital Signs

Pulse, respiration, and blood pressure provide information regarding the adequacy of circulation and the possible underlying cause of altered consciousness. Autonomic activity is most intensively disturbed in cases of deep coma or brainstem lesions.

Body temperature is often elevated, and sometimes the elevation may be extreme. High temperature is most frequently a sign of an acute infectious process or heat stroke but may also be caused by ingestion of some drugs (especially salicylates, alcohol, and barbiturates) or intracranial bleeding, especially subarachnoid hemorrhage. Hypothalamic involvement may cause elevated or decreased temperature. Coma of a toxic origin may produce hypothermia.

The pulse varies and may be rapid, slow and bounding, or feeble. Blood pressure may be normal, elevated, or very low. The Cushing reflex, or pressor response, causes a slowing of the pulse and an increase in blood pressure and is uncommon in children; when it occurs it is a very late sign of ICP. Medications may affect the vital signs. For assessment purposes actual *changes* in pulse and blood pressure are more important than the direction of the change.

Respirations are often slow, deep, and irregular. Slow, deep breathing is often seen in the heavy sleep caused by sedatives, after seizures, or in cerebral infections. Slow, shallow breathing may result from sedatives or opioids (narcotics). Hyperventilation (deep and rapid respirations) is usually a result of metabolic acidosis or abnormal stimulation of the respiratory center in the medulla caused by salicylate poisoning, hepatic coma, or Reye's syndrome (RS).

Breathing patterns have been described with a number of terms (e.g., *apneustic, cluster, ataxic, Cheyne-Stokes*). However, it is better to describe what is being observed rather than placing a label on it because the traditional terms are often used and interpreted incorrectly. Periodic or irregular breathing is an ominous sign of brainstem (especially medullary) dysfunction that often precedes complete apnea. The odor of the breath may provide additional clues (e.g., the fruity, acetone odor of ketosis; the foul odor of uremia; the fetid odor of hepatic failure; or the odor of alcohol).

Skin

The skin may offer clues to the cause of unconsciousness. The head should be examined for trauma such as lacerations, ecchymosis, or hematoma; the body surface should be examined for signs of injury, needle marks, petechiae, bites, and ticks. Evidence of toxic substances may be found on the hands, face, mouth, and clothing, especially in small children.

Eyes

Pupil size and reactivity are assessed (Fig. 45-3; see also Fig. 45-2). Pinpoint pupils are commonly observed in poisoning such as opiate or barbiturate poisoning and in brainstem dysfunction. Widely dilated and reactive pupils are often seen after seizures and may involve only one side. Dilated pupils may also be caused by eye trauma. Widely dilated and fixed pupils suggest paralysis of cranial nerve III secondary to pressure from herniation of the brain through

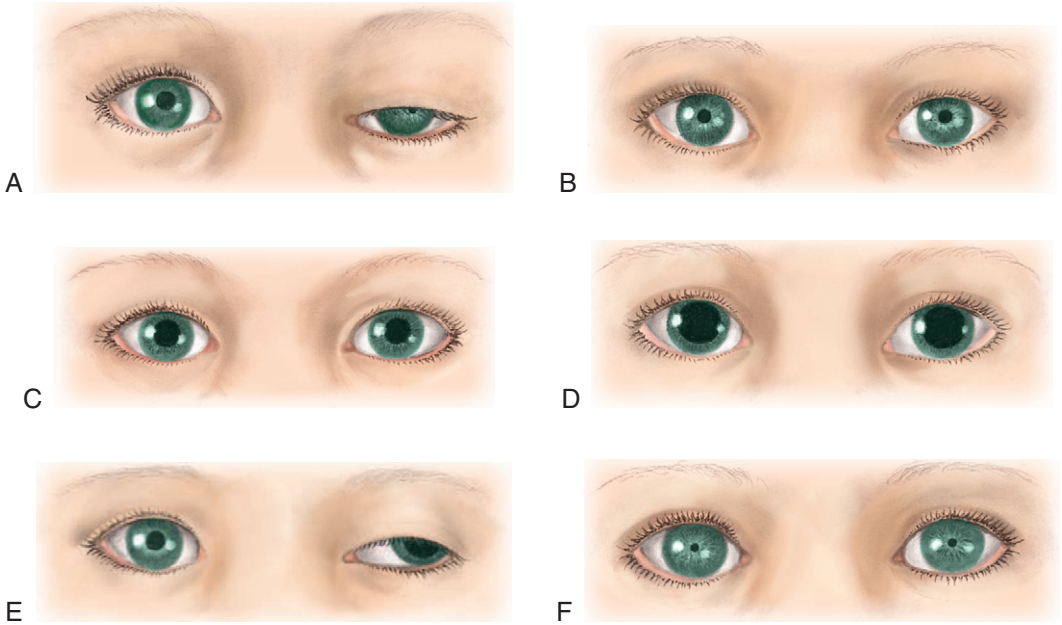

FIG 45-3 Variations in pupil size with altered states of consciousness. **A,** Ipsilateral pupillary constriction with slight ptosis. **B,** Bilateral small pupils. **C,** Midposition, light fixed to all stimuli. **D,** Bilateral dilated and fixed pupils. **E,** Dilated pupils, left eye abducted with ptosis. **F,** Pinpoint pupils.

the tentorium. A unilateral fixed pupil usually suggests a lesion on the same side. If pupils are fixed bilaterally for more than 5 minutes, brainstem damage is usually implied. Dilated and nonreactive pupils are also seen in hypothermia, anoxia, ischemia, poisoning with atropine-like substances, or prior instillation of mydriatic drugs.

! NURSING ALERT

The sudden appearance of a fixed and dilated pupil(s) is a neurologic emergency.

The description of eye movements should indicate whether one or both eyes are involved and how the reaction was elicited. The parents should be asked about preexisting strabismus, which causes the eyes to appear normal under compromise. Posttraumatic strabismus indicates cranial nerve VI damage.

Special tests, usually performed by qualified persons, include:

- Doll's head maneuver–Elicited by rotating the child's head quickly to one side and then to the other. Conjugate (paired or working together) movement of the eyes in the direction opposite to the head rotation is normal. Absence of this response suggests dysfunction of the brainstem or oculomotor nerve (cranial nerve III).

! NURSING ALERT

Any tests that require head movement are not attempted until after cervical spine injury has been ruled out.
